asymptomatic neurocognitive impairment, minor neurocognitive disorder and HIV-associated dementia (also called HIV encephalopathy). The proportion of patients with symptomatic HAND increases with declining CD4 counts. HIV-associated dementia is a subcortical dementia characterised by impairment of executive function, psychomotor retardation and impaired memory. There is no diagnostic test for HIV-associated dementia. CT or MRI shows diffuse cerebral atrophy out of keeping with age. It is important to exclude depression, cryptococcal meningitis and neurosyphilis. ART usually improves HIV-associated dementia but milder forms of HAND often persist.

### Progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy (PML) is a progressive disease that presents with stroke-like episodes and cognitive impairment. Vision is often impaired due to involvement of the occipital cortex. PML is caused by the JC virus. A combination of characteristic appearances on MRI (Fig. 14.12) and detection of JC virus DNA in the cerebrospinal fluid (CSF) by PCR is diagnostic. No specific treatment exists and prognosis remains poor despite ART.

### CMV encephalitis

This presents with behavioural disturbance, cognitive impairment and a reduced level of consciousness. Focal signs may also occur. Detection of CMV DNA in the CSF supports the diagnosis. Response to anti-CMV therapy is usually poor.

### Space-occupying lesions

Space-occupying lesions in AIDS patients typically present over days to weeks. The most common cause is toxoplasmosis. As toxoplasmosis responds rapidly to therapy, a trial of anti-toxoplasmosis therapy should be given to all patients presenting with space-occupying lesions while the results of diagnostic tests are being awaited.

### Cerebral toxoplasmosis

Cerebral toxoplasmosis is caused by reactivation of residual *Toxoplasma gondii* cysts from past infection, which results in the development of space-occupying lesions. The characteristic findings on imaging are multiple space-occupying lesions with ring enhancement on contrast and surrounding oedema (Fig. 14.13). *Toxoplasma* serology shows evidence of previous exposure (positive immunoglobulin (Ig)G antibodies); a negative

**Fig. 14.12** Progressive multifocal leucoencephalopathy. Non-enhancing white-matter lesions without surrounding oedema are seen.

serological test effectively rules out toxoplasmosis but a positive test is not specific. The standard therapy for toxoplasmosis is sulfadiazine with pyrimethamine, together with folinic acid, to reduce the risk of bone marrow suppression (see [Box 14.10](#)). However, co-trimoxazole has been shown to be as effective and less toxic, and is also much more widely available. Response to a trial of therapy is usually diagnostic, with clinical improvement in 1–2 weeks and shrinkage of lesions on imaging in 2–4 weeks. Definitive diagnosis is by brain biopsy, but this is seldom necessary.

### Primary CNS lymphoma

Primary CNS lymphomas (PCNSLs) are high-grade B-cell lymphomas associated with EBV infection. Characteristically, imaging demonstrates a single homogeneously enhancing, periventricular lesion with surrounding oedema ([Fig. 14.14](#)). If it is considered safe to perform a lumbar

**Fig. 14.13** Cerebral toxoplasmosis. Multiple ring-enhancing lesions with surrounding oedema are characteristic.

**Fig. 14.14** Primary CNS lymphoma. A single enhancing periventricular lesion with moderate oedema is typical.

puncture, PCR for EBV DNA in the CSF has a high sensitivity and specificity for PCNSL. Brain biopsy is definitive but carries a risk of morbidity and may be non-diagnostic in up to one-third. The prognosis is poor.

### Tuberculoma

Lesions resemble toxoplasmosis on imaging, except that oedema tends to be less marked and single lesions occur more commonly. There may be evidence of tuberculosis elsewhere. The CSF may show features consistent with tuberculous meningitis. Response to antituberculosis therapy is slow and paradoxical expansion of lesions despite therapy is not uncommon.

### Stroke

There is a higher incidence of stroke in patients with HIV disease. Atherosclerosis is accelerated by the presence of inflammation due to the immune response to HIV, which is not completely suppressed by ART, and by dyslipidaemia caused by some antiretroviral drugs. HIV vasculopathy, which is thought to be a vasculitis, can also cause a stroke. It is important to exclude tuberculous meningitis and meningovascular syphilis in all PLWH who present with a stroke.

### Meningitis

#### Cryptococcal meningitis

*Cryptococcus neoformans* is the most common cause of meningitis in AIDS patients. Patients usually present subacutely with headache, vomiting and decreased level of consciousness. Neck stiffness is present in less than half. CSF pleocytosis is often mild or even absent, and protein and glucose concentrations are variable. It is important to request CSF cryptococcal antigen tests in all PLWH undergoing lumbar puncture, as this test has a high sensitivity and specificity. Treatment is with amphotericin B (liposomal amphotericin B if this is available) plus flucytosine for 1 week, followed by fluconazole (see [Box 14.10](#)). Raised intracranial pressure is common and should be treated with repeated therapeutic lumbar punctures, as this is a communicating hydrocephalus, removing sufficient CSF to reduce pressure to less than 20 cmH<sub>2</sub>O.

#### Tuberculous meningitis

The presentation and CSF findings of tuberculous meningitis are similar to those in HIV-negative patients except that concomitant tuberculosis at other sites is more common in HIV infection.

### Peripheral nerve disease

HIV infection causes axonal degeneration, resulting in a sensorimotor peripheral neuropathy in about one-third of AIDS patients. The incidence increases with lower CD4 counts, older age and increased height. Sensory symptoms predominate. Treatment involves foot care, analgesia and analgesic adjuvants. ART has minimal effect on halting or reversing the process.

Acute inflammatory demyelinating polyneuropathy is an uncommon manifestation, usually occurring in primary infection. It resembles Guillain-Barré syndrome, except that CSF pleocytosis is more prominent. Mononeuritis may also occur, commonly involving the facial nerve.

### Myelopathy and radiculopathy

The most common cause of myelopathy in HIV infection is cord compression from tuberculous spondylitis. Vacuolar myelopathy is seen in advanced disease and is due to HIV. It typically presents with a slowly progressive paraparesis with no sensory level. MRI of the spine is important to exclude other causes. Most patients have concomitant HIV-associated dementia.

CMV polyradiculitis presents with painful legs, progressive flaccid paraparesis, saddle anaesthesia, absent reflexes and sphincter dysfunction. CSF shows a neutrophil pleocytosis (which is unusual for a viral infection), and the detection of CMV DNA by PCR confirms the diagnosis. Functional recovery is poor despite treatment with ganciclovir or valganciclovir.

## Psychiatric disease

Significant psychiatric morbidity is common and is a major risk factor for poor adherence. Reactive depression is the most common disorder. Diagnosis is often difficult, as many patients have concomitant HAND. Substance misuse is common in many groups of people at risk of HIV. Some of the HIV antiretroviral drugs cause psychiatric adverse effects.

## Retinopathy

CMV retinitis presents with painless, progressive visual loss in patients with severe immune suppression. On fundoscopy, the vitreous is clear. Haemorrhages and exudates are seen in the retina (p. 350), often with sheathing of vessels ('frosted branch angiitis'). The disease usually starts unilaterally but progressive bilateral involvement occurs in most untreated patients. Diagnosis is usually clinical, but if there is doubt, demonstrating CMV DNA by PCR of vitreous fluid is diagnostic. Treatment with ganciclovir or valganciclovir stops progression of the disease but lost vision does not recover. Some patients may develop immune recovery uveitis in response to ART, with intraocular inflammation, macular oedema and cataract formation that require prompt treatment with oral and intraocular glucocorticoids to prevent further visual loss.

Three other conditions may mimic CMV retinitis: ocular toxoplasmosis, which typically presents with a vitritis and retinitis without retinal haemorrhages; HIV retinopathy, a microangiopathy that causes cotton wool spots, which are not sight-threatening; and varicella zoster virus, which can cause rapidly progressive outer retinal necrosis.

## Rheumatological disease

The immune dysregulation associated with HIV infection may result in autoantibody formation, usually in low titres. Mild arthralgias and a fibromyalgia-like syndrome are common in PLWH.

## Arthritis

HIV can cause a seronegative arthritis, which resembles rheumatoid arthritis. A more benign oligoarthritis may also occur. Reactive arthritis is more severe in HIV infection (p. 1035).

## Diffuse infiltrative lymphocytosis syndrome

Diffuse infiltrative lymphocytosis syndrome (DILS) is a benign disorder involving polyclonal CD8 lymphocytic infiltration of tissues, which has some features in common with Sjögren syndrome. It is linked to human leucocyte antigen (HLA)-DRB1. Most patients have a marked CD8 lymphocytosis. DILS usually presents in patients with mild immune suppression. The most common manifestation is bilateral parotid gland enlargement; the glands are often massive, with lymphoepithelial cysts on histology (Fig. 14.15). Sicca symptoms are common but usually mild. Lymphocytic interstitial pneumonitis is the most common manifestation outside the salivary glands. Generalised lymphadenopathy may occur, with nodes larger than those seen with persistent generalised lymphadenopathy of HIV. Hepatitis, mononeuritis, polyarthritis and polymyositis may also occur. The manifestations outside the salivary glands usually respond to systemic glucocorticoids. Parotid gland enlargement may be treated by aspiration of parotid cysts and instillation of a sclerosant for cosmetic reasons; surgery is best avoided. DILS may regress on ART but response is variable.

## Haematological abnormalities

Disorders of all three major cell lines may occur in HIV. In advanced disease, haematopoiesis is impaired due to the direct effect of HIV and by cytokines. Pancytopenia may occur as a consequence of HIV but it is important to exclude a disorder infiltrating the bone marrow, such as mycobacterial or fungal infections, or lymphoma.

## Anaemia

Normochromic, normocytic anaemia is very common in advanced HIV disease. Opportunistic diseases may cause anaemia of chronic disease (e.g. tuberculosis) or marrow infiltration (e.g. MAC, tuberculosis, lymphoma, fungi). Anaemia is a common adverse effect of zidovudine, which also causes a macrocytosis. Red cell aplasia is rare and may be caused either by parvovirus B19 infection or by the NRTIs lamivudine and emtricitabine.

## Neutropenia

Isolated neutropenia is occasionally due to HIV but is nearly always caused by drug toxicity (e.g. zidovudine, co-trimoxazole, ganciclovir).

## Thrombocytopenia

Mild thrombocytopenia is common in PLWH. Transient thrombocytopenia is frequently found in primary infection. The most common disorder causing severe thrombocytopenia is immune-mediated platelet destruction resembling idiopathic thrombocytopenic purpura (p. 988). This responds to glucocorticoids or intravenous immunoglobulin, together with ART. Splenectomy should be avoided if possible because it further increases the risk of infection with encapsulated bacteria. Severe thrombocytopenia with a microangiopathic anaemia also occurs in a thrombotic thrombocytopenic purpura-like illness, which has a better prognosis and fewer relapses than the classical disease.

## Renal disease

Acute kidney injury is common, usually due to acute infection or nephrotoxicity of drugs (e.g. tenofovir (see Box 18.25), amphotericin B). HIV-associated nephropathy (HIVAN) is the most important cause of chronic kidney disease (CKD) and is seen more frequently in patients of African descent and those with low CD4 counts. Progression to end-stage disease is more rapid than with most other causes of CKD, and renal size is usually preserved. HIVAN presents with nephrotic syndrome, CKD or a combination of both. ART has some effect in slowing progression of HIVAN. Other important HIV-associated renal diseases include HIV immune complex kidney diseases and thrombotic microangiopathy. With the overall improvement in life expectancy from ART, conditions such as diabetes mellitus, hypertension and vascular disease add to the burden of CKD. Outcomes of renal transplantation are good in patients on ART.

**Fig. 14.15** CT scan of parotid glands. Multiple cysts (arrows) seen in a patient with the diffuse infiltrative lymphocytosis syndrome.

## Cardiac disease

HIV-associated cardiomyopathy resembles idiopathic dilated cardiomyopathy (p. 474) but progresses more rapidly. ART may improve cardiac failure but does not reverse established cardiomyopathy. Pericardial disease due to opportunistic diseases is not uncommon; globally, the most common cause is tuberculous pericardial effusion. Tuberculous constrictive pericarditis is less common than in HIV-uninfected people. KS and lymphoma may cause pericardial effusions. Septic pericarditis, usually due to *S. pneumoniae*, is uncommon.

HIV is associated with an increased risk of myocardial infarction due to accelerated atherogenesis caused by the inflammatory state, which is not completely suppressed by ART, and by dyslipidaemia caused by some antiretroviral drugs.

## HIV-related cancers

The AIDS-defining cancers are KS (see above), cervical cancer and non-Hodgkin lymphoma (NHL). NHL may occur at any CD4 count but is more commonly seen with counts below 200 cells/mm<sup>3</sup>. Almost all NHLs are B-cell tumours and most are stage 3 or 4. Long-term remission rates similar to those in patients without HIV can be achieved with NHL in AIDS patients using ART and chemotherapy (including the anti-B-cell monoclonal antibody rituximab if it is a B-cell tumour).

The incidence of several other cancers induced by viruses is also increased in PLWH (Box 14.13). Regular cytological examination of the cervix should be performed to detect pre-malignant lesions, which are easier to treat – studies are under way to determine optimal strategies to reduce the risk of anal cancer in people who practise receptive anal sex. In general, the incidence of cancers that are not induced by viruses is similar to that in the general population.

## Prevention of opportunistic infections

The best way to prevent opportunistic infections is to improve the CD4 count with ART. However, infections continue to occur in the ART era as CD4 counts take time to improve if ART is initiated in patients with profound immune suppression, immune reconstitution on ART may be sub-optimal, and CD4 counts may decline if antiretroviral resistance develops.

## Preventing exposure

The best method for avoiding infection is to prevent exposure to the infectious agent. However, this strategy is possible only for a few opportunistic infections. Many opportunistic infections occur after reactivation of latent/dormant infection after prior exposure; examples include herpes simplex virus, zoster (shingles), CMV, toxoplasmosis, cryptococcosis and the endemic mycoses.

## Safe water and food

Cryptosporidiosis, microsporidiosis and cystoisosporiasis may be water-borne. If there is no access to safe water, then water should be boiled before drinking. Food-borne illnesses are also important in HIV infection, notably *Salmonella* species. *Toxoplasma* exposure is related to eating raw or undercooked meat. PLWH should be informed about food hygiene and the importance of adequately cooking meat.

## Tuberculosis

Preventing exposure to tuberculosis is important when there is an infectious case in the household, in clinics and in hospitals. Adequate ventilation, masks and safe coughing procedures reduce the risk of exposure.

## Malaria vector control

All PLWH living in malarious areas should practise vector control, as malaria occurs more frequently and is more severe in PLWH. The most cost-effective way to achieve this is by using insecticide-impregnated bed nets. Other modalities of vector control that are of benefit to the community, such as reducing standing water and spraying with residual insecticides and larvicides, should also be implemented.

## Safer sex

PLWH should practise safer sex to reduce the transmission of HIV. Even if their partners are PLWH, condoms should be used, as HIV mutants that have developed antiretroviral drug resistance can be transmitted. Safer sex will also lower the risk of acquiring herpes simplex virus and human herpesvirus 8.

## Pets

*Toxoplasma gondii* can be acquired from kittens or cat litter, and people living with HIV infection should avoid handling either. Cryptosporidiosis can be transmitted from animals, and patients should be advised to wash their hands after handling animals.

## Chemoprophylaxis

Chemoprophylaxis is the use of antimicrobial agents to prevent infections. Primary prophylaxis is used to prevent opportunistic infections that have not yet occurred. Secondary prophylaxis is used to prevent recurrence of opportunistic infections because many may recur after an initial response to therapy (see Box 14.10). Secondary prophylaxis can be discontinued when ART results in immune reconstitution, with CD4 counts increasing to over 200 cells/mm<sup>3</sup>, but for CMV and MAC, prophylaxis can be stopped if CD4 counts increase to more than 100 cells/mm<sup>3</sup>.

## Co-trimoxazole primary prophylaxis

Co-trimoxazole (sulfamethoxazole–trimethoprim) reduces the incidence of several opportunistic infections (Box 14.14), resulting in lower hospitalisation and mortality rates. The indications for initiating co-trimoxazole are either clinical evidence of immune suppression (WHO clinical stages 3 or 4) or laboratory evidence of immune suppression (CD4 count <200 cells/mm<sup>3</sup>). In low-income countries where malaria and/or severe bacterial infections are highly prevalent, the WHO recommends initiating co-trimoxazole regardless of CD4 counts or clinical stage. The recommended dose

14

### 14.13 Approximate incidence ratio of virus-related cancers compared to the general population

Viral cancers	Incidence ratio
<b>Human herpesvirus 8-related</b>	
Kaposi's sarcoma	3600
<b>Epstein–Barr virus-related</b>	
Non-Hodgkin lymphoma	80
Hodgkin lymphoma	10
<b>Human papillomavirus-related</b>	
Cervical cancer	6
Vulval cancer	6
Anal cancer	30
Penile cancer	4
<b>Hepatitis B/C virus-related</b>	
Hepatocellular carcinoma	5

of co-trimoxazole is 960mg daily. Co-trimoxazole prophylaxis can be discontinued when CD4 counts increase to more than 200 cells/mm<sup>3</sup> on ART, except in low-income countries where it should be continued life-long.

Co-trimoxazole prophylaxis is well tolerated. The most common side-effect is hypersensitivity, causing a maculo-papular rash. If therapy is discontinued, desensitisation or rechallenge under antihistamine cover should be attempted, unless the rash was accompanied by systemic symptoms or mucosal involvement. Prophylactic doses of co-trimoxazole can also cause neutropenia, but this is very uncommon and routine monitoring of blood counts is not necessary. If co-trimoxazole cannot be tolerated, then dapsone 100mg daily should be substituted. Dapsone is equally effective at reducing the incidence of *P. jirovecii* pneumonia (PCP), but has little or no effect on reducing the other opportunistic infections prevented by co-trimoxazole.

## Tuberculosis preventive therapy

Trials in patients not on ART showed that preventive therapy, either with isoniazid or combinations of rifamycins with isoniazid, reduces the risk of tuberculosis only in PLWH with a positive tuberculin skin test. However, recent evidence indicates that tuberculin skin tests do not predict benefit in patients starting ART or established on ART in high tuberculosis prevalence settings.

There is no CD4 count or clinical threshold for starting tuberculosis preventive therapy. It is important to rule out active tuberculosis before starting preventive therapy, and symptom screening has been shown to be adequate to achieve this (Box 14.15). The usual duration of isoniazid preventive therapy is 6 months. Rifampicin or rifapentine combined with isoniazid for 12 weeks has been shown to be at least as effective as 6–12 months of isoniazid.

## Mycobacterium avium complex prophylaxis

In high-income countries, a macrolide (azithromycin or clarithromycin) is recommended to prevent MAC in patients with a CD4 count below 50 cells/mm<sup>3</sup>, which can be discontinued once the CD4 count has risen to over 100 cells/mm<sup>3</sup> on ART. MAC is uncommon in low- and middle-income countries and primary prophylaxis is thus not warranted.

## Preventing cryptococcosis

Serum cryptococcal antigen test should be done in patients with a CD4 count below 100 cells/mm<sup>3</sup>. If this is positive, pre-emptive therapy with fluconazole should be commenced.

## Immunisation

There are significant problems associated with vaccination in HIV infection. First, vaccination with live organisms is contraindicated in patients with severe immune suppression, as this may result in disease from the

### 14.14 Opportunistic infections reduced by co-trimoxazole

- *Pneumocystis jirovecii* pneumonia
- Bacteraemia
- Cerebral toxoplasmosis
- Cystoisosporiasis
- Bacterial pneumonia
- Malaria

### 14.15 Symptom screen for tuberculosis before isoniazid preventive therapy

- All of the following must be absent:
- Active cough
  - Night sweats
  - Weight loss
  - Fever

attenuated organisms. Secondly, immune responses to vaccination are impaired in PLWH. If the CD4 count is below 200 cells/mm<sup>3</sup>, then immune responses to immunisation are poor. Therefore, it is preferable to wait until the CD4 count has increased to more than 200 cells/mm<sup>3</sup> on ART before immunisation is given; this is essential if live virus vaccines are used. All patients should be given a conjugate pneumococcal vaccine and annual influenza vaccination. Hepatitis B vaccination should be given to those who are not immune. In the UK, the following additional vaccines are also recommended:

- *hepatitis A*: in those at risk
- *human papillomavirus*: in people < 40 years old
- *measles, mumps and rubella (MMR)*: in those with negative measles serology
- *meningococcus*: in people < 25 years old, those with asplenia or complement deficiency, during outbreaks
- *diphtheria/tetanus/acellular pertussis (dTaP)/inactivated poliovirus vaccine (IPV)*: meeting general indications
- *chickenpox*: if seronegative; those who are seropositive should receive the shingles vaccine.

Bacille Calmette–Guérin (BCG) is contraindicated in PLWH.

## Antiretroviral therapy

ART has transformed HIV from a progressive illness with a fatal outcome into a chronic manageable disease with a near-normal life expectancy.

The goals of ART are to:

- reduce the viral load to an undetectable level for as long as possible
- improve the CD4 count to over 200 cells/mm<sup>3</sup> so that severe HIV-related disease is unlikely
- improve the quantity and quality of life without unacceptable drug toxicity
- reduce HIV transmission.

Many of the antiretroviral drugs that were initially used have largely been abandoned because of toxicity or poor efficacy. The pill burden of currently recommended ART is low; the currently recommended first-line regimens are available as a single pill. The drugs that are currently recommended are shown in Box 14.16, and their targets in the HIV life cycle in Fig. 14.1.

## Selecting antiretroviral regimens

The standard combination antiretroviral regimens are two NRTIs together with an NNRTI, protease inhibitor (PI) or integrase inhibitor. However, effective combinations have been developed with just two drugs. Currently used PIs are always administered with the pharmacoenhancers ('boosters') ritonavir or cobicistat, which dramatically increase the concentrations of other PIs by inhibiting their metabolism by the cytochrome P450 isoenzyme CYP3A.

### 14.16 Currently preferred antiretroviral drugs

Classes	Drugs
Nucleoside reverse transcriptase inhibitors (NRTIs)	Abacavir, emtricitabine, lamivudine, tenofovir
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz*, rilpivirine (only if viral load < 100 000)
Protease inhibitors (PIs)	Atazanavir*, darunavir, lopinavir*
Integrase inhibitors	Dolutegravir, bictegravir

\*These drugs are no longer recommended as first-line options due to their toxicity.

By far the commonest preferred agents for first-line ART globally are a second-generation integrase inhibitor (bictegravir or dolutegravir) combined with the NRTIs tenofovir plus emtricitabine or lamivudine (which have the same mechanism of action and so are never combined).

In high-income countries ART regimen switches for virological failure are guided by the results of resistance testing (see below). In low- and middle-income countries, where resources for resistance testing are limited or absent, a standardised second-line regimen is recommended

## Starting ART

Guidelines now recommend starting ART in all people with confirmed HIV infection, irrespective of CD4 count or clinical status. Early initiation of ART, compared with the previous strategy of deferring ART until CD4 thresholds or clinical disease occurs, has been shown to reduce morbidity and mortality, and has the additional benefit of reducing the risk of transmission. In asymptomatic PLWH initiating ART on the same day that the diagnosis is confirmed has been shown to improve retention in care. Disclosure of HIV status, joining support groups and using patient-nominated treatment supporters should be encouraged, as these have been shown to improve adherence. Recognition and management of depression and substance abuse is important.

In patients with major opportunistic infections, ART should generally be started within 2 weeks, with two important exceptions: in cryptococcal meningitis, ART should be deferred for 5 weeks, as earlier initiation increases the risk of death; and in tuberculosis, ART should be deferred until 8 weeks (except if the CD4 count is  $<50$  cells/mm<sup>3</sup>), as earlier initiation increases the risk of the immune reconstitution inflammatory syndrome (see below).

## Monitoring efficacy

The most important measure of ART efficacy is the viral load. A baseline viral load should be measured prior to initiating treatment. Viral load measurement should be repeated 4 weeks after starting ART, when there should be at least a 10-fold decrease. The viral load should be suppressed after 6 months. Once the viral load is suppressed, measurement should be repeated 6 to 12 monthly. Failure of ART is defined by the viral load becoming detectable after suppression. In most guidelines, a viral load threshold is used to define virological failure, e.g. more than 200 (UK) or more than 1000 (WHO) copies/mL. Adherence support should be enhanced if virological failure is detected.

CD4 counts can be monitored together with the viral load, but there is little point in repeating the CD4 count in patients who maintain virological suppression and whose CD4 count is  $>350$  cells/mm<sup>3</sup>. The CD4 count increases rapidly in the first month, followed by a more gradual increase. In the first year, the CD4 count typically increases by 100–150 cells/mm<sup>3</sup>, and about 80 cells/mm<sup>3</sup> per annum thereafter until the normal range is reached, provided the viral load is suppressed. However, CD4 responses are highly variable: in about 15%–30% of patients the CD4 count does not increase despite virological suppression, and in a similar proportion of patients the CD4 response is good despite the presence of virological failure. If ART is stopped, the CD4 count rapidly falls to the baseline value before ART was commenced.

## Antiretroviral resistance

Reverse transcription is error-prone, generating many mutations. If the viral load is suppressed on ART, viral replication is suppressed and resistance mutations will not be selected. If there is ongoing replication on ART, due to either resistant mutations or suboptimal adherence, mutations conferring resistance to antiretroviral drugs will be selected. Antiretroviral drugs differ in their ability to select for HIV resistance mutations. Some drugs (e.g. emtricitabine, lamivudine, efavirenz, raltegravir) have a low genetic barrier to resistance, rapidly selecting for a single mutation conferring high-level resistance. PIs and the second-generation integrase inhibitors (bictegravir and dolutegravir) select for resistance mutations

slowly, and multiple mutations may need to accumulate before the drug's efficacy is lost. Patients who develop antiretroviral resistance will eventually develop clinical failure if the regimen is not changed, and may transmit resistant virus to others.

Antiretroviral resistance is assessed by sequencing the relevant viral genes to detect mutations that are known to confer resistance. The patient must be taking ART when the test is performed, as otherwise the wild-type virus will predominate and resistant mutations will not be detected. However, the resistant proviral DNA archived in latent CD4 cells will re-emerge rapidly on re-exposure to the antiretroviral. In high-income countries resistance testing is recommended at baseline (to detect primary resistance) and at every confirmed virological failure, in order to select the most appropriate antiretrovirals in a new regimen.

## ART complications

### Immune reconstitution inflammatory syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a common early complication of ART, especially in patients who start ART with CD4 counts below 50 cells/mm<sup>3</sup>. IRIS presents either with paradoxical deterioration of an existing opportunistic disease (including infections that are responding to appropriate therapy) or with the unmasking of a new infection. The clinical presentation of IRIS events is often characterised by an exaggerated immune response, with pronounced inflammatory features. For example, patients with CMV retinitis developing IRIS on ART develop a uveitis; inflammatory haloes occur around KS lesions. Paradoxical tuberculosis IRIS events are common but it is important to exclude multidrug resistance, which could be responsible for the deterioration. IRIS is associated with a mortality of around 5% but this is higher when it complicates CNS infections.

The management of IRIS is to continue ART and to ensure that the opportunistic disease is adequately treated. Symptomatic treatments are helpful. Glucocorticoids are often used for more severe IRIS manifestations but they should not be given to patients with KS, as this can result in rapid progression of KS lesions.

### Antiretroviral adverse drug reactions

Currently recommended antiretrovirals are generally well tolerated. Integrase inhibitors may cause insomnia. NNRTIs commonly cause hypersensitivity rashes; efavirenz commonly causes mild neuropsychiatric effects, but tolerance develops in a few weeks in most patients. The NRTI tenofovir occasionally causes nephrotoxicity and loss of bone mineral density, but the newer pro-drug tenofovir alafenamide is less toxic. PIs may cause gastrointestinal symptoms (nausea, vomiting and diarrhoea), and some are associated with dyslipidaemia.

## ART in special situations

### Pregnancy

All pregnant women should have HIV testing at an early stage in pregnancy. The CD4 count falls by about 25% during pregnancy due to haemodilution. The course of HIV disease progression is not altered by pregnancy. In the pre-ART era, the rate of mother-to-child transmission was 15%–40%, with rates being influenced by several factors (see [Box 14.3](#)).

ART has dramatically reduced the risk of mother-to-child transmission of HIV to less than 1%. All pregnant women who are ART-naïve should start ART as soon as possible. Pregnant women on ART may need to have their regimens modified as only a limited number of antiretrovirals are recommended in pregnancy. Close viral load monitoring is essential during pregnancy.

Caesarean section is associated with a lower risk of mother-to-child transmission than vaginal delivery, but the mode of delivery does not affect transmission risk if the viral load is suppressed on ART.

### 14.17 HIV infection in old age

- **Epidemiology:** the HIV-positive population is ageing due to the life-prolonging effects of ART.
- **Immunity:** age-related decline increases the risk of infections. CD4 counts decline more rapidly as age extends beyond 40 years, resulting in faster disease progression. CD4 responses to ART decrease with increasing age.
- **Dementia:** HIV causes cerebral atrophy and neurocognitive disorders; dementia is therefore more common and more severe than in the HIV-uninfected older adults.
- **Vascular disease:** HIV is associated with an increased risk, exacerbated by some antiretrovirals that cause dyslipidaemia or insulin resistance.
- **Fragility fractures:** bone mineral density is lower in PLHW, which can be exacerbated by the NRTI tenofovir.
- **Polypharmacy:** treatment of co-morbidities is complex due to drug–drug interactions with antiretrovirals.

HIV is also transmitted by breastfeeding. In high-income countries, exclusive formula feeding is generally recommended. In resource-poor settings, however, formula feeding is associated with a risk of infant morbidity and mortality, which may negate the benefit of not transmitting HIV to the infant. There is minimal risk of transmitting HIV by breastfeeding in women with a suppressed viral load on ART. Furthermore, providing antiretrovirals to infants (usually nevirapine monotherapy) while they are breastfeeding has been shown to reduce the risk of transmission. Breastfeeding is therefore now encouraged in resource-poor settings. Infants should be exclusively breastfed for the first 6 months, as mixed feeding (with formula or solids) is associated with a higher risk of transmission.

### Old age

The specific manifestations of HIV infection in older people are shown in [Box 14.17](#).

### Prevention of HIV

An effective HIV vaccine remains elusive due to the extensive genetic diversity of HIV and the lack of a safe attenuated virus. Measures for the prevention of HIV transmission are shown in [Box 14.18](#).

### Pre-exposure prophylaxis

Pre-exposure prophylaxis (PrEP) with daily tenofovir plus emtricitabine has been shown to reduce the risk of HIV acquisition in people who are at ongoing high risk (e.g. from sex or injecting drug use) and is well tolerated. Regular HIV testing should be done in people on PrEP.

### 14.18 Prevention measures for HIV transmission

#### Sexual

- Sex education programmes in schools
- Easily accessible voluntary counselling and testing centres
- Promotion of safer sex practices (delaying sexual debut, condom use, fewer sexual partners)
- Effective ART for HIV-infected individuals
- Pre-exposure prophylaxis (PrEP) for high-risk groups
- Male circumcision
- Post-exposure prophylaxis

#### Parenteral

- Blood product transmission: donor questionnaire, routine screening of donated blood
- Injection drug use: education, needle/syringe exchange, avoidance of 'shooting galleries', methadone maintenance programmes

#### Perinatal

- Routine 'opt-out' antenatal HIV antibody testing
- Measures to reduce vertical transmission (see text)

#### Occupational

- Education/training: universal precautions, needlestick injury avoidance
- Post-exposure prophylaxis

### Post-exposure prophylaxis

Post-exposure prophylaxis (PEP) is recommended after a potential exposure to HIV when the risk is deemed to be significant after a careful risk assessment, in both occupational and non-occupational settings. The first dose should be given as soon as possible. The effectiveness of PEP diminishes with time and it is ineffective (and therefore should not be started) if given more than 72 hours after exposure. Tenofovir together with emtricitabine is the most widely used dual NRTI combination, together with either a PI or an integrase inhibitor depending on ART exposure in the source patient. PEP should not be given if the exposed person is HIV-infected. HIV antibody testing should be performed 3 months after exposure.

## Multiple Choice Questions

14.1. HIV infects cells bearing the CD4 receptor. Which co-receptor is required for HIV to enter the cell?

- A. CD8
- B. Chemokine receptor 5 (CCR5)
- C. CD20
- D. Major histocompatibility complex (MHC)
- E. CD3

Answer: B.

Entry of HIV into the cell commences with binding of the envelope glycoprotein gp120 to the CD4 receptor. This results in a conformational change in gp120 that permits binding to one of two chemokine co-receptors, CCR5 or CXCR4. The chemokine co-receptor CCR5 is utilised during initial infection, but subsequently the virus may adapt to use CXCR4. Individuals who are homozygous for the CCR5 delta 32 mutation do not express CCR5 on CD4 cells and are immune to HIV infection.

14.2. Select the most important measure of the efficacy of antiretroviral therapy.

- A. CD4 lymphocyte count
- B. Weight gain
- C. Viral load
- D. Resolution of HIV symptoms
- E. Absence of opportunistic infections

Answer: C.

The most important measure of effective antiretroviral therapy (ART) is a decrease in the level of HIV viraemia measured by quantitative PCR of HIV RNA, or 'viral load'. Baseline viral load should be measured prior to initiating ART and this should be repeated 4 weeks after starting ART, when there should be at least a 10-fold decrease. Once the viral load is suppressed (as defined according to local guidance) measurement should be repeated every 6–12 months.

The CD4 count is the most important laboratory indicator of the degree of immune suppression in HIV infection and CD4 counts usually increase rapidly in the first month after starting ART. However, CD4 responses are highly variable between patients and do not provide a rapid, sensitive and reliable measurement of the effectiveness of ART.

Weight gain, resolution of HIV symptoms and absence of opportunistic infections are all clinical markers of effective ART. However, as these are dependent on recovery of effective immune function, they change too slowly to provide a rapid, sensitive and reliable measurement of the initial and ongoing effectiveness of ART.

14.3. Access to antiretroviral therapy has markedly changed the epidemiology of HIV. Which of the following statements is correct about global epidemiology of HIV over the 5-year period 2014–2019?

- A. Prevalence has decreased and incidence has decreased
- B. Prevalence has decreased and incidence has increased
- C. Prevalence has remained similar and incidence has decreased
- D. Prevalence has increased and incidence has decreased
- E. Prevalence has decreased and incidence has remained similar

Answer: D.

The incidence and prevalence of HIV infection are measures of the number of new infections per year and the total number of people living with HIV (PLWH) respectively.

In 2019 it was estimated that there were 1.7 million new HIV infections, compared with 3.1 million in 2001 and 2.6 million in 2009; and there were 38 million PLWH, compared with 28.6 million in 2001 and 33.3 million in 2009.\* Therefore, the incidence of HIV infection has decreased but the prevalence has increased.

Although behavioural modification is likely to have contributed to the decrease in new infections, the main influence on both incidence and prevalence has been expansion of access to effective antiretroviral therapy (ART). ART reduces the incidence of new infections by reducing the likelihood of PLWH infecting other people and increases the prevalence by prolonging the survival of PLWH.

# Sexually transmitted infections

## Clinical examination in sexually transmitted infection 370

### Aetiology 372

### Clinical assessment 372

### Presenting problems 372

- Urethral discharge 372
- Genital itch, rash and discomfort 373
- Vaginal discharge 374
- Genital ulceration 374
- Genital lumps 375
- Proctitis 375
- Lower abdominal pain 375

### Epidemiology 375

## Prevention 376

### Sexually transmitted bacterial infections 377

- Syphilis 377
- Gonorrhoea 379
- Chlamydial infection 379
- Mycoplasma genitalium* 380
- Other sexually transmitted bacterial infections 380

### Sexually transmitted viral infections 380

- Genital herpes simplex 380
- Human papillomavirus and anogenital warts 382
- Molluscum contagiosum 382
- Viral hepatitis 383

## Clinical examination in sexually transmitted infection

**5 Vagina and cervix**

Abnormal discharge  
Warts  
Ulcers  
Inflammation  
In women with lower abdominal pain, bimanual examination for adnexal tenderness (pelvic inflammatory disease)

▲ Speculum

**4 Labia majora and minora**

Ulcers  
Vulvitis  
Note normal vestibular papillae and sebaceous glands

▲ Vulval carcinoma

**3 Skin of pubic area**

Warts  
Tinea cruris

▲ Pthirus pubis (crab louse)

**2 Inguinal glands**

Significant enlargement

**1 Abdomen**

Abnormal masses or tenderness  
Tip: Gentle abdominal palpation is a non-threatening prelude to genital examination in an anxious patient

**6 Skin of penis**

(Retract foreskin if present)  
Genital warts  
Ulcers  
Be aware of normal anatomical features such as coronal papillae, or prominent sebaceous or parafoveal glands

▲ Coronal papillae

**7 Urethral meatus**

▲ Sampling discharge at urethral meatus

**8 Scrotal contents**

Abnormal masses or tenderness (epididymo-orchitis)

**9 Perineum and perianal skin**

Warts  
Ulcers  
Inflammation

▲ Perianal warts

**10 Rectum**

▲ Proctoscope

▲ Proctitis

**Consent**  
Explain what genital examination will involve and confirm informed consent. Presence of a chaperone is routine

**Observation**

- Mouth
- Eyes
- Joints
- Skin:
  - Rash of secondary syphilis
  - Scabies
  - Manifestations of HIV (Ch. 14)

Insets (Coronal papillae, Discharge at urethral meatus, Perianal warts, Vulval carcinoma) From Clutterbuck DJ. Specialist training in sexually transmitted infections and HIV. St Louis: Mosby, Elsevier Inc.; 2004. (Proctitis) From McMillan A, Young H, Ogilvie MM, Scott GR. Clinical practice in sexually transmissible infections. Philadelphia: Saunders, Elsevier Inc.; 2002.

## Identifying STIs in the population

- Testing for STIs in those who present with clinical symptoms identifies only a small minority of prevalent infections and other methods of case-finding are widely employed.
- STI testing for asymptomatic individuals is provided through specialist clinics and primary care providers but also directly to populations at risk through screening programmes and opportunistic testing.
- Point-of-care testing (PoCT) in the community, home-based self-testing (where the test is performed at home) and self-sampling (where it is posted to a laboratory) are well proven technologies used internationally for HIV and increasingly for syphilis testing.
- Self-sampling for chlamydia and gonorrhoea testing is widely used in the UK both for home-based testing and in clinics for convenience and efficiency. Technology allows testing for an increasing range of organisms, including *Mycoplasma genitalium*, *Trichomonas vaginalis* and others to be undertaken on the same sample.
- STI testing may be offered remotely from clinical assessment – through online ordering of self-sampling or self-testing kits, or tests provided in non-clinical outreach settings such as youth groups or sex-on-premises venues such as gay saunas.

## Investigations for STIs

- Samples for combined nucleic acid amplification test (NAAT) for gonorrhoea and chlamydia are taken from anatomical sites at risk – these may be identified by face-to-face or online assessment of gender, partner gender and sexual practices.
- First-void urine (FVU) is the specimen of choice to test for infection of the male urethra and a self-taken swab is preferred for vaginal samples. Clinician-obtained urethral, cervical or vaginal swabs are alternatives. Pharyngeal and rectal swabs may be indicated by sexual history and are often offered universally to MSM.
- For gonorrhoea, either as an alternative or adjunct to NAAT testing, swabs from the pharynx, urethra, cervix or rectum plated directly on a selective medium such as modified New York City (MNYC), or sent in an appropriate transport medium, can be cultured for assessment of antimicrobial sensitivities. NAAT-based sensitivity testing is increasingly available.
- Blood for serological tests including syphilis (STS), e.g. enzyme immunoassay (EIA) for antitreponemal immunoglobulin G (IgG) ± IgM antibody. Repeat testing may be necessary in the event of negative test results in the first few weeks following exposure.
- Human immunodeficiency virus (HIV) test. HIV testing should always be offered as part of STI testing. Informed consent is required, but extensive pre-test discussion is not.
- Serological tests for hepatitis B (and sometimes hepatitis A and/or C) are offered to those at epidemiological risk.
- Additional tests routinely used in the investigation of symptomatic patients in sexual health clinics include direct microscopy of Gram-stained samples from the male urethra for the diagnosis of urethritis, or of wet-mount and Gram-stained samples from the vagina for the diagnosis of *Trichomonas vaginalis*, bacterial vaginosis, aerobic vaginitis or candidiasis.

## Examples of risk factors for STIs

### Demographic factors

- Younger age (<25)\*
- Men who have sex with men (MSM)
- Prior STI diagnosis

### Behavioural factors

- Frequent partner change or concurrent partners
- Non-use of condoms, condom errors
- Use of drugs during sex ('chemsex')
- Use of geospatial mobile phone dating applications ('dating apps')

\*But note that the possibility of STI should never be excluded on the grounds of older age alone.

## Sexual health and gender identity

- Medical care in all settings must be inclusive of all patients regardless of sexual orientation or gender identity. This has particular relevance in sexual health.
- Gender identity is a characteristic protected by law in the UK and many other jurisdictions.
- Definitions of terms commonly used:
  - Gender identity: An individual's innate sense of their own gender, which may or may not be congruent with the sex they were assigned at birth.
  - Cisgender/Cis: A cis person's gender identity is generally congruent with the sex they were assigned at birth.
  - Trans: an umbrella term to describe people whose gender identity differs from the sex they were assigned at birth. There is a spectrum of trans identities, including but not limited to: trans woman, trans man, transgender, genderqueer, non-binary, agender.
  - Non-binary (genderqueer): a term for individuals whose gender identity does not align with either of the binary categories of 'man', 'woman', or 'male', 'female'.
- Long-established social norms, health care structures, clinical practice and teaching may create barriers to inclusive care for trans and non-binary individuals (for example by failing to provide cervical screening to trans men who have a cervix, or providing only male and female options in waiting rooms, services or on registration forms).
- Clinicians and services can ensure inclusivity by asking about gender identity, preferred pronouns and gender of partners and providing tests and investigations on the basis of anatomical sites at risk rather than by binary gender.

## Tips on sexual history-taking

1. A simple framing statement before taking the sexual history helps avoid any sense of apology or embarrassment. 'So, thinking about your sex life ...'; 'Some questions about your sex life ...'.
2. Use open language to avoid the impression of being judgemental; inclusive words such as 'partner' rather than 'boyfriend'.
3. Avoid euphemisms ('down below'). Straightforward anatomical terms are advisable (in the UK 'vagina' is generally understood but 'vulva' often is not). 'So, you mean on the lips of your vagina?'
4. Focusing on events helps to avoid labels and generalisations. 'When did you last have sex, any sort of sex ...?', 'When did you last have sex with anyone else/ any other partner?'
5. Use permission-giving in questioning (explicit permission for a range of answers). 'Have your partners been men, women or both?'
6. Invite the 'non-acceptable' or non-sanctioned answer. 'So was that without a condom ...?'
7. Understand and mitigate the ways in which your own values might affect your questioning. 'When was your last previous partner?' (assumes serial monogamy – so avoid).

## Aetiology

Sexually transmitted infections (STIs) are infections usually but not exclusively transmitted via the moist mucous membranes of the penis, vulva, vagina, cervix, anus, rectum, mouth and pharynx during sexual activity. STIs include syphilis, gonorrhoea, genital herpes, genital warts, chlamydia, *Mycoplasma genitalium*, trichomoniasis and lymphogranuloma venereum (LGV). Chancroid and granuloma inguinale are STIs seen in tropical countries but are rare in the UK. Sexually transmissible blood-borne viruses including human immunodeficiency virus (HIV) and hepatitis B and C (see Ch. 14) are those in which sexual contact is an important, but not the only mode of transmission. Enteric hepatitis virus A and sexually transmitted enteric infections (STEI) including *Salmonella* and *Shigella* may be spread by oro-anal sexual contact, although this is responsible for only a minority of cases. Other viruses, including Zika virus and SARS-CoV-2 (the coronavirus causing COVID-19) (see Ch. 13) are found in semen and may be sexually transmitted, although this is not a commonly recognised route of acquisition. Untreated STIs can lead to chronic pain or infertility and can lead to genital cancers such as cervical and anal carcinoma. Ulcerative STIs increase the risk of transmission of untreated HIV about threefold and up to a third of worldwide HIV transmissions are thought to be attributable to herpes simplex virus (HSV) type 2. STIs in pregnancy can cause serious complications, including stillbirth, neonatal death, prematurity, neonatal sepsis, low birth weight and congenital abnormalities (Box 15.1), or disseminated infection in the mother. Other conditions, including bacterial vaginosis (BV) and genital candidiasis, are not regarded as STIs, although they are common causes of vaginal discharge. Genital itch, discomfort or rash with a wide variety of underlying causes in sexually active individuals also present to sexual health clinicians.

## Clinical assessment

The use of a recognisable set of signs and symptoms to identify the likely infective cause and guide antimicrobial treatment without diagnostic testing is termed syndromic management and has been a mainstay of clinical care of STIs worldwide for several decades. The risk of widespread antimicrobial resistance (AMR) is currently one of the greatest challenges in STI control, so syndromic management is increasingly supported by improvements in availability, reliability and speed of diagnostic testing technologies, in particular nucleic acid amplification testing (NAAT). However, diagnosis on the basis of observed syndromes (e.g. vaginal discharge) remains valuable even in resource-rich settings where sophisticated tests are widely available. The majority of those presenting with genital syndromes do not have STI. Conversely, around 50% of all gonorrhoea and syphilis and 80% of chlamydial infections are asymptomatic and many of those who are symptomatic do not seek care. A detailed understanding of symptoms and of social and behavioural risk factors for STI in an individual directs examination, investigations

## 15.2 History-taking for STI

- **Symptoms:** genital ulceration, rash, irritation, pain, swelling and urinary symptoms, especially dysuria. Urethral discharge, vaginal discharge, pelvic pain or dyspareunia. Testicular pain, abdominal and systemic symptoms.
- **Medical history:** medical problems including previous STI, allergies, medication (prescribed, over the counter, recreational drugs including 'chemsex'), vaccinations (hepatitis A and B, HPV); obstetric and gynaecological history, cervical smears and contraception.\*
- **Sexual history:** last sexual contact, partner gender, partner status (one off/regular/other), partner geographical origin, consent to sex, payment/transactional sex. Other recent partners.
- **Sexual practices:** digital or penile insertive or receptive vaginal or anal, orogenital or oro-anal, protection (condoms, PrEP).

\*In any sexual health consultation with a woman of reproductive age, contraception should always be discussed and where possible provided.

(HPV = human papilloma virus; PrEP = pre-exposure prophylaxis)

indicated and anatomical sites sampled. For example, rectal samples are indicated in those who have had condomless receptive anal sex. A good sexual history is key to identifying these factors (Box 15.2).

## STI in children

The presence of an STI in a child may be indicative of sexual abuse, although vertical transmission may explain some presentations in the first 2 years. In an older child and in adolescents, STI may be the result of voluntary sexual activity. Specific issues regarding the management of STI and other infections in adolescence are discussed in Box 13.23.

## Presenting problems

### Urethral discharge

Discharge from the male urethra is a very common presenting problem whereas discharge from the female urethra alone is rare. Male urethral discharge caused by gonorrhoea (gonococcal urethritis) is distinguished from the more frequently seen non-gonococcal urethritis (NGU). Causes of NGU include *Chlamydia trachomatis*, *Mycoplasma genitalium* and less frequently *Trichomonas vaginalis*, HSV, other mycoplasmas, urea plasmas or adenoviruses. Some cases are thought not to have an infectious aetiology and are termed non-specific urethritis (NSU).

Gonococcal urethritis usually causes symptoms within 7 days of exposure. The discharge is typically profuse and purulent. Chlamydial urethritis has an incubation period of 1–4 weeks, and tends to result in milder symptoms than gonorrhoea. However, a confirmed microbiological diagnosis should always be the aim.

## 15.1 Possible outcomes of STI in pregnancy

Organism	Mode of transmission	Outcome for fetus/neonate	Outcome for mother
<i>Treponema pallidum</i>	Transplacental	Ranges from no effect to severe stigmata or miscarriage/stillbirth	None directly relating to the pregnancy
<i>Neisseria gonorrhoeae</i>	Intrapartum	Severe conjunctivitis	Possibility of ascending infection post partum
<i>Chlamydia trachomatis</i>	Intrapartum	Conjunctivitis, pneumonia	Possibility of ascending infection post partum
Herpes simplex	Usually intrapartum, but transplacental infection may occur rarely	Ranges from no effect to severe disseminated infection	Rarely, primary infection during 2nd/3rd trimesters becomes disseminated, with high maternal mortality
Human papillomaviruses	Intrapartum	Anogenital warts or laryngeal papillomas are very rare	Warts may spread and enlarge during pregnancy, but usually regress post partum

## Investigations

If microscopy facilities are available, a Gram-stained smear of urethral exudate (Fig. 15.1) reveals significant numbers of polymorphonuclear leucocytes (PMNL). Urethritis is defined as  $\geq 5$  PMNL per high-power field in the UK (the US Centers for Disease Control recommends a lower threshold of  $\geq 2$ ). If Gram-negative intracellular diplococci (GNDC) are also seen, a working diagnosis of gonorrhoea is made and further

**Fig. 15.1** A Gram-stained urethral smear from a man with gonococcal urethritis. Gram-negative diplococci are seen within polymorphonuclear leucocytes.

investigations for gonorrhoea are undertaken; if no GNDC are seen, a label of NGU is applied. In all settings, a FVU sample or swab should be taken for a combined nucleic acid amplification test (NAAT) for gonorrhoea, chlamydia and, where available, *M. genitalium*.

## Management

Syndromic management with prescription of multiple antimicrobials to cover the possibility of chlamydia, *M. genitalium* and sometimes gonorrhoea may be appropriate where diagnostic tests are unavailable or results delayed. Antibiotic use and selection is influenced by concerns about antibiotic resistance in both *N. gonorrhoeae* and *M. genitalium*. Microscopy findings allow a more accurate presumptive diagnosis. Additional treatment for gonorrhoea may be given on receipt of sensitivity results obtained by culture or NAAT technology (p. 103).

## Genital itch, rash and discomfort

Genital symptoms including itch, irritation or discomfort may present acutely or as chronic problems with or without rash. Causes are infectious, non-infectious or multifactorial. Box 15.3 provides a guide to diagnosis.

Balanitis usually presents acutely and refers to inflammation of the glans penis, often extending to the under-surface of the prepuce (foreskin), in which case it is called balanoposthitis. Candidiasis affecting the glans penis or vulvovagina is sometimes associated with immune deficiency, diabetes mellitus and the use of broad-spectrum antimicrobials,

### 15.3 Differential diagnosis of genital itch and/or rash

Likely diagnosis	Acute or chronic	Itch	Pain	Discharge	Specific characteristics	Diagnostic test	Treatment
Candidiasis	Acute	✓	–	White	Post-coital in men	Microscopy	Antifungal cream, e.g. clotrimazole or single dose oral antifungal, e.g. fluconazole 150 mg
Candidiasis	Chronic/recurrent	✓	±	White	Usually cyclical, rare in men	Microscopy (culture for yeasts other than <i>Candida albicans</i> in recurrent/refractory disease)	Oral antifungal, e.g. fluconazole 150 mg weekly for 6 months
Dermatoses, e.g. eczema or psoriasis	Either	✓	–	–	Similar to lesions elsewhere on skin	Clinical	Mild topical glucocorticoid, e.g. hydrocortisone
Genital herpes	Acute	±	✓	–	Atypical ulcers are not uncommon	Swab for HSV NAAT	Oral antiviral, e.g. aciclovir
<i>Pthirus pubis</i> ('crab lice') infection	Either	✓	–	–	Lice and nits seen attached to pubic hairs	Can be by microscopy but usually visual	According to local sensitivities Often permethrin
Lichen planus (p. 1103)	Either	±	–	–	Violaceous papules ± Wickham's striae	Clinical	None or mild topical glucocorticoid, e.g. hydrocortisone
Lichen sclerosus	Chronic	±	–	–	Ivory-white plaques, scarring	Clinical or biopsy	Strong topical glucocorticoid, e.g. clobetasol
Plasma cell balanitis of Zoon (penis)	Chronic	✓	–	±	Shiny, inflamed circumscribed areas	Clinical or biopsy	Strong topical glucocorticoid, e.g. clobetasol
Circinate balanitis (penis)	Either	–	–	–	Painless erosions with raised edges; usually as part of SARA (p. 1035)	Clinical	Mild topical glucocorticoid, e.g. hydrocortisone
Anaerobic (erosive) balanitis	Acute	±	–	Yellow	Offensive tight prepuce and poor hygiene may be aggravating factors	Clinical	Saline bathing ± metronidazole
Vulvodinia and vulvo vestibulitis	–	✓	–	–	Dyspareunia common, pain on touching erythematous area	Clinical	Refer to specialist vulva clinic

(HSV = herpes simplex virus; NAAT = nucleic acid amplification test; SARA = sexually active reactive arthritis)

15.4 Infections that cause vaginal discharge		
Cause	Clinical features	Treatment (in pregnancy seek specialist advice)
<b>Candidiasis</b>	Vulval and vaginal inflammation	Fluconazole <sup>1</sup> 150 mg orally as a single dose <i>or</i>
	Curdy white discharge adherent to walls of vagina	Clotrimazole <sup>2</sup> 500 mg pessary once at night and clotrimazole cream twice daily
	Low vaginal pH	
<b>Trichomoniasis</b>	Vulval and vaginal inflammation	Metronidazole <sup>3</sup> 400 mg orally twice daily for 5–7 days <i>or</i>
	Frothy yellow/green discharge	Metronidazole <sup>3</sup> 2 g orally as a single dose
<b>Bacterial vaginosis</b>	No inflammation	Metronidazole <sup>3</sup> 2 g stat or 400 mg twice daily orally for 5–7 days <i>or</i>
	White homogeneous discharge	Metronidazole <sup>3</sup> vaginal gel 0.75% daily for 5 days <i>or</i>
	High vaginal pH	Clindamycin <sup>4</sup> vaginal cream 2% daily for 7 days
<b>Aerobic vaginitis: streptococcal/staphylococcal infection</b>	Purulent vaginal discharge	Choice of antibiotic depends on sensitivity tests

<sup>1</sup>Avoid in pregnancy and breastfeeding. <sup>2</sup>Clotrimazole, and clindamycin damage latex condoms and diaphragms. <sup>3</sup>Avoid alcoholic drinks until 48 hours after finishing treatment. Avoid high-dose regimens in pregnancy or breastfeeding. <sup>4</sup>*Clostridioides difficile* colitis has been reported with the use of clindamycin cream.

glucocorticoids or antimetabolic drugs. Chronic persistent or recurrent itch, commonly affecting the vulva, may be due to recurrent candidiasis with hypersensitivity to candidal antigens. Avoiding irritants such as scented hygiene products, soaps and detergents may be helpful in any case of chronic itch or discomfort.

The importance of psychological issues such as relationship or STI concerns, or a psychiatric diagnosis as a cause or a consequence of chronic or recurrent genital symptoms should always be considered.

## Vaginal discharge

The normal physiological vaginal discharge may vary considerably over the menstrual cycle and under the influence of other hormonal changes such as puberty, pregnancy or prescribed contraception. An increase or change in vaginal discharge may also be due to a number of infective and non-infective conditions (Box 15.4). Worldwide, the most common treatable STI causing vaginal discharge is trichomoniasis; other possibilities include gonorrhoea and chlamydia. However, even in areas of high STI prevalence, most of those presenting with vaginal discharge alone will not have STI, so syndromic management of first presentation of vaginal discharge is often appropriate. Symptoms can help to distinguish the causes and anatomical origin of a vaginal discharge including:

- an increased discharge without any itch or irritation accompanied by an unpleasant or fishy odour, worse after sexual intercourse and during menstruation, indicates the possibility of BV
- vulval itching accompanied by a thick, white vaginal discharge, vulval burning, external dysuria and superficial dyspareunia may indicate candidiasis
- a purulent or mucopurulent discharge, with bloodstaining and/or post-coital or intermenstrual bleeding indicates the possibility of a discharge originating from an inflamed cervix, more commonly associated with STI including chlamydia and gonorrhoea.

**Fig. 15.2** Gram stain of a Clue cell from a patient with bacterial vaginosis. The margin of this vaginal epithelial cell is obscured by a coating of anaerobic organisms. From McMillan A, Young H, Ogilvie MM, Scott GR. *Clinical practice in sexually transmissible infections*. Philadelphia: Saunders, Elsevier Inc.; 2002.

Testing for STI should usually be decided by risk assessment rather than symptoms and usually includes vulvovaginal swabs for NAAT tests for chlamydia, gonorrhoea and with increasing availability *Trichomonas vaginalis*. Speculum examination, supported in specialist sexual health services by testing with narrow range pH paper and Gram-stain microscopy, allows rapid diagnosis in many cases. A homogeneous off-white discharge, vaginal pH greater than 4.5, and microscopy revealing reduced lactobacilli with Gram-variable organisms coating vaginal squamous cells (so-called Clue cells, Fig. 15.2), suggests BV. If there is vulval and vaginal erythema, a curdy discharge, vaginal pH less than 4.5, and fungal spores and pseudohyphae on microscopy, the diagnosis is candidiasis. A profuse yellow or green discharge with significant vulvovaginal inflammation and a very high pH suggests trichomoniasis, confirmed by finding motile flagellate protozoa on a wet-mount microscopy slide, by culture or by NAAT testing.

A purulent discharge from an inflamed cervix may contain GNDC on Gram-stain microscopy, allowing presumptive treatment for gonorrhoea. However, clinical examination and microscopy has very low sensitivity for *N. gonorrhoeae* in women, so NAAT and/or culture tests for STI should always be taken in women with behavioural or demographic risk factors for STI.

Treatment of infections causing vaginal discharge is shown in Box 15.4.

## Genital ulceration

The most common cause of genital ulceration is genital herpes, but the possibility of other diagnoses including syphilis and LGV must be considered in all cases, with a higher index of suspicion if the patient is a MSM or has had a sexual partner from a region where tropical STIs are more common. Clinical signs and symptoms can help to distinguish between herpes and syphilis but certainty requires diagnostic testing. In herpes, multiple painful ulcers typically affect the introitus, labiae and perineum of the female genitalia and the glans, coronal sulcus or shaft of penis (Fig. 15.3). The presence of multiple lesions at different stages (erythematous, vesicular/blistering, ulcerating and resolving) is strongly supportive of a herpes diagnosis. Perianal herpes ulcers may be seen and are usually associated with receptive anal sex. Inguinal lymphadenopathy and systemic features, such as fever and malaise, are more common in women than in men.

In contrast, the classic lesion of primary syphilis (chancre) is single, painless and indurated; however, multiple (usually <5) lesions are commonly seen and anal chancres are often painful. Ulcers also occur in the primary stage of LGV and should be considered in MSM, especially if inguinal lymphadenopathy ensues.

**Fig. 15.3** Penile herpes simplex (HSV-2) infection.

Diagnosis is made by gently swabbing the lesion(s) for detection of HSV DNA and increasingly for *Treponema pallidum* by NAAT. A swab for testing for LGV (see [Box 15.12](#)) may be taken in MSM. In specialist sexual health services, syphilis may be diagnosed in-clinic by dark-ground microscopy of material obtained from a chancre. Serological tests for syphilis should always be performed in patients presenting with genital ulcer.

Other infective causes seen in the UK include varicella zoster virus (p. 282) and trauma with secondary infection. Tropical STIs, such as chancroid and granuloma inguinale, are rare and are described in [Box 15.12](#).

Non-infective inflammatory causes include lichen sclerosus, aphthosis, Stevens–Johnson syndrome (see Ch. 27), Behçet’s disease (p. 1047) and fixed drug reactions. In older patients, squamous cell carcinoma and vulvar or penile intra-epithelial neoplasia (VIN and PIN) should be considered and excluded by biopsy in cases of doubt. The possibility of a pre-existing underlying pathology with a co-incident infection should be considered if lesions recur or fail to resolve.

## Genital lumps

The most common cause of genital ‘lumps’ is warts. These are classically found in areas of friction during sex, such as the parafrenal skin and prepuce of the penis, the inner aspect of the vulval labia, the fourchette and perineum. Warts may also be seen on the keratinised epithelium of the shaft of the penis, pubis or inner thighs and less commonly in the urethral meatus. Perianal warts are relatively common in both men and women even in the absence of a history of receptive anal sex.

The differential diagnosis includes molluscum contagiosum and skin tags. Normal anatomical features may be confused with warts by young men and women and occasionally by clinicians. These include coronal papillae, parafrenal glands or sebaceous glands (Fordyce spots) in men and vulval papillae and sebaceous glands in women.

## Proctitis

Proctitis due to STI is almost exclusively diagnosed in MSM, but occasionally presents in women. STIs that may cause proctitis include gonorrhoea, chlamydia, herpes and syphilis. Lymphogranuloma venereum (LGV), caused by sub strains L1–3 of *Chlamydia trachomatis*, is now a common cause of severe proctitis in MSM in the UK.

Symptoms include mucopurulent anal discharge, rectal bleeding, pain and tenesmus. Examination may show mucopus and erythema with contact bleeding (p. 370). In addition to the diagnostic tests listed on page 371, a PCR test for HSV should be performed, with NAAT for LGV subtypes if chlamydia NAAT is positive. Treatment is directed at the individual infections.

Gastrointestinal symptoms including diarrhoea may indicate sexually transmitted enteric infection (STEI) with organisms such as *Salmonella*, *Shigella*, *Campylobacter*, *Cryptosporidium* and *Entamoeba histolytica* (see Ch. 13).

## Lower abdominal pain

Lower abdominal and pelvic pain presenting in women of reproductive age has a wide differential diagnosis. In sexually active women, this includes complications of early pregnancy as well as those of STI. Pelvic inflammatory disease (PID) is usually the result of infection ascending from the endocervix to cause inflammation of the endometrium, fallopian tubes and ovaries, sometimes extending to the parametrium and the pelvic peritoneum or causing tubo-ovarian abscess. A diagnosis of chlamydia, gonorrhoea or *M. genitalium* infection supports the diagnosis but PID commonly occurs without STI. A definitive diagnosis of PID can only be made by laparoscopy, which is not practical or appropriate in the majority of cases. Early treatment improves outcomes, so a clinical diagnosis is made with a low threshold for initiating empirical antibiotic treatment. Other symptoms suggesting PID include deep dyspareunia, abnormal vaginal discharge and/or bleeding and symptoms of systemic infection such as fever and malaise. On examination, lower abdominal tenderness is usually bilateral, and bimanual vaginal examination reveals adnexal tenderness with or without cervical motion tenderness. Diagnostic tests (p. 371) should include a pregnancy test because the differential diagnosis includes ectopic pregnancy.

If a clinical diagnosis of PID is thought likely, broad-spectrum antibiotics active against gonorrhoea, chlamydia and Gram-negative organisms, such as ceftriaxone, doxycycline and metronidazole, should be initiated immediately. Hospital admission for intravenous therapy may be required in severe cases. Delaying treatment increases the likelihood of adverse sequelae, such as abscess formation, and tubal scarring that may lead to ectopic pregnancy, infertility or chronic pain.

Acute or chronic pain in the male pelvis may be attributable to infective prostatitis or abacterial prostatic pain syndromes. Infections are usually associated with organisms causing urinary infection and STI is not implicated.

## Epidemiology

The World Health Organization (WHO) estimates that there were over 376 million cases of the four major curable STIs (syphilis, gonorrhoea, chlamydia and trichomoniasis) in adults aged 15–49 throughout the world in 2016, with 90% in lower-income countries. Most of the complications of untreated STI, including chronic pain, infertility, genital cancers and the increased risk of acquiring HIV infection, disproportionately affect women.

STI transmission depends partly on the number of sexual partners (high rates of partner change) and concurrency (having sex with more than one partner during the same time period) in any given population. Hence increases in STI prevalence are driven by changes in sexual

15.5 Examples of public health interventions to prevent STI in subpopulations with increased prevalence					
	Primary prevention: Structural/societal	Primary prevention: Biomedical	Primary prevention: Behavioural	Secondary prevention	Tertiary prevention
<b>Syphilis in MSM</b>	Marriage equality Targeted MSM services	Prophylactic antibiotics (research only)	Inclusive schools sex and relationship education (SRE)	Free online syphilis self-testing provision	App-based partner notification, 1-to-1 behaviour change interventions
<b>HPV-related cervical cancer in low-income women</b>	Gender equal pay legislation Countering 'anti-Vacc' propaganda through social media	HPV vaccination Smoking cessation medication	Condom skills demonstration in youth services	Cervical (pre) cancer screening	Surgical treatment for CIN (e.g. loop diathermy)
<b>HIV in transgender women</b>	Hate crime legislation Trans-inclusive health services	Promotion and provision of PrEP	Safer sex advice in holistic gender services	Outreach HIV testing services	Treatment as Prevention (TasP) PrEP for partners

(CIN = cervical intra-epithelial neoplasia; HPV = human papilloma virus; MSM = men who have sex with men; PrEP = pre-exposure prophylaxis)

behaviour, ways of increasing sexual mixing (finding new partners outside a social group or geographical area), such as travel or the use of mobile phone apps, and early sexual debut. Rates of different infections may also be affected by microbiological factors such as the emergence of strains carrying genetic mutations conferring antimicrobial resistance or causing asymptomatic infection. Human biological factors include changes in the prevalence of particular sexual behaviours (such as oral or anal sex), increased geographical mobility within and between countries, or the rates of vaccination and use of protection, for example condoms and pre-exposure HIV prophylaxis (PrEP). Consequently, STI incidence can vary dramatically by geography and over time, affected by structural changes such as economic decline, mass migration, legislation or changes in social mores and sexual behaviour, but also the availability of tests and services, treatment, prevention and vaccination programmes. In common with other infectious diseases, demographic risk factors relating to race, age, gender and sexual orientation combined with geographical and social deprivation ('syndemics') are often associated with increased STI prevalence in subpopulations across the world. These factors are also commonly barriers to access to education, prevention, testing and treatment services. For those affected by multiple risk factors, the population from whom they choose a sexual partner is likely to be a more significant determinant of STI risk than their individual sexual behaviours. The inability of individuals (in particular women) to make choices about consent to sex and reproductive health, including the necessity of transactional sex (exchange of sex for money, goods or protection) is an important additional factor for many such populations.

## Prevention

STI prevention involves making deliberate changes to affect the epidemiological factors described above at all levels to reduce the risk of acquisition of infection (Box 15.5). This may involve structural and legislative interventions (such as UK marriage equality, gender recognition laws) and deliberate social influencing (such as addressing HIV or trans stigma through TV drama). Primary biomedical and behavioural interventions (to prevent acquisition of infection) such as hepatitis B vaccination for MSM may be applied to populations or individuals at risk. Secondary prevention includes the early detection of infection to reduce the spread of infection by limiting the period of infectivity and mitigate harm and often involves designing services to provide equity of access

15.6 Management goals in diagnosed bacterial STI	
Goal	Interventions
Prevention of onward transmission	Advice to abstain until treatment completed Notification of sexual partners for testing/epidemiological treatment
Prevention of antimicrobial resistance	Antibiotic selection based on current local resistance data Antimicrobial test-of-cure Culture/NAAT based antimicrobial resistance testing
Identify other undiagnosed STI/BBV infection	Routine testing for other STIs, including HIV
Prevention of viral STIs for those at increased risk	Vaccination (HPV, hepatitis A, hepatitis B) PrEP for HIV
Opportunistic health improvement	Contraceptive advice and provision Address problematic alcohol/recreational drug use Brief behaviour change interventions

(BBV = blood-borne virus; HPV = human papilloma virus; NAAT = nucleic acid amplification test; PrEP = pre-exposure prophylaxis)

to groups affected by higher prevalence of infection (e.g. chlamydia screening for young people, antenatal HIV testing in maternity services). Tertiary prevention includes biomedical interventions such as ensuring access to effective early treatment for the individual to prevent onward transmission. Partner notification (contact tracing) is a cornerstone of STI prevention (Box 15.6). It involves identifying recent sexual contacts at risk of infection to allow testing and in some cases the provision of treatment without confirming the individual is infected (termed epidemiological treatment). Partner notification may be undertaken by the patient, sometimes with professional help, or by the provider (clinician), requiring high levels of sensitivity and respect for confidentiality and anonymity. It is increasingly supported by technology such as dedicated partner notification apps and online systems. The benefits of provision of antibiotics for partners without a confirmed diagnosis must be carefully weighed

against the risks of antibiotic resistance in the community. Behaviour change interventions, applied to populations or individuals at increased STI risk, sometimes following an initial STI diagnosis, have a good evidence base. However, proving or excluding a direct effect of population interventions that are 'distal' to the outcome measure (i.e. STI rates), such as schools sex and relationships education (SRE) or mass media campaigns, is extremely challenging due to multiple confounding factors.

## Sexually transmitted bacterial infections

### Syphilis

Syphilis is caused by infection, through abrasions in the skin or mucous membranes, with the spirochaete *Treponema pallidum* subspecies *pallidum*. In adults the infection is usually sexually acquired; however, transmission by kissing, blood transfusion and percutaneous injury has been reported. Congenital syphilis, caused by transplacental infection of the fetus, remains rare in the UK, but an estimated one million pregnant women worldwide had active syphilis in 2016, causing about 200 000 stillbirths or neonatal deaths. Rates of infectious syphilis have risen in the UK over the last decade to levels last seen in the 1940s. About 75% of syphilis cases in the UK are in MSM.

The natural history of untreated syphilis is variable. Primary and secondary syphilis symptoms resolve spontaneously without treatment, meaning that the disease may go unrecognised and untreated with a risk of late complications. Infection may remain latent throughout, or clinical features may develop at any time.

### Acquired syphilis

#### Early syphilis

##### Primary syphilis

Following exposure, the incubation period is typically around 21 days, with a range of 9–90 days. A primary lesion or chancre (Fig. 15.4) develops at the site of infection, usually in the genital area. A dull red macule develops, becomes papular and then erodes to form an indurated ulcer (chancre). Chancres may be multiple or atypical. The draining inguinal lymph nodes may become moderately enlarged, mobile, discrete and rubbery. The chancre and the lymph nodes are both painless and non-tender, unless there is concurrent or secondary infection. Without treatment, the chancre will resolve within 2–6 weeks to leave a thin atrophic scar.

Chancres may develop on the vaginal wall and on the cervix. Extragenital chancres are found in up to a third of MSM, affecting sites such as the finger, lip, tongue, tonsil, nipple, anus or rectum. Anal chancres often resemble fissures and may be painful.

##### Secondary syphilis

This occurs 6–8 weeks after the development of the chancre, when treponemes disseminate to produce a multisystem disease. Constitutional symptoms, such as mild fever, malaise and headache, are common. Over 75% of patients present with a rash on the trunk and limbs that may later involve the palms and soles; this is initially macular but evolves to maculopapular or papular forms, which are generalised, symmetrical and non-irritable. Scales may form on the papules later. Lesions are red, changing to a 'gun-metal' grey as they resolve. Without treatment, the rash may last for up to 12 weeks and is easily confused with psoriasis, pityriasis rosea, scabies, allergic drug reaction, erythema multiforme or pityriasis (tinea) versicolor, particularly if risk factors for syphilis infection have not been identified. Primary HIV infection (Ch. 14) is an important differential diagnosis.

Condylomata lata (papules coalescing to plaques) may develop in warm, moist sites such as the vulva or perianal area. Generalised non-tender lymphadenopathy is present in over 50% of patients.

**Fig. 15.4 Primary syphilis.** A painless ulcer (chancre) is shown in the coronal sulcus of the penis. This is usually associated with inguinal lymphadenopathy. From Clutterbuck DJ. *Specialist training in sexually transmitted infections and HIV*. St Louis: Mosby, Elsevier Inc.; 2004.

Mucosal lesions, known as mucous patches, may affect the genitalia, mouth, pharynx or larynx. Rarely, confluence produces characteristic 'snail track ulcers' in the mouth.

Other features of secondary syphilis may present with or without rash; these include meningitis, cranial nerve palsies, anterior or posterior uveitis, hepatitis, gastritis, glomerulonephritis or periostitis. Although neurosyphilis has often been regarded as a manifestation of late syphilis, the commonest presentation of neurosyphilis in the UK is neurovascular syphilis presenting in the secondary stage.

The clinical manifestations of secondary syphilis will resolve without treatment but relapse occurs in up to 25% of cases within the 2 years of infection. The disease then enters the phase of latency.

##### Latent syphilis

This phase is characterised by the presence of positive syphilis serology or the diagnostic cerebrospinal fluid (CSF) abnormalities of neurosyphilis in an untreated patient with no evidence of clinical disease. In early latency (within 2 years of infection), syphilis may be transmitted sexually. In late latent syphilis the patient is no longer sexually infectious. Transmission of syphilis from a pregnant woman to her fetus, and rarely by blood transfusion, is possible for several years following infection.

##### Late syphilis

###### Late latent syphilis

Without treatment, over 60% of patients will suffer little or no ill health from untreated syphilis, although many of these have asymptomatic pathological changes identifiable at autopsy. This is termed late latent syphilis. Other manifestations of late syphilis are now rarely seen in the UK, partly because of the prescription of antibiotics for other illnesses, such as respiratory tract or skin infections, may treat syphilis serendipitously.

###### Cardiovascular syphilis

The commonest late manifestation of untreated syphilis is involvement of the ascending aorta and sometimes the aortic arch, presenting between 10 and 30 years after infection as aortic incompetence, angina and aortic aneurysm (p. 442).

###### Benign tertiary syphilis

A chronic granulomatous lesion called a gumma is characteristic and may be single or multiple, developing 3–10 years after infection. It is rarely seen in the UK. Mucosal lesions may occur in the mouth, pharynx, larynx or nasal septum, appearing as punched-out ulcers. Gummas of the tibia, skull, clavicle and sternum have been described, as has involvement of

## 15.7 Clinical features of congenital syphilis

### Early congenital syphilis (neonatal period)

- Maculopapular rash
- Condylomata lata
- Mucous patches
- Fissures around mouth, nose and anus
- Rhinitis with nasal discharge (snuffles)
- Hepatosplenomegaly
- Osteochondritis/periostitis
- Generalised lymphadenopathy
- Choroiditis
- Meningitis
- Anaemia/thrombocytopenia

### Late congenital syphilis

- Benign tertiary syphilis
- Periostitis
- Paroxysmal cold haemoglobinuria
- Neurosyphilis
- 8th nerve deafness
- Interstitial keratitis
- Clutton's joints (painless effusion into knee joints)

### Stigmata

- Hutchinson's incisors (anterior–posterior thickening with notch on narrowed cutting edge)
- Mulberry molars (imperfectly formed cusps/deficient dental enamel)
- High arched palate
- Maxillary hypoplasia
- Saddle nose (following snuffles)
- Rhagades (radiating scars around mouth, nose and anus following rash)
- Salt and pepper scars on retina (from choroiditis)
- Corneal scars (from interstitial keratitis)
- Sabre tibia (from periostitis)
- Bossing of frontal and parietal bones (healed periosteal nodes)

the brain, spinal cord, liver, testis and, rarely, other organs. Resolution of active disease should follow treatment, though some tissue damage may be permanent. Paroxysmal cold haemoglobinuria (p. 959) may be seen.

### Neurosyphilis

This may also take years to develop. Asymptomatic infection is associated with CSF abnormalities in the absence of clinical signs. Meningovascular disease, tabes dorsalis and general paralysis of the insane constitute the symptomatic forms (p. 1178).

## Congenital syphilis

Where antenatal serological screening is routinely practised with high uptake, including the UK, congenital syphilis is rare. Antisyphilitic treatment in pregnancy treats the fetus, if infected, as well as the mother.

Treponemal infection may give rise to a variety of outcomes after 4 months of gestation, when the fetus becomes immunocompetent:

- miscarriage or stillbirth, prematurely or at term
- birth of a syphilitic baby (a very sick baby with hepatosplenomegaly, bullous rash and perhaps pneumonia)
- birth of a baby who develops signs of early congenital syphilis during the first few weeks of life (Box 15.7)
- birth of a baby with latent infection who either remains well or develops congenital syphilis/stigmata later in life (see Box 15.7).

### Investigations in adult cases

Nucleic acid testing such as PCR for *Treponema pallidum* is available increasingly routinely for the diagnosis of early syphilis in samples of serum collected from chancres, or from moist or eroded lesions in secondary syphilis. Dark field microscopy remains in use as the fastest near patient test in many specialist sexual health services.

Serological tests for syphilis (STS) such as treponemal enzyme immunoassays (EIAs) for IgG and IgM antibodies are more commonly used for routine testing in most settings and for antenatal screening. Other treponemal and non-treponemal tests are usually done if an initial screening test is positive or for follow up for positive cases and are listed in Box 15.8. Syphilis IgM becomes positive at approximately 2 weeks, while non-treponemal tests become positive about 4 weeks after primary syphilis.

## 15.8 Serological tests for syphilis

### Non-treponemal tests: detect antibodies non-specific to syphilis antigens

- Venereal Diseases Research Laboratory (VDRL) test
- Rapid plasma reagin (RPR) test

### Treponemal antibody tests: specific for antibody to syphilis antigens

- Treponemal antigen-based enzyme immunoassay (EIA) for IgG and IgM
- *Treponema pallidum* haemagglutination assay (TPHA)
- *T. pallidum* particle agglutination assay (TPPA)
- Fluorescent treponemal antibody-absorbed (FTA-Abs) test

Following treatment, non-treponemal tests are routinely monitored for declining titres, usually to low or undetectable levels within 12–18 months for primary or secondary syphilis. In patients with longstanding untreated late syphilis there may be high antibody titres with little change even after adequate treatment. Consequently, positive syphilis serology may be found during the investigation of other conditions (e.g. dementia), reflecting infection that has been treated deliberately or by accident, many years previously. Interpretation of results requires knowledge of any treatment, which may include antibiotics given for other indications.

Biological false-positive reactions occur occasionally; these are most commonly seen with Venereal Diseases Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests, which do not require laboratory facilities so are used as screening tests in many countries. False positives are identified when treponemal tests are negative. Acute false-positive reactions may be associated with infections, such as infectious mononucleosis, chickenpox and malaria, and may also occur in pregnancy. Chronic false-positive reactions may be associated with autoimmune diseases.

The CSF should also be examined in patients with clinical signs of neurosyphilis (p. 1178) and in both early and late congenital syphilis.

Chest X-ray, electrocardiogram (ECG) and echocardiogram are useful in the investigation of cardiovascular syphilis. Biopsy may be required to diagnose gumma.

Endemic treponematoses, such as yaws, endemic (non-venereal) syphilis (bejel) and pinta (see Ch. 13), are caused by treponemes that are morphologically indistinguishable from *T. pallidum* and cannot be reliably differentiated by serological tests.

### Investigations in suspected congenital syphilis

A newborn baby may have positive serological tests due to passively transferred maternal antibodies, but non-treponemal tests should become negative within 3–6 months of birth if the mother is adequately treated and child is uninfected. A neonate with a positive EIA test for antitreponemal IgM suggests early congenital syphilis. A diagnosis of congenital syphilis mandates investigation of the mother, her partner and any siblings.

### Management

Penicillin remains the drug of choice for all stages of infection almost 80 years after its introduction. A single dose of 2.4 megaunits of long-acting intramuscular benzathine benzylpenicillin is recommended for early syphilis (<2 years' duration), or three doses at weekly intervals for late syphilis. A 14-day course of intramuscular procaine penicillin 2.4 megaunits once daily with oral probenecid 500mg 4 times daily is recommended for the treatment of neurosyphilis, supplemented by a 3-day course of prednisolone (see below). Oral doxycycline is indicated for patients allergic to penicillin, except in pregnancy (see below). Azithromycin showed promise as an alternative treatment but resistance has been reported. All patients must be followed up until clinical signs have resolved and for partner notification. Serology is usually repeated for a year following treatment.

### Pregnancy

Penicillin is the treatment of choice in pregnancy. If there is penicillin hypersensitivity, options include penicillin desensitisation, treatment with

**Fig. 15.5 Gonococcal ophthalmia neonatorum.** From McMillan A, Scott GR. *Sexually transmitted infections: a colour guide*. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2000.

erythromycin (with penicillin for the baby at birth because it crosses the placenta poorly), or intramuscular ceftriaxone 500 mg daily for 10 days (2 g daily for late infection/neurosyphilis).

#### Treatment reactions

- *Anaphylaxis*. Penicillin is a common cause; adrenaline and resuscitation equipment should be immediately to hand (p. 183).
- *Jarisch–Herxheimer reaction*. This is an acute febrile reaction that follows treatment and is characterised by headache, malaise and myalgia; it resolves within 24 hours. It is common in early syphilis and rare in late syphilis. Fetal distress or premature labour can occur in pregnancy. The reaction may also cause worsening of neurological (cerebral artery occlusion) or ophthalmic (uveitis, optic neuritis) disease, myocardial ischaemia (inflammation of the coronary ostia) and laryngeal stenosis (swelling of a gumma). Prednisolone 40–60 mg daily for 3 days is recommended to prevent the reaction in patients with these forms of the disease; antibiotic treatment can be started 24 hours after the first steroid dose. In high-risk situations the first antibiotic dose should be given in hospital.
- *Procaine reaction*. Fear of impending death occurs immediately after the accidental intravenous injection of procaine penicillin and may be associated with short-lived hallucinations or fits. Aspiration before any intramuscular injection is mandatory.

## Gonorrhoea

Gonorrhoea is caused by the Gram-negative diplococcus *Neisseria gonorrhoeae* and usually involves columnar epithelium in the lower genital tract, rectum, pharynx and eyes. Transmission is usually the result of vaginal, anal or oral sex. Gonococcal conjunctivitis may be caused by accidental infection from contaminated fingers. Untreated mothers may infect babies during delivery, resulting in ophthalmia neonatorum (Fig. 15.5).

#### Clinical features

The incubation period is usually 2–10 days. Infection of the male urethra causes urethral discharge and dysuria; only a minority are asymptomatic. The female urethra, paraurethral glands/ducts, Bartholin's glands/ducts or endocervical canal may be infected, but about 80% of women are asymptomatic. There may be vaginal discharge or dysuria but these symptoms may be due to co-existing infections, such as chlamydia (see below), trichomoniasis or candidiasis. Intermenstrual or post-coital

### 15.9 Complications of delayed therapy in gonorrhoea

- Acute prostatitis
- Epididymo-orchitis
- Bartholin's gland abscess
- Pelvic inflammatory disease (may lead to infertility or ectopic pregnancy)
- Disseminated gonococcal infection

bleeding suggests involvement of the cervix and lower abdominal/pelvic pain and dyspareunia suggests that the infection has ascended to the upper genital tract (PID)

Rectal infection is seen in MSM and in women due either to anal sex or to contamination from a urogenital site. It is usually asymptomatic but may present with anal discomfort, discharge or rectal bleeding.

Clinical examination may show no abnormality, but mucopurulent or purulent urethral discharge may be seen at infected sites. This is often obvious at the male urethra (p. 372). Discharge may be expressed from the female urethra, paraurethral ducts or Bartholin's ducts. The cervix may be inflamed, with mucopurulent discharge and contact bleeding. Proctoscopy may reveal either no abnormality, or clinical evidence of proctitis (p. 375) such as inflamed rectal mucosa and mucus.

Pharyngeal gonorrhoea is usually symptomless and is largely attributed to receptive orogenital sex. Gonococcal conjunctivitis is an uncommon complication of adults and neonates, presenting with purulent discharge from the eye(s), severe inflammation of the conjunctivae and oedema of the eyelids, pain and photophobia. Conjunctivitis must be treated urgently to prevent corneal damage.

Other complications arise if diagnosis or treatment is delayed (Box 15.9). Disseminated gonococcal infection (DGI) is rare. Symptoms include arthritis of one or more joints, pustular skin lesions, tenosynovitis and fever. Gonococcal endocarditis has been described.

#### Investigations

Gram-negative diplococci may be seen on microscopy of smears from infected sites (see Fig. 15.1). Pharyngeal smears are not helpful due to the presence of commensal *Neisseria* spp., which have the same microscopic appearance. Nucleic acid amplification tests (NAAT) are a widely used diagnostic test (see Box 15.1), with culture on selective medium in positive cases for antibiotic sensitivity surveillance. Nucleic acid probes for specific antibody resistance mutations (e.g. to ciprofloxacin) are increasingly available, with the prospect of whole-genome sequencing in the near future.

#### Management of adults

*Neisseria gonorrhoeae* is a highly adaptable organism and has developed high-level resistance to a range of antibiotics over time, with frequent changes to recommended antibiotics and dosage. Multi-drug-resistant gonorrhoea (MDRGC) has emerged as a significant concern in recent years. Current UK treatment recommendations are for a single 1 g dose of IM ceftriaxone. Longer courses of antibiotics are required for complicated infection. NAAT-based antibiotic sensitivity testing available at the time of diagnosis offers the possibility of selective use of antibiotics previously rendered unsuitable for blind treatment (see Box 15.10).

The partner(s) of patients with gonorrhoea should be seen as soon as possible.

## Chlamydial infection

Chlamydia is transmitted and presents in a similar way to gonorrhoea. In women, the cervix and urethra are commonly involved. Infection is asymptomatic in about 80%, but may cause intermenstrual and/or post-coital bleeding, dysuria or vaginal discharge. Lower abdominal pain and dyspareunia are features of PID. Examination may reveal mucopurulent cervicitis, contact bleeding from the cervix, evidence of PID or no obvious clinical signs.

15.10 Treatment of uncomplicated anogenital gonorrhoea
<b>Uncomplicated anogenital or pharyngeal infection</b>
<ul style="list-style-type: none"> <li>• Ceftriaxone 1 g IM as a single dose</li> <li>• Ciprofloxacin 500 mg orally as a single dose<sup>1,2</sup></li> </ul>
<b>Pregnancy and breastfeeding</b>
<ul style="list-style-type: none"> <li>• Ceftriaxone 1 g IM as a single dose</li> <li>• Spectinomycin 2 g IM stat<sup>3</sup></li> </ul>
<b>Disseminated gonorrhoea</b>
<ul style="list-style-type: none"> <li>• Ceftriaxone 1 g IM or IV once daily or</li> <li>• Cefotaxime 1 g IV 3 times daily</li> <li>• Switched to an oral alternative according to sensitivities after 48 hrs and continued for 7 days</li> </ul>
<p><sup>1</sup>Contraindicated in pregnancy and breastfeeding. <sup>2</sup>Only where nucleic acid amplification test (NAAT) or culture-based sensitivity testing shows sensitivity at all sites. <sup>3</sup>Not routinely available. (IM = intramuscular; IV = intravenous)</p>

15.11 Treatment of chlamydial infection
<b>Uncomplicated infection</b>
<ul style="list-style-type: none"> <li>• First choice: Doxycycline 100 mg orally twice daily for 7 days<sup>1</sup></li> <li>• Second choice: Azithromycin 1 g orally as a single dose followed by 500 mg once daily for 2 days</li> </ul>
<b>Infection with possible complications (epididymo-orchitis, PID, SARA)<sup>2</sup></b>
<ul style="list-style-type: none"> <li>• First choice: Doxycycline 100 mg orally twice daily for 14 days<sup>1</sup></li> <li>• Second choice: Ofloxacin 400 mg orally twice daily for 14 days<sup>3</sup></li> </ul>
<p><sup>1</sup>Contraindicated in pregnancy and breastfeeding. <sup>2</sup>With additional antibiotics to cover other possible organisms. <sup>3</sup>Quinolones are now less commonly used first line because of concerns about rare permanent and disabling side-effects. (PID = pelvic inflammatory disease; SARA = sexually acquired reactive arthritis)</p>

Other complications include perihepatitis (Fitz-Hugh–Curtis syndrome, p. 856), chronic pelvic pain, conjunctivitis and sexually acquired reactive arthritis (SARA) (p. 1035). Perinatal transmission may lead to ophthalmia neonatorum and/or pneumonia in the neonate. The majority of chlamydial infections clear spontaneously without treatment but others persist. The individual's risk of 'silent' tubal damage and subsequent infertility or ectopic pregnancy following asymptomatic chlamydial infection is low, but is a concern because of the high prevalence of chlamydial infection in the sexually active population.

In men, urethral symptoms are usually milder than those of gonorrhoea and may be absent in over 50% of cases. Conjunctivitis is also milder than in gonorrhoea; pharyngitis does not occur, although chlamydia is detected in pharyngeal samples in a small proportion of individuals. The incubation period varies from 1 week to a few months. Without treatment, symptoms may resolve but the patient remains infectious for several months. Complications, such as epididymo-orchitis and SARA are rare. Sexually transmitted pathogens, such as chlamydia or gonococci, are usually responsible for epididymo-orchitis in men aged less than 35 years, whereas bacteria such as Gram-negative enteric organisms are more commonly implicated in older men.

Treatments for chlamydia (Box 15.11) are also used for empirical treatment of NGU. Antibiotic resistance has not yet been a significant issue. Sexual partners should be traced and may be tested and/or treated epidemiologically depending on circumstances. Technologies supporting testing, treatment and partner notification for chlamydia include app-based notification systems and electronic treatment vouchers which can be redeemed at community pharmacies.

### ***Mycoplasma genitalium***

*Mycoplasma genitalium* is strongly associated with NGU (p. 372) and is implicated in the pathogenesis of PID. Its role in the development of

other STI syndromes is not clear. A very high proportion of *M. genitalium* isolates in the UK are resistant to macrolides. This has led to doxycycline replacing azithromycin as the first choice empirical treatment of chlamydial infection and NGU. Where azithromycin is used, the multiple-dose regimen shown in Box 15.11 is preferred over a single dose because this may be both more effective and reduce the risk of macrolide resistance developing in *M. genitalium*.

### **Other sexually transmitted bacterial infections**

Chancroid, granuloma inguinale and LGV as causes of genital ulcers in the tropics are described in Box 15.12. LGV now much more commonly presents as proctitis in MSM, having been acquired in Europe (p. 375).

## **Sexually transmitted viral infections**

### **Genital herpes simplex**

Infection with herpes simplex virus type 1 (HSV-1) or type 2 (HSV-2) produces a wide spectrum of clinical problems (p. 290), and facilitates the transmission of untreated HIV. Herpes is usually acquired sexually (vaginal, anal, orogenital or oro-anal), but perinatal transmission to the neonate may also occur. Primary infection at the site of HSV entry may be symptomatic or asymptomatic. HSV then establishes latency in local sensory ganglia, intermittently reactivating to cause either symptomatic or asymptomatic recurrences at the same site with viral shedding, during which transmission may occur. Most transmissions are thought to originate from people unaware of their infection. Although HSV-1 is classically associated with orolabial herpes and HSV-2 with anogenital herpes, HSV-1 accounts for more than 50% of anogenital infections in the UK.

#### **Clinical features**

Symptomatic episodes usually involve the external genitalia with irritable vesicles that soon rupture to form small, tender ulcers which scab and heal without scarring (Fig. 15.6 and see Fig. 15.3). A symptomatic episode at the time of acquisition is usually the most severe, but may occasionally be delayed following asymptomatic primary infection. Constitutional symptoms such as fever, headache and malaise are common. Complications, such as urinary retention due to autonomic neuropathy, and aseptic meningitis, are occasionally seen. Inguinal lymph nodes become enlarged and tender, and there may be nerve root pain in the 2nd and 3rd sacral dermatomes. Lesions at other sites (e.g. urethra, vagina, cervix, perianal area, anus or rectum) may cause dysuria, urethral or vaginal discharge, or anal, perianal or rectal pain. First episodes usually heal within 2–4 weeks without treatment; recurrences are similar but usually milder and of shorter duration than the initial attack.

Extragenital lesions may develop at other sites, such as the buttock, finger or eye, due to auto-inoculation.

HSV-1 and HSV-2 episodes are clinically identical, but recurrences occur more often in HSV-2 infection and their frequency tends to decrease more slowly with time. Prodromal symptoms, such as irritation or burning at the affected site, or neuralgic pain affecting buttocks, legs or hips often occur prior to a symptomatic recurrence.

#### **Diagnosis**

Swabs are taken from vesicular fluid or ulcers for detection of HSV-1 and 2 DNA by NAAT. Type-specific antibody tests for HSV-1 and 2 are available but not routinely used for diagnosis.

#### **Management**

##### **First episode**

Oral antiviral treatment will shorten the duration of symptoms if started within 5 days of the beginning of the episode, or while lesions are still forming. Occasionally, intravenous therapy may be indicated if oral

## 15.12 Salient features of lymphogranuloma venereum, chancroid and granuloma inguinale (Donovanosis)

Infection and distribution	Organism	Incubation period	Genital lesion	Lymph nodes	Diagnosis	Management

Africa, Asia, Central and S America	<i>Haemophilus ducreyi</i> (short Gram-negative bacillus)	3–10 days	Single or multiple painful ulcers with ragged undermined edges	As above but unilobar, suppurative bubo; inguinal nodes involved in ~50%	Microscopy and culture of scrapings from ulcer or pus from bubo	Azithromycin <sup>3</sup> 1 g orally once <i>or</i> Ceftriaxone 250 mg IM once <i>or</i> Ciprofloxacin <sup>2</sup> 500 mg orally twice daily for 3 days
<b>Granuloma inguinale</b>						
Australia, India, Caribbean, S Africa, S America, Papua New Guinea	<i>Klebsiella granulomatis</i> (Donovan bodies)	3–40 days	Ulcers or hypertrophic granulomatous lesions; usually painless <sup>4</sup>	Initial swelling of inguinal nodes, then spread of infection to form abscess or ulceration through adjacent skin	Microscopy of cellular material for intracellular bipolar-staining Donovan bodies	Azithromycin <sup>3</sup> 1 g orally weekly or 500 mg orally daily <i>or</i> Doxycycline <sup>2</sup> 100 mg orally twice daily <i>or</i> Ceftriaxone 1 g IM daily
<p><b>N.B.</b> Partners of patients with LGV, chancroid and granuloma inguinale should be investigated and treated, even if asymptomatic.</p> <p><sup>1</sup>LGV acquired as a rectal infection in MSM commonly presents as proctitis. <sup>2</sup>Doxycycline and ciprofloxacin are contraindicated in pregnancy and breastfeeding. <sup>3</sup>The safety of azithromycin in pregnancy and breastfeeding has not been fully assessed. <sup>4</sup>Mother-to-baby transmission of granuloma inguinale may rarely occur.</p> <p>(IM = intramuscular; NAAT = nucleic acid amplification test)</p>						

**Fig. 15.6** Herpetic ulceration of the vulva. From McMillan A, Scott GR. *Sexually transmitted infections: a colour guide*. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2000.

therapy is poorly tolerated or aseptic meningitis occurs. Many possible oral dosage regimens are used, including:

- aciclovir 400 mg 3 times daily for 5 days
- valaciclovir 500 mg twice daily for 5 days.

Topical and oral analgesia is helpful and patients are advised to use a warm shower spray to ease urination. Catheterisation via the suprapubic route is occasionally required for urinary retention. Treatment may be continued for longer than 5 days if new lesions develop.

#### Recurrent genital herpes

Symptomatic recurrences are usually mild and may require no specific treatment other than saline bathing, although the psychosexual impact of herpes stigma in a minority of patients should be considered. For more severe or prolonged episodes, patient-initiated treatment within 24 hours of onset, with one of the following oral regimens, should reduce the duration of the recurrence:

- aciclovir 800 mg 3 times daily for 2 days
- valaciclovir 500 mg twice daily for 5 days.

In a few patients, treatment started at the onset of prodromal symptoms may abort recurrence.

Those with recurrences that are severe and/or frequent may benefit from suppressive therapy. Daily treatment should be given for a minimum of 1 year before stopping to assess recurrence rate. The rate of decay in frequency of recurrence is low, so only about 20% of patients will experience significantly reduced rates. For others, resumption of suppressive therapy is justified. Aciclovir 400 mg twice daily is most commonly prescribed.

### Management in pregnancy

The risk of disseminated infection is increased in pregnancy, particularly in the third trimester. A pregnant woman with no previous anogenital herpes and a partner with a history of HSV infection should be advised on avoiding acquisition, which may include consistent condom use during pregnancy to reduce genital-to-genital transmission. Antibody testing can identify the type-specific HSV serostatus of a woman and her partner and inform the advice given. Treatment with aciclovir is usually offered for genital herpes acquired during pregnancy after appropriate discussion; although aciclovir is not licensed for use in pregnancy in the UK, there is considerable clinical evidence to support its safety.

Vaginal delivery is routine in most women with herpes in pregnancy. Caesarean section is sometimes considered if there is a recurrence at the beginning of labour, although the risk of neonatal herpes through vaginal transmission is very low. Caesarean section is often recommended if primary infection occurs after 34 weeks because the risk of viral shedding in labour is very high and the antibody response to HSV which develops in the mother and protects the neonate by transplacental transmission may not have fully developed.

### Human papillomavirus and anogenital warts

Human papillomavirus (HPV) subtypes (p. 1091) that preferentially infect the genital skin and are mainly sexually transmitted include benign genotypes (HPV-6 and 11) causing anogenital warts as well as genotypes such as 16 and 18, which do not cause genital warts but are associated with cervical, vulval, penile and anal intra-epithelial neoplasia (CIN, VIN, PIN and AIN) and the associated invasive cancers, as well as with cancers of the oropharynx. HPV is commonly transmitted through non-penetrative sex so affects individuals from the early years of adolescence onwards. Asymptomatic infection without any clinical sequelae is usual with all subtypes and infection with multiple subtypes is common.

#### Clinical features

Anogenital warts caused by HPV may be single or multiple, exophytic, papular or flat. Rarely, a giant condyloma (Buschke–Löwenstein tumour) develops, with local tissue destruction. Because of the association with intra-epithelial neoplasia, warts with an atypical appearance should be biopsied. Perianal warts (p. 370) are more common in MSM, but are also found in women and in heterosexual men. In pregnancy, warts may dramatically increase in size and number, making treatment difficult. Rarely, they are large enough to obstruct labour so delivery by caesarean section is required. Perinatal transmission of HPV occasionally leads to anogenital warts and rarely to laryngeal papillomas in the neonate.

#### Management

The use of condoms can help prevent the transmission of HPV to non-infected partners, but as condoms do not cover all of the genital skin, protection is incomplete. Vaccination against genital HPV infection is routine in many countries. There are three types of vaccine:

- A *bivalent vaccine* offers protection against HPV types 16 and 18, which account for approximately 75% of cervical cancers in the UK.
- A *quadrivalent vaccine* offers additional protection against HPV types 6 and 11, which account for over 90% of genital warts.
- A *nonavalent vaccine* protects against five additional high-risk types (31, 33, 45, 52 and 58).

All vaccines have been shown to be highly effective in the prevention of cervical intra-epithelial neoplasia in young women, and the quadrivalent and nonavalent vaccines have also been demonstrated to be highly effective in protecting against HPV-associated genital warts. HPV vaccination is usually administered prior to the onset of sexual activity, typically at age 11–13, in a course of three injections. In the UK, vaccination has

**Fig. 15.7** Molluscum contagiosum of the shaft of the penis. From McMillan A, Scott GR. *Sexually transmitted infections: a colour guide*. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2000.

been offered to girls since 2007 (with quadrivalent vaccine from 2012) and the recommendation was extended to boys from 2020.

Benign anogenital warts sometimes resolve spontaneously without treatment and in the vast majority of cases are a harmless, if sometimes distressing, inconvenience. Topical self-administered treatments commonly prescribed for use at home include:

- Podophylotoxin, 0.5% solution or 0.15% cream (contraindicated in pregnancy)
- Imiquimod cream (contraindicated in pregnancy), also used in the treatment of HPV-associated intra-epithelial neoplasia
- Catephen, an extract of the green tea plant, *Camellia sinensis*.

Ablative therapies, usually performed by a clinician, are sometimes used first line or for warts that are keratinised, extensive or resistant to topical treatment.

- *Cryotherapy* using liquid nitrogen to freeze warty tissue often requires repeated clinic visits, although home cryotherapy is available. It is one of the few options for treatment of warts in pregnancy.
- *Hyfrecation* – surgical electrofulguration using the heat from an electric current to destroy tissue – is suitable for external and internal warts.
- *Surgical removal* may be used to excise extensive and/or refractory warts, especially pedunculated perianal lesions, under local or general anaesthesia.

### Molluscum contagiosum

Infection by molluscum contagiosum virus, both sexual and non-sexual, produces flesh-coloured, umbilicated, hemispherical papules usually up to 5 mm in diameter after an incubation period of 3–12 weeks (Fig. 15.7). Lesions are often multiple and, once established in an individual, may spread by auto-inoculation. Infection in childhood is common; many individuals are immune by adulthood. If not, sexually acquired infection causes lesions on the genitalia, lower abdomen and upper thighs. The diagnosis is usually clinical. Typically, lesions persist for several months before spontaneous resolution occurs. Treatment regimens are therefore cosmetic; they include cryotherapy, hyfrecation or topical applications of 0.15% podophylotoxin cream (contraindicated in pregnancy). The hard, pearly central core of each lesion can be removed using a needle and results in resolution, but this carries a risk of scarring.

## Viral hepatitis

The hepatitis viruses A–D (p. 884) may be sexually transmitted:

- *Hepatitis A (HAV)*. Enteric infection may be transmitted through insertive oro-anal, digital-anal sex or peno-anal sex. Outbreaks of hepatitis A occur in MSM populations, most recently across Europe in 2016–18.
- *Hepatitis B (HBV)*. Hepatitis B is highly transmissible through all forms of penetrative sex, including oral sex, and is seen more commonly in groups with higher rates of partner change including sex workers and MSM, or with partners from endemic areas. Hepatitis D (HDV) may also be sexually transmitted.
- *Hepatitis C (HCV)*. Hepatitis C is much less transmissible through sex than HBV. Sex involving mucosal trauma (such as anal sex) carries a higher risk and sexually transmitted HCV is seen more commonly in MSM, particularly those co-infected with HIV, than in other populations.

Active immunisation against HAV and HBV should be offered to susceptible people at risk of infection. Many STI clinics offer a combined HAV and HBV vaccine to all MSM.

Partner notification, for testing and advice on preventing onward transmission, is offered to all those diagnosed with sexually transmitted viral hepatitis, with vaccination for HAV and HBV. No active or passive immunisation is available for protection against HCV but the consistent use of condoms is likely to protect susceptible partners until the index patient is able to complete treatment.

## Multiple Choice Questions

15.1. The preferred treatment for uncomplicated chlamydial infection has changed from single dose azithromycin to a 7-day course of doxycycline primarily because of concerns about the development of antimicrobial resistance in which organism?

- A. *Chlamydia trachomatis*
- B. *Mycoplasma genitalium*
- C. *Haemophilus ducreyi*
- D. *Treponema pallidum*
- E. *Trichomonas vaginalis*

Answer: B.

Rates of macrolide resistance in *Mycoplasma genitalium* in the UK are thought to be around 40%, probably driven by the widespread use of single dose azithromycin for the treatment of chlamydial infection in sexually active individuals. Treatment of antibiotic resistant *M. genitalium* in symptomatic individuals such as men with non-gonococcal urethritis (NGU) can be difficult. Azithromycin has never been a first-line treatment for syphilis in the UK, but resistance does occur in *Treponema pallidum*. Azithromycin is a potential treatment for chancroid and resistance in *Haemophilus ducreyi* is not currently widely reported.

15.2. A 49-year-old woman who has had two new male partners in the past 4 weeks presents to her general practitioner with vaginal discharge having a 'fishy' smell which is worse after sex. She has had 3 days of intermenstrual bleeding which is unusual, but no abdominal or pelvic pain. On examination a thin grey discharge is seen without evidence of vulvitis. The optimal management plan is:

- A. Empirical treatment for bacterial vaginosis (BV) with clindamycin cream and a cervical smear test
- B. Swabs for NAAT for gonorrhoea and chlamydia and await results
- C. High vaginal swab for microscopy for *Trichomonas vaginalis* (TV) and bacterial vaginosis and empirical treatment with oral metronidazole
- D. Swabs for NAAT testing for gonorrhoea, chlamydia and *Trichomonas vaginalis* and empirical treatment with oral metronidazole.
- E. Treatment with IM ceftriaxone, oral doxycycline and metronidazole for possible gonococcal, chlamydial, TV or BV infection

Answer: D.

The commonest cause of a vaginal discharge with smell is bacterial vaginosis. BV does not cause inflammation or cervical bleeding. Intermenstrual bleeding is common in perimenopausal women. In a postmenopausal woman it may be a cause for concern but STIs should be excluded before investigating other causes. STIs have a much higher prevalence in young people but are seen in older sexually active individuals, particularly those with multiple partners. Both gonorrhoea and chlamydial infection cause cervicitis so should be excluded. *Trichomonas vaginalis* does not usually cause a cervicitis without significant vaginal inflammation and vulvitis, but should also be considered. NAAT testing for TV is not universally available but may be possible. Empirical treatment with metronidazole will usually cure both TV and BV. Syndromic management – giving treatment to cover all possible infections – would not usually be a preferred approach where testing is available unless there were symptoms and signs of ascending infection (pelvic inflammatory disease).

15.3. A 21-year-old woman presented to a walk-in sexual health clinic complaining of a painful rash on her vulva for the past 4 days, which she had not had before. She said that 7 days ago she had left her male partner because he had disclosed that he had been having sex with several other partners, both male and female, during their relationship so she would like testing for other STI. She uses recreational drugs and occasionally injects. She does not have a current sexual partner.

On examination you identified a vesicular rash on her vulva that you diagnosed clinically as genital herpes, for which you treated her empirically with oral aciclovir 400 mg 3 times daily for 5 days. She had no symptoms or signs to suggest other STI or BBV infection. You carried out relevant diagnostic tests and full testing for other STI and BBV. She returns to the clinic a few days later to see a Health Adviser, who telephones to ask your advice on management and advises of the following results:

- PCR for *Chlamydia trachomatis* – positive
- HIV1 Ag/Ab test – negative
- PCR for *Neisseria gonorrhoeae* – negative
- Hepatitis B surface antigen (HBsAg) – negative
- Hepatitis B core antibody (anti-HBc) – positive
- Hepatitis C antibody – positive
- PCR of vesicle fluid for herpes simplex virus type 1 (HSV1) – negative
- PCR of vesicle fluid for herpes simplex virus type 2 (HSV2) – positive
- Treponema pallidum* EIA – positive

Which one of the following actions would be appropriate on the basis of the above results?

- A. Advise treatment with oral azithromycin 1 g orally followed by 500 mg once daily for 2 days
- B. Send a further blood sample for hepatitis B PCR (viral load)
- C. Send a further blood sample for hepatitis C PCR (viral load)
- D. Initiate suppressive therapy for HSV 2 with aciclovir 400 mg 12-hourly for 3 months
- E. Advise treatment with a single dose of 2.4 megaunits of long-acting intramuscular benzathine benzylpenicillin

Answer: C.

The positive *Chlamydia* PCR indicates current infection. However, the recommended treatment is with doxycycline rather than azithromycin, to take into account possible coexisting infection with macrolide-resistant *Mycoplasma genitalium*. The positive anti-HBc indicates past infection with hepatitis B and the negative HBsAg indicates an absence of current infection; there is therefore no indication to test her viral load. The positive hepatitis C antibodies are a marker of either current or past infection so should be investigated further by hepatitis C PCR, which, if positive, would indicate current infection. A first episode of genital herpes is usually treated with a 5-day course of aciclovir; longer-term suppressive therapy is reserved for patients who have severe and/or frequent recurrences. The *T. pallidum* EIA is a screening test for both IgG and IgM, so may indicate either past or current infection; therefore further investigation is necessary (with *T. pallidum* IgM and a non-treponemal test) rather than treatment for syphilis.

15.4. A 23-year-old man presents for the first time to a specialist sexual health service with a 4-day history of dysuria and purulent urethral discharge. He has had condomless insertive vaginal, oral and anal sex with three female sexual partners over the last 3 weeks. Direct microscopy of a Gram-stained sample of urethral discharge shows many pus cells and Gram-negative intracellular diplococci. The preferred management plan is:

- A. Take samples for gonorrhoea NAAT testing and culture from the urethra, and blood for HIV and syphilis serology, treat empirically for urethral gonorrhoea with IM ceftriaxone 1 g single dose and notify the most recent female partner
- B. Take samples for NAAT testing for *Neisseria gonorrhoea* and *Chlamydia trachomatis* from the urethra and pharynx, along with cultures for gonococcal antimicrobial sensitivities and HIV and syphilis serology. Treat for suspected gonorrhoea with IM ceftriaxone 1 g single dose. Obtain details of three recent partners for partner notification
- C. Take samples for NAAT testing for *Neisseria gonorrhoea* and *Chlamydia trachomatis* from the urethra and pharynx and blood for HIV and syphilis serology and treat with oral doxycycline 100mg twice daily for 7 days for possible chlamydial infection. Treat for gonorrhoea and notify partners depending upon antimicrobial sensitivity results.
- D. Take samples for NAAT testing and culture for gonococcal antimicrobial sensitivities from the urethra, treat for both gonorrhoea and chlamydial infection and notify all three recent partners
- E. Perform NAAT testing for *Neisseria gonorrhoea* and *Chlamydia trachomatis* from the urethra, pharynx and rectum

along with cultures for gonococcal antimicrobial sensitivities and blood for HIV and syphilis serology. Treat for suspected gonorrhoea with IM ceftriaxone 1 g single dose. Obtain details of the most recent partner for partner notification.

Answer: B.

Gram-stained microscopy has high sensitivity and specificity for the diagnosis of urethral gonorrhoea in men. Immediate treatment with ceftriaxone 1 g IM single dose on the basis of a presumptive diagnosis is appropriate but treatment for possible co-existing chlamydial infection is not routinely given. Resistance to ceftriaxone remains rare but is a major concern, so optimal management includes culture for antimicrobial sensitivity which should be taken from all potentially exposed sites, which would usually include the rectum in women and MSM but not in men-who-have-sex-with-women (MSW). Testing for HIV and syphilis should be part of routine testing for STI in all cases in all individuals. Symptoms of urethral gonorrhoea in men usually develop within 7 days of contact with an infected individual, however in symptomatic men all partners within the last 4 weeks would usually be traced for testing and/or treatment.

#### 4 Examination of the arterial pulse

- The character of the pulse is determined by stroke volume and arterial compliance, and is best assessed by palpating a major artery, such as the carotid or brachial artery.
- Aortic regurgitation, anaemia, sepsis and other causes of a large stroke volume typically produce a bounding pulse with a high amplitude and wide pulse pressure (panel A).
- Aortic stenosis impedes ventricular emptying. If severe, it causes a slow-rising, weak and delayed pulse (panel A).
- Sinus rhythm produces a pulse that is regular in time and volume. Arrhythmias may cause irregularity. Atrial fibrillation produces a pulse that is irregular in time and volume (panel B).

A

B

#### 8 Auscultation of the heart

- Use the diaphragm to examine at the apex, lower left sternal border (tricuspid area) and upper left (pulmonary area) and right (aortic area) sternal borders.
- Use the bell to examine low-pitched noises, particularly at the apex for the mid-diastolic murmur of mitral stenosis.
- Time the sounds and murmurs by feeling the carotid pulse; the first heart sound (S1) just precedes the upstroke of the pulse and the

second heart sound (S2) is out of step with it. If present, a third heart sound (S3) immediately follows S2, and a fourth heart sound (S4) just precedes S1. Systolic murmurs are synchronous with the pulse.

- Listen for radiation of systolic murmurs, over the base of the neck (aortic stenosis) and in the axilla (mitral incompetence).
- Listen over the left sternal border with the patient sitting forward (aortic incompetence), then at the apex with the patient rolled on to the left side (mitral stenosis).

#### 5 Examination of the jugular venous pulse

The internal jugular vein, superior vena cava and right atrium are in continuity, so the height of the jugular venous pulsation reflects right atrial pressure. When the patient is placed at 45°, with the head supported and turned to the left, the jugular venous pulse is visible along the line of the sternocleidomastoid muscle (see opposite). In health it is normally just visible above the clavicle.

- The height of the jugular venous pulse is determined by right atrial pressure and is therefore elevated in right heart failure and reduced in hypovolaemia.
- If the jugular venous pulse is not easily seen, it may be exposed by applying firm pressure over the abdomen.
- In sinus rhythm, the two venous peaks, the a and v waves, approximate to atrial and ventricular systole, respectively.
- The x descent reflects atrial relaxation and apical displacement of the tricuspid valve ring. The y descent reflects atrial emptying early in diastole. These signs are subtle.
- Tricuspid regurgitation produces giant v waves that coincide with ventricular systole.

#### i Distinguishing venous/arterial pulsation in the neck

- The venous pulse has two peaks in each cardiac cycle; the arterial pulse has one peak.
- The height of the venous pulse varies with respiration (falls on inspiration) and position.
- Abdominal compression causes the venous pulse to rise.
- The venous pulse is not easily palpable and can be occluded with light pressure.

#### 7 Palpation of the precordium

##### Technique

- Place fingertips over apex (1) to assess for position and character. Place heel of hand over left sternal border (2) for a parasternal heave or 'lift'. Assess for thrills in all areas, including the aortic and pulmonary areas (3). Normal position is the 5th or 6th intercostal space, at the mid-clavicular line.

##### Common abnormalities of the apex beat

- Volume overload, such as mitral or aortic regurgitation: displaced, thrusting
- Pressure overload, such as aortic stenosis, hypertension: discrete, heaving
- Dyskinetic, such as left ventricular aneurysm: displaced, incoordinate

##### Other abnormalities

- Palpable S1 (tapping apex beat: mitral stenosis)
- Palpable P2 (severe pulmonary hypertension)
- Left parasternal heave or 'lift' felt by heel of hand (right ventricular hypertrophy)
- Palpable thrill (aortic stenosis)

Cardiovascular disease is the commonest cause of death worldwide. The World Health Organization estimates that more people have died from cardiovascular disease since 1990 than any other category of illness, including infectious diseases. Strategies for the treatment and prevention of heart disease can be highly effective and have been subjected to rigorous evaluation by randomised trials. The evidence base for the treatment of cardiovascular disease is stronger than for almost any other disease group.

Coronary heart disease is the leading cause of death, with 3.8 million men and 3.4 million women dying each year. Although the incidence has been falling in some countries, it is rising in lower-income countries, where it accounts for more than 60% of the global burden of coronary heart disease. Valvular heart disease is also common but the aetiology varies in different parts of the world. In South Asia and in Africa it is predominantly due to rheumatic fever, whereas calcific aortic valve disease is the commonest problem in high-income countries.

Prompt recognition of the development of heart disease is limited by two key factors. First, it is often clinically silent for prolonged periods and coronary heart disease can proceed to an advanced stage before the patient notices any symptoms. Second, the diversity of symptoms attributable to heart disease is limited, so different pathologies may frequently present with the same symptoms.

## Functional anatomy and physiology

### Anatomy

The heart acts as two serial pumps that share several electrical and mechanical components. The right heart circulates blood to the lungs where it is oxygenated, and the left heart circulates it to the rest of the body (Fig. 16.1). The atria are thin-walled structures that act as priming pumps for the ventricles which provide most of the energy required to maintain the circulation. The atria are situated posteriorly within the mediastinum where the left atrium (LA) sits anterior to the oesophagus and descending aorta. The right atrium (RA) receives blood from the superior and inferior venae cavae and the coronary sinus. The LA receives blood from four pulmonary veins, two from each of the left and right lungs. The ventricles are thick-walled structures that pump blood through large

vascular beds under pressure. The atria and ventricles are separated by the annulus fibrosus, which forms the skeleton for the atrioventricular (AV) valves and electrically insulates the atria from the ventricles. The right ventricle (RV) is about 2–3 mm thick and triangular in shape. It extends from the annulus fibrosus to near the cardiac apex and sits anterior and to the right of the left ventricle (LV). The anterosuperior surface of the RV is rounded and convex, and its posterior extent is bounded by the interventricular septum, which bulges into the chamber. Its upper extent forms the conus arteriosus or outflow tract, from which the pulmonary artery arises. The LV is more conical in shape and in cross-section is nearly circular. It extends from the LA to the apex of the heart. The LV myocardium is approximately 10 mm thick because it pumps blood at a higher pressure than the RV.

Normally, the heart occupies less than 50% of the transthoracic diameter in the frontal plane, as seen on a chest X-ray. On the patient's left, the cardiac silhouette is formed by the aortic arch, the pulmonary trunk, the left atrial appendage and the LV. On the right, the silhouette is formed by the RA and the superior and inferior venae cavae, and the lower right border is formed by the RV (Fig. 16.2). In disease states or congenital cardiac abnormalities, the silhouette may change as a result of hypertrophy or dilatation.

### Coronary circulation

The left main and right coronary arteries arise from the left and right sinuses of the aortic root, distal to the aortic valve (Fig. 16.3). Within 2.5 cm of its origin, the left main coronary artery divides into the left anterior descending artery (LAD), which runs in the anterior interventricular groove, and the left circumflex artery (CX), which runs posteriorly in the atrioventricular groove. The LAD gives branches to supply the anterior part of the septum (septal perforators) and the anterior, lateral and apical walls of the LV. The CX gives marginal branches that supply the lateral, posterior and inferior segments of the LV. The right coronary artery (RCA) runs in the right atrioventricular groove, giving branches that supply the RA, RV and inferoposterior aspects of the LV. The posterior descending artery runs in the posterior interventricular groove and supplies the inferior part of the interventricular septum. This vessel is a branch of the RCA in approximately 90% of people (dominant right system) and is supplied by the CX in the remainder (dominant left system). The coronary anatomy varies greatly from person to person and there are many normal variants.

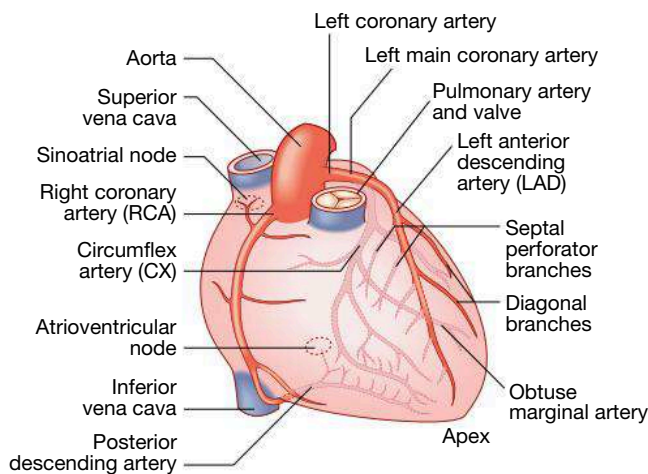

**Fig. 16.1** Direction of blood flow through the heart. The blue arrows show deoxygenated blood moving through the right heart to the lungs. The red arrows show oxygenated blood moving from the lungs to the systemic circulation. The normal pressures are shown for each chamber in mmHg.

**Fig. 16.2** Surface anatomy of the heart. The positions of the major cardiac chambers and heart valves are shown. (LV = left ventricle; RA = right atrium; RV = right ventricle)

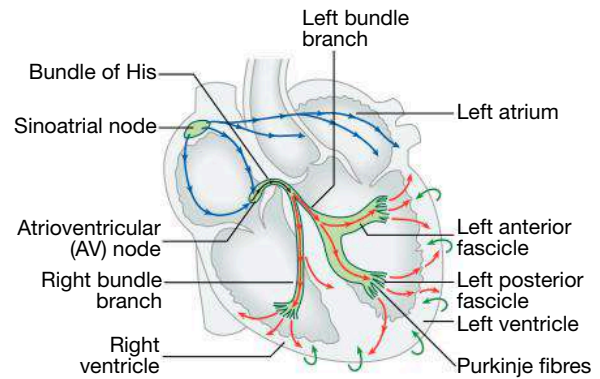

**Fig. 16.3** The coronary arteries: anterior view.

The RCA supplies the sinoatrial (SA) node in about 60% of individuals and the AV node in about 90%. Proximal occlusion of the RCA therefore often results in sinus bradycardia and may also cause AV nodal block. Abrupt occlusion of the RCA, due to coronary thrombosis, results in infarction of the inferior part of the LV and often the RV. Abrupt occlusion of the LAD or CX causes infarction in the corresponding territory of the LV, and occlusion of the left main coronary artery is usually fatal.

The venous system follows the coronary arteries but drains into the coronary sinus in the atrioventricular groove, and then to the RA. An extensive lymphatic system drains into vessels that travel with the coronary vessels and then into the thoracic duct.

## Conduction system

The SA node is situated at the junction of the superior vena cava and RA (Fig. 16.4). It comprises specialised atrial cells that depolarise at a rate influenced by the autonomic nervous system and by circulating catecholamines. During normal (sinus) rhythm, this depolarisation wave propagates through the atria via sheets of atrial myocytes. The annulus fibrosus

**Fig. 16.4** The cardiac conduction system. Depolarisation starts in the sinoatrial node and spreads through the atria (blue arrows), and then through the atrioventricular node (black arrows). Depolarisation then spreads through the bundle of His and the bundle branches to reach the ventricular muscle (red arrows). Repolarisation spreads from epicardium to endocardium (green arrows).

forms a conduction barrier between atria and ventricles, preventing transmission of conduction except through the AV node. The AV node is a midline structure, extending from the right side of the interatrial septum, penetrating the annulus fibrosus anteriorly. It conducts relatively slowly, producing a necessary time delay between atrial and ventricular contraction. The His–Purkinje system is composed of the bundle of His extending from the AV node into the interventricular septum, the right and left bundle branches passing along the ventricular septum and into the respective ventricles, the anterior and posterior fascicles of the left bundle branch, and the smaller Purkinje fibres that ramify through the ventricular myocardium. The tissues of the His–Purkinje system conduct very rapidly and allow near-simultaneous depolarisation of the entire ventricular myocardium.

## Nerve supply of the heart

The heart is innervated by both sympathetic and parasympathetic fibres. Adrenergic nerves from the cervical sympathetic chain supply muscle fibres in the atria and ventricles, and the electrical conducting system. Activation of  $\beta_1$ -adrenoceptors in the heart results in positive inotropic and chronotropic effects, whereas activation of  $\beta_2$ -adrenoceptors in vascular smooth muscle causes vasodilatation. Parasympathetic pre-ganglionic fibres and sensory fibres reach the heart through the vagus nerves. Cholinergic nerves supply the AV and SA nodes via muscarinic (M2) receptors. Under resting conditions, vagal inhibitory activity predominates and the heart rate is slow. Adrenergic stimulation, associated with exercise, emotional stress, fever and so on, causes the heart rate to increase. In disease states, the nerve supply to the heart may be affected. For example, in heart failure the sympathetic system may be up-regulated, and in diabetes mellitus the nerves themselves may be damaged by autonomic neuropathy so that there is little variation in heart rate.

## Physiology

### Myocardial contraction

Myocardial cells (myocytes) are about 50–100  $\mu\text{m}$  long; each cell branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction via gap junctions, and mechanical conduction via the fascia adherens, to adjacent cells (Fig. 16.5A). The basic unit of contraction is the sarcomere (2  $\mu\text{m}$  long), which is aligned to those of adjacent myofibrils, giving a striated appearance due to the Z-lines (Fig. 16.5B and C). Actin filaments are attached at right angles to the Z-lines and interdigitate with thicker parallel myosin filaments. The cross-links between actin

and myosin molecules contain myofibrillar adenosine triphosphatase (ATPase), which breaks down adenosine triphosphate (ATP) to provide the energy for contraction (Fig. 16.5E). Two chains of actin molecules form a helical structure, with a second molecule, tropomyosin, in the grooves of the actin helix, and a further molecule complex, troponin, attached to every seventh actin molecule (Fig. 16.5D).

During the plateau phase of the action potential, calcium ions enter the cell and are mobilised from the sarcoplasmic reticulum. They bind to troponin and thereby precipitate contraction by shortening of the sarcomere through the interdigitation of the actin and myosin molecules. The force of cardiac muscle contraction, or inotropic state, is regulated by the influx of calcium ions through 'slow calcium channels'. The extent to which the sarcomere can shorten determines stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or marked exercise. However, the enlargement of the heart seen in heart failure is due to slippage of the myofibrils and adjacent cells rather than lengthening of the sarcomere.

### Cardiac peptides

Cardiomyocytes secrete peptides that have humoral effects on the vasculature and kidneys. Atrial natriuretic peptide (ANP) is a 28-amino acid peptide that acts as a vasodilator, reducing blood pressure (BP), and as a diuretic, promoting renal excretion of water and sodium. It is released by atrial myocytes in response to stretch. Brain natriuretic peptide (BNP; originally identified in extracts of porcine brain) is a 32-amino acid peptide produced by ventricular cardiomyocytes in response to

stretch, as occurs in heart failure. Like ANP, it has diuretic properties. Nephilysin, an enzyme produced by the kidney and other tissues, breaks down ANP, BNP and other proteins and, in so doing, acts as a vasoconstrictor. It forms a therapeutic target in patients with heart failure.

### Circulation

The RA receives deoxygenated blood from the superior and inferior venae cavae and discharges blood to the RV, which in turn pumps it into the pulmonary artery. Blood is oxygenated as it passes through the pulmonary arterial and alveolar capillary bed before draining into the pulmonary veins and LA. Blood then passes into the LV which pumps it into the aorta (see Fig. 16.1). During ventricular contraction (systole), the tricuspid valve in the right heart and the mitral valve in the left heart close, and the pulmonary and aortic valves open. In diastole, the pulmonary and aortic valves close, and the two AV valves open. Collectively, these atrial and ventricular events constitute the cardiac cycle of filling and ejection of blood from one heart beat to the next. Blood passes from the heart through the large central elastic arteries into muscular arteries before encountering the resistance vessels, and ultimately the capillary bed, where there is exchange of nutrients, oxygen and waste products of metabolism. The central arteries, such as the aorta, are predominantly composed of elastic tissue with little or no vascular smooth muscle cells. When blood is ejected from the heart, the compliant aorta expands to accommodate the volume of blood before the elastic recoil sustains BP and blood flow following cessation of cardiac contraction. This 'Windkessel' effect prevents excessive rises in systolic

**Fig. 16.5** Schematic of myocytes and the contraction process within a muscle fibre. **A** Myocytes are joined together through intercalated discs. **B** Within the myocytes, myofibrils are composed of longitudinal and transverse tubules extending from the sarcoplasmic reticulum. **C** The expanded section shows a schematic of an individual sarcomere with thick filaments composed of myosin and thin filaments composed primarily of actin. **D** Actin filaments are composed of troponin, tropomyosin and actin subunits. **E** The three stages of contraction, resulting in shortening of the sarcomere. (1) The actin-binding site is blocked by tropomyosin. (2) ATP-dependent release of calcium ions, which bind to troponin, displacing tropomyosin. The binding site is exposed. (3) Tilting of the angle of attachment of the myosin head, resulting in fibre shortening. (ADP = adenosine diphosphate; ATP = adenosine triphosphate)

BP while sustaining diastolic BP, thereby reducing cardiac afterload and maintaining coronary perfusion. These benefits are lost with progressive arterial stiffening, which occurs with ageing and advanced renal disease. Passing down the arterial tree, vascular smooth muscle cells progressively play a greater role until the resistance arterioles are encountered. Although all vessels contribute, the resistance vessels (diameter 50–200  $\mu\text{m}$ ) provide the greatest contribution to systemic vascular resistance, with small changes in radius having a marked influence on blood flow; resistance is inversely proportional to the fourth power of the radius (Poiseuille's Law). The tone of these resistance vessels is tightly regulated by humoral, neuronal and mechanical factors. Neurogenic constriction operates via  $\alpha$ -adrenoceptors on vascular smooth muscle, and dilatation via muscarinic and  $\beta_2$ -adrenoceptors. In addition, systemic and locally released vasoactive substances influence tone; vasoconstrictors include noradrenaline (norepinephrine), angiotensin II and endothelin-1, whereas adenosine, bradykinin, prostaglandins and nitric oxide are vasodilators. Resistance to blood flow rises with viscosity and is mainly influenced by the haematocrit.

Coronary blood vessels receive sympathetic and parasympathetic innervation. While stimulation of  $\alpha$ -adrenoceptors causes vasoconstriction and stimulation of  $\beta_2$ -adrenoceptors causes vasodilatation, the predominant effect of sympathetic stimulation in coronary arteries is vasodilatation. Parasympathetic stimulation also causes modest dilatation of normal coronary arteries. Because of these homeostatic mechanisms that regulate vessel tone, narrowing or stenosis in a coronary artery does not limit flow, even during exercise, until the cross-sectional area of the vessel is reduced by at least 70%.

## Endothelium

The endothelium plays a vital role in the control of vascular homeostasis. It synthesises and releases many vasoactive mediators that cause vasodilatation, including nitric oxide, prostacyclin and endothelium-derived hyperpolarising factor, and vasoconstriction, including endothelin-1 and angiotensin II. A balance exists whereby the release of such factors contributes to the maintenance and regulation of vascular tone and BP. Damage to the endothelium may disrupt this balance and lead to vascular dysfunction, tissue ischaemia and hypertension.

The endothelium has a major influence on key regulatory steps in the recruitment of inflammatory cells and on the formation and dissolution of thrombus. Once activated, the endothelium expresses surface receptors such as E-selectin, intercellular adhesion molecule type 1 (ICAM-1) and platelet-endothelial cell adhesion molecule type 1 (PECAM-1), which mediate rolling, adhesion and migration of inflammatory leucocytes into the subintima. The endothelium also stores and releases the multimeric glycoprotein von Willebrand factor, which promotes thrombus formation by linking platelet adhesion to denuded surfaces, especially in the arterial vasculature. In contrast, once intravascular thrombus forms, tissue plasminogen activator is rapidly released from a dynamic storage pool within the endothelium to induce fibrinolysis and thrombus dissolution. These processes are critically involved in the development and progression of atherosclerosis, and endothelial function and injury are seen as central to the pathogenesis of many cardiovascular disease states.

## Respiration

Cardiac output, BP and pulse rate change with respiration as the result of changes in blood flow to the right and left heart, as summarised in Box 16.1. During inspiration, the fall in intrathoracic pressure causes increased return of venous blood into the chest and right side of the heart, which increases cardiac output from the RV. However, blood is sequestered in the lungs due to the increased capacitance of the pulmonary vascular bed, leading to a reduction in blood flow to the LV and a slight fall in BP. With expiration the opposite sequence of events occurs; there is a fall in venous return to the right heart with a reduction in RV output, and a rise in the venous return to the left side of the heart with an increase in LV output. As the result of these changes, BP normally falls

## 16.1 Haemodynamic effects of respiration

	Inspiration	Expiration
Jugular venous pressure	Falls	Rises
Blood pressure	Falls (up to 10 mmHg)	Rises
Heart rate	Accelerates	Slows
Second heart sound	Splits*	Fuses*

\*Inspiration prolongs right ventricular ejection, delaying P<sub>2</sub>, and shortens left ventricular ejection, bringing forward A<sub>2</sub>; expiration produces the opposite effects.

during inspiration but rises during expiration. These changes are exaggerated in patients with severe airways obstruction secondary to asthma or chronic obstructive pulmonary disease (COPD) leading to pulsus paradoxus, which describes an exaggerated fall in BP during inspiration. As well as being found in airways obstruction, pulsus paradoxus is also characteristic of cardiac tamponade. Here, cardiac filling is constrained by external pressure, and on inspiration, compression of the RV impedes the normal increase in flow during inspiration. The interventricular septum then moves to the left, impeding left ventricular filling and cardiac output. This produces an exaggerated fall in BP (> 10 mmHg fall during inspiration).

## Investigation of cardiovascular disease

Several investigations may be required in the diagnosis of cardiac disease and assessment of its severity. Basic tests, such as electrocardiography, chest X-ray and echocardiography, can be performed in an outpatient clinic or at the bedside, whereas more complex procedures such as cardiac catheterisation, radionuclide imaging, computed tomography (CT) and magnetic resonance imaging (MRI) require specialised facilities.

## Electrocardiogram

The electrocardiogram (ECG) is used to assess cardiac rhythm and conduction as well as the diagnosis of myocardial ischaemia and infarction.

The ECG is recorded by electrodes on the body surface which detect the electrical depolarisation of myocardial tissue produced from a small dipole current. These signals are amplified and either printed or displayed on a monitor (Fig. 16.6). During sinus rhythm, the SA node triggers atrial depolarisation, producing a P wave. Depolarisation proceeds slowly

**Fig. 16.6** The electrocardiogram. The components correspond to depolarisation and repolarisation, as depicted in Fig. 16.4. The upper limit of the normal range for each interval is given in brackets.

16.2 How to read a 12-lead electrocardiogram: examination sequence	
<b>Rhythm strip (lead II)</b>	To determine heart rate and rhythm
<b>Cardiac axis</b>	Normal if QRS complexes +ve in leads I and II
<b>P-wave shape</b>	Tall P waves denote right atrial enlargement (P pulmonale) and notched P waves denote left atrial enlargement (P mitrale)
<b>PR interval</b>	Normal = 0.12–0.20 sec. Prolongation denotes impaired atrioventricular nodal conduction. A short PR interval occurs in Wolff–Parkinson–White syndrome
<b>QRS duration</b>	If > 0.12 sec, ventricular conduction is abnormal (left or right bundle branch block)
<b>QRS amplitude</b>	Large QRS complexes occur in slim young patients and in patients with left ventricular hypertrophy
<b>Q waves</b>	May signify previous myocardial infarction
<b>ST segment</b>	ST elevation may signify myocardial infarction, pericarditis or left ventricular aneurysm; ST depression may signify ischaemia or infarction
<b>T waves</b>	T-wave inversion has many causes, including myocardial ischaemia or infarction, and electrolyte disturbances
<b>QT interval</b>	Normal < 0.44 sec (male), 0.46 sec (female) corrected for heart rate. QT prolongation may occur with congenital long QT syndrome, low K <sup>+</sup> , Mg <sup>2+</sup> or Ca <sup>2+</sup> , and some drugs (see Box 16.28)
<b>ECG conventions</b>	Depolarisation towards electrode: +ve deflection Depolarisation away from electrode: –ve deflection Sensitivity: 10 mm = 1 mV Paper speed: 25 mm per sec Each large (5 mm) square = 0.2 sec Each small (1 mm) square = 0.04 sec Heart rate = 1500/RR interval (mm) (i.e. 300 ÷ number of large squares between beats)

through the AV node, which is too small to produce a depolarisation wave detectable from the body surface. The bundle of His, bundle branches and Purkinje system are then activated, initiating ventricular myocardial depolarisation, which produces the QRS complex. The muscle mass of the ventricles is much larger than that of the atria, so the QRS complex is larger than the P wave. The interval between the onset of the P wave and the onset of the QRS complex is termed the 'PR interval' and largely reflects the duration of AV nodal conduction. Injury to the left or right bundle branch delays ventricular depolarisation, widening the QRS complex. Selective injury of one of the left fascicles (hemiblock) affects the electrical axis. Repolarisation is slower and spreads from the epicardium to the endocardium. Atrial repolarisation does not cause a detectable signal but ventricular repolarisation produces the T wave. The QT interval represents the total duration of ventricular depolarisation and repolarisation.

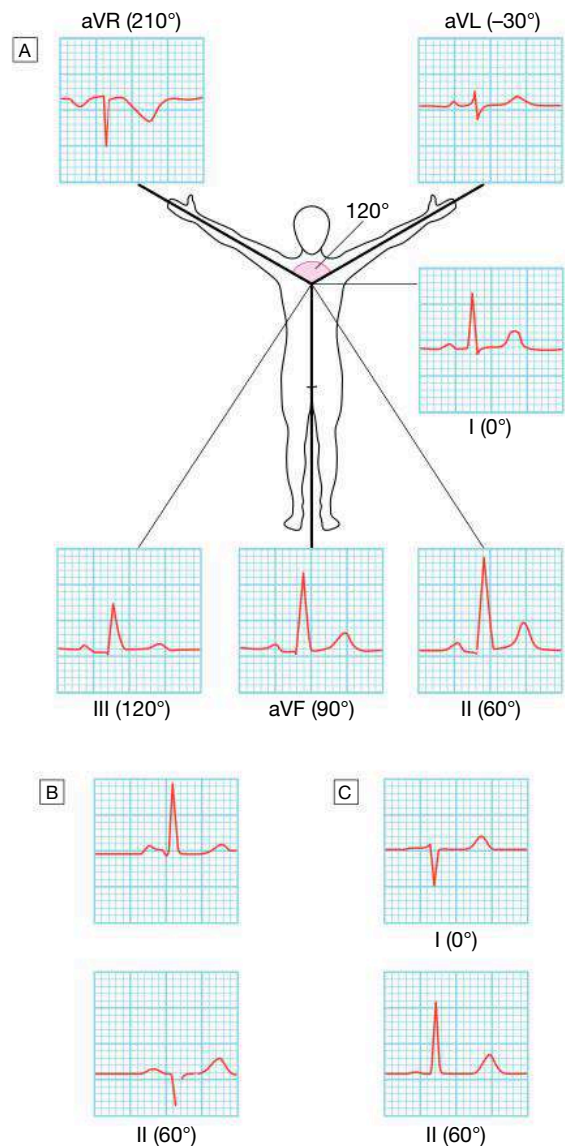

### The 12-lead ECG

The 12-lead ECG (Box 16.2) is generated from 10 electrodes that are attached to the skin. One electrode is attached to each limb and six electrodes are attached to the chest. In addition, the left arm, right arm and left leg electrodes are attached to a central terminal acting as an additional virtual electrode in the centre of the chest (the right leg electrode acts as an earthing electrode). The 12 'leads' of the ECG refer to recordings made from pairs or sets of these electrodes. They comprise three

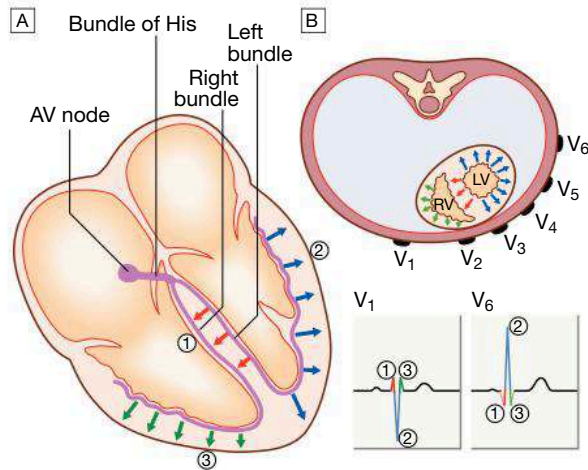

groups: three dipole limb leads, three augmented voltage limb leads and six unipole chest leads.

Leads I, II and III are the dipole limb leads and refer to recordings obtained from pairs of limb electrodes. Lead I records the signal between the right (negative) and left (positive) arms. Lead II records the signal between the right arm (negative) and left leg (positive). Lead III records the signal between the left arm (negative) and left leg (positive). These three leads thus record electrical activity along three different axes in the frontal plane. Leads aVR, aVL and aVF are the augmented voltage limb leads. These record electrical activity between a limb electrode and a modified central terminal. For example, lead aVL records the signal between the left arm (positive) and a central (negative) terminal, formed by connecting the right arm and left leg electrodes (Fig. 16.7). Similarly augmented signals are obtained from the right arm (aVR) and left leg (aVF). These leads also record electrical activity in the frontal plane, with each lead 120° apart. Lead aVF thus examines activity along the axis +90°, and lead aVL along the axis –30°, and so on.

When depolarisation moves towards a positive electrode, it produces a positive deflection in the ECG; depolarisation in the opposite direction produces a negative deflection. The average vector of ventricular depolarisation is known as the frontal cardiac axis. When the vector is at right

**Fig. 16.7** The appearance of the ECG from different leads in the frontal plane. **A** Normal. **B** Left axis deviation, with negative deflection in lead II and positive in lead I. **C** Right axis deviation, with negative deflection in lead I and positive in lead II.

**Fig. 16.8** The sequence of activation of the ventricles. **A** Activation of the septum occurs first (red arrows), followed by spreading of the impulse through the left ventricle (LV, blue arrows) and then the right ventricle (RV, green arrows). **B** Normal electrocardiographic complexes from leads  $V_1$  and  $V_6$ . (AV = atrioventricular)

angles to a lead, the depolarisation in that lead is equally negative and positive (isoelectric). In Fig. 16.7A, the QRS complex is isoelectric in aVL, negative in aVR and most strongly positive in lead II; the main vector or axis of depolarisation is therefore  $60^\circ$ . The normal cardiac axis lies between  $-30^\circ$  and  $+90^\circ$ . Examples of left and right axis deviation are shown in Fig. 16.7B and C.

There are six chest leads,  $V_1$ – $V_6$ , derived from electrodes placed on the anterior and lateral left side of the chest, over the heart. Each lead records the signal between the corresponding chest electrode (positive) and the central terminal (negative). Leads  $V_1$  and  $V_2$  lie approximately over the RV,  $V_3$  and  $V_4$  over the interventricular septum, and  $V_5$  and  $V_6$  over the LV (Fig. 16.8). The LV has the greater muscle mass and contributes the major component of the QRS complex.

The shape of the QRS complex varies across the chest leads. Depolarisation of the interventricular septum occurs first and moves from left to right; this generates a small initial negative deflection in lead  $V_6$  (Q wave) and an initial positive deflection in lead  $V_1$  (R wave). The second phase of depolarisation is activation of the body of the LV, which creates a large positive deflection or R wave in  $V_6$  (with reciprocal changes in  $V_1$ ). The third and final phase involves the RV and produces a small negative deflection or S wave in  $V_6$ .

## Exercise ECG

In exercise or stress electrocardiography, a 12-lead ECG is recorded during exercise on a treadmill or bicycle ergometer. It is similar to a resting ECG, except that the limb electrodes are placed on the shoulders and hips rather than the wrists and ankles. The Bruce Protocol is the most commonly used. During an exercise ECG, BP is recorded and symptoms are assessed. Common indications for exercise testing are shown in Box 16.3. The test is considered positive if angina occurs, BP falls or fails to increase, or if there are ST segment shifts of more than 1 mm (see Fig. 16.57). Exercise testing is useful in confirming the diagnosis of coronary artery disease in patients with suspected angina, and under these circumstances has reasonable sensitivity and excellent specificity (see Box 16.3). False-negative results can occur in patients with coronary artery disease, and not all patients with a positive test have coronary disease. This is especially true in low-risk individuals, such as asymptomatic young or middle-aged women, in whom an abnormal response is more likely to represent a false-positive than a true-positive test. Stress testing is contraindicated in the presence of acute coronary syndrome, decompensated heart failure and severe hypertension.

## 16.3 Exercise testing

### Indications

- To confirm the diagnosis of angina
- To evaluate stable angina
- To assess prognosis following myocardial infarction
- To assess outcome after coronary revascularisation, e.g. coronary angioplasty
- To diagnose and evaluate the treatment of exercise-induced arrhythmias

### High-risk findings

- Low threshold for ischaemia (within stage 1 or 2 of the Bruce Protocol)
- Fall in blood pressure on exercise
- Widespread, marked or prolonged ischaemic ECG changes
- Exercise-induced arrhythmia

## Ambulatory ECG

Ambulatory ECG recordings can be obtained using a portable digital recorder. These devices usually provide limb lead ECG recordings only, on a continuous basis for periods of between 1 and 7 days. The main indication for ambulatory ECG is in the investigation of patients with suspected arrhythmia, such as those with intermittent palpitation, dizziness or syncope. In this situation, a standard ECG provides only a snapshot of the cardiac rhythm and is unlikely to detect an intermittent arrhythmia, so a longer period of recording is required (see Fig. 16.30). Ambulatory ECG can also be used to assess rate control in patients with atrial fibrillation, and to detect transient myocardial ischaemia using ST segment analysis. If symptoms are infrequent, special recorders can be issued that can be activated by the patient when a symptom episode occurs and placed on the chest wall to record the cardiac rhythm at that point in time. With some devices, the recording can be transmitted to hospital electronically. If the symptoms are very infrequent but potentially serious, such as syncope, implantable 'loop recorders' resembling a leadless pacemaker can be used and implanted subcutaneously to record cardiac rhythm for prolonged periods of between 1 and 3 years (see Fig. 16.51).

## Cardiac biomarkers

Several biomarkers are available that can be measured in peripheral blood to assess myocardial dysfunction and ischaemia.

### Brain natriuretic peptide

Brain natriuretic peptide (BNP) is a peptide hormone of 32 amino acids with diuretic properties. It is secreted by the LV as a 108-amino acid prohormone, which is cleaved to produce active BNP, and an inactive 76-amino acid N-terminal fragment (NT-proBNP). Serum concentrations are elevated in conditions associated with LV systolic dysfunction. Generally, NT-proBNP is measured in preference to BNP since it is more stable. Measurements of NT-proBNP are indicated for the diagnosis of LV dysfunction and to assess prognosis and response to therapy in patients with heart failure.

### Cardiac troponins

Troponin I and troponin T are structural cardiac muscle proteins (see Fig. 16.5) that are released during myocyte damage and necrosis, and represent the cornerstone of the diagnosis of acute myocardial infarction (MI, see Box 16.47). Modern assays are extremely sensitive and can detect minor degrees of myocardial damage, so that elevated plasma troponin concentrations may be observed in conditions other than acute MI, such as pulmonary embolus, septic shock and pulmonary oedema.

## Chest X-ray

This is useful for determining the size and shape of the heart, and the state of the pulmonary blood vessels and lung fields. Most information is given by a postero-anterior (PA) projection taken in full inspiration. Anteroposterior (AP) projections can be performed when patient movement is restricted but result in magnification of the cardiac silhouette.

An estimate of overall heart size can be made by comparing the maximum width of the cardiac outline with the maximum internal transverse diameter of the thoracic cavity. The term cardiomegaly is used to describe an enlarged cardiac silhouette when the ratio of cardiac width to the width of the lung fields is greater than 0.5. Cardiomegaly can be caused by chamber dilatation, especially left ventricular dilatation, or by a pericardial effusion, but may also be due to a mediastinal mass or pectus excavatum. Cardiomegaly is not a sensitive indicator of left ventricular systolic dysfunction since the cardiothoracic ratio is normal in many patients with poor left ventricular function and is not specific, since many patients with cardiomegaly on chest X-ray have normal echocardiograms.

Dilatation of individual cardiac chambers can be recognised by the characteristic alterations to the cardiac silhouette (Fig. 16.9):

- Left atrial dilatation results in prominence of the left atrial appendage, creating the appearance of a straight left heart border, a double cardiac shadow to the right of the sternum, and widening of the angle of the carina (bifurcation of the trachea) as the left main bronchus is pushed upwards.
- Right atrial enlargement projects from the right heart border towards the right lower lung field.
- Left ventricular dilatation causes prominence of the left heart border and enlargement of the cardiac silhouette. Left ventricular hypertrophy produces rounding of the left heart border (Fig. 16.10).
- Right ventricular dilatation increases heart size, displaces the apex upwards and straightens the left heart border.

Lateral or oblique projections may be useful for detecting pericardial calcification in patients with constrictive pericarditis or a calcified thoracic aortic aneurysm, as these abnormalities may be obscured by the spine on the PA view.

The lung fields on the chest X-ray may show congestion and oedema in patients with heart failure (see Fig. 16.25), and an increase in pulmonary blood flow ('pulmonary plethora') in those with left-to-right shunt. Pleural effusions may also occur in heart failure.

## Echocardiography

### Transthoracic echocardiography

Transthoracic echocardiography, commonly referred to as 'echo', is obtained by placing an ultrasound transducer on the chest wall to image the heart structures as a real-time two-dimensional 'slice'. This can be used for rapid evaluation of various aspects of cardiac structure and function (Box 16.4).

### Doppler echocardiography

Doppler echocardiography provides information on blood flow within the heart and the great vessels. It is based on the Doppler principle that sound waves reflected from moving objects, such as red blood cells, undergo a frequency shift. Doppler echocardiography can therefore detect the speed and direction of blood flow in the heart chambers and great vessels. The information can be presented either as a plot of blood velocity against time for a particular point in the heart (Fig. 16.11) or as a colour overlay on a two-dimensional real-time echo picture (colour-flow Doppler, Fig. 16.12). Doppler echocardiography is useful in the detection

**Fig. 16.9** Chest X-ray of a patient with mitral stenosis and regurgitation indicating enlargement of the LA and prominence of the pulmonary artery trunk.

**Fig. 16.10** Chest X-ray of a patient with aortic regurgitation, left ventricular enlargement and dilatation of the ascending aorta.

### i

#### 16.4 Common indications for echocardiography

- Assessment of left ventricular function
- Diagnosis and quantification of severity of valve disease
- Identification of vegetations in endocarditis
- Identification of structural heart disease in atrial fibrillation, cardiomyopathies or congenital heart disease
- Detection of pericardial effusion
- Identification of structural heart disease or intracardiac thrombus in systemic embolism

of valvular regurgitation, where the direction of blood flow is reversed and turbulence is seen, and is also used to detect pressure gradients across stenosed valves. For example, the normal resting systolic flow velocity across the aortic valve is approximately 1 m/sec; in the presence of aortic

**Fig. 16.11 Doppler echocardiography in aortic stenosis.** **A** The aortic valve is imaged and a Doppler beam passed directly through the left ventricular outflow tract and the aorta into the turbulent flow beyond the stenosed valve. **B** The velocity of the blood cells is recorded to determine the maximum velocity and hence the pressure gradient across the valve. In this example, the peak velocity is approximately 450 cm/sec (4.5 m/sec), indicating severe aortic stenosis (peak gradient of 81 mmHg). (LA = left atrium; LV = left ventricle)

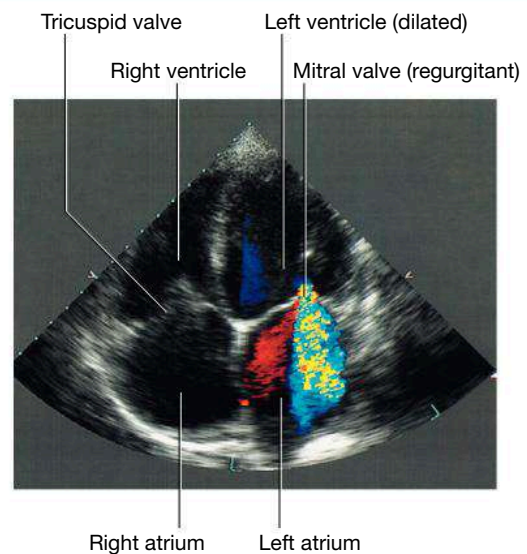

stenosis, this is increased as blood accelerates through the narrow orifice. In severe aortic stenosis, the peak aortic velocity may be increased to 5 m/sec (see Fig. 16.11). An estimate of the pressure gradient across a valve or lesion is given by the modified Bernoulli equation:

$$\text{Pressure gradient (mmHg)} \\ = 4 \times (\text{peak velocity (m/sec)})^2$$

Advanced techniques include three-dimensional echocardiography, intravascular ultrasound (defines vessel wall abnormalities and guides coronary intervention), intracardiac ultrasound (provides high-resolution images), tissue Doppler imaging (quantifies myocardial contractility and diastolic function) and speckle tracking (assesses myocardial motion and strain).

### Transoesophageal echocardiography

Transoesophageal echocardiography (TOE) involves passing an endoscope-like ultrasound probe into the oesophagus and upper stomach under light sedation and positioning it behind the LA. It is particularly useful for imaging structures such as the left atrial appendage, pulmonary veins, thoracic aorta and interatrial septum, which may be poorly visualised by transthoracic echocardiography, especially if the patient is overweight or has obstructive airways disease. The high-resolution

**Fig. 16.12 Echocardiographic illustration of the principal cardiac structures in the 'four-chamber' view.** Colour-flow Doppler has been used to demonstrate mitral regurgitation: a flame-shaped (yellow/blue) turbulent jet into the left atrium.

images that can be obtained makes TOE particularly valuable for investigating patients with prosthetic (especially mitral) valve dysfunction, congenital abnormalities such as atrial septal defects, aortic dissection, infective endocarditis (vegetations that are too small to be detected by transthoracic echocardiography) and systemic embolism (intracardiac thrombus or masses).

### Stress echocardiography

Stress echocardiography is used to investigate patients with suspected coronary artery disease who are unsuitable for exercise stress testing, such as those with mobility problems or pre-existing bundle branch block. A two-dimensional echo is performed before and during infusion of a moderate to high dose of an inotrope, such as dobutamine. Myocardial segments with poor perfusion become ischaemic and contract poorly under stress, manifesting as a wall motion abnormality on the scan. Stress echocardiography is sometimes used to examine myocardial viability in patients with impaired left ventricular function. Low-dose dobutamine can induce contraction in 'hibernating' myocardium; such patients may benefit from bypass surgery or percutaneous coronary intervention.

### Computed tomography

Computed tomography (CT) is useful for imaging the cardiac chambers, great vessels, pericardium, and mediastinal structures and masses. Multidetector scanners can acquire up to 320 slices per rotation, allowing very high-resolution imaging in a single heartbeat. CT is often performed using a timed injection of X-ray contrast to produce clear images of blood vessels and associated pathologies. Contrast scans are very useful for imaging the aorta in suspected aortic dissection (see Fig. 16.73), and the pulmonary arteries and branches in suspected pulmonary embolism.

Some centres use cardiac CT scans for quantification of coronary artery calcification, which may serve as an index of cardiovascular risk. However, modern multidetector scanning allows non-invasive coronary angiography (Fig. 16.13) with a spatial resolution approaching that of conventional coronary arteriography and at a lower radiation dose. CT coronary angiography is particularly useful in the initial assessment of patients with chest pain and a low or intermediate likelihood of disease, since it has a high negative predictive value in excluding coronary artery

disease. Modern volume scanners are also able to assess myocardial perfusion, often at the same sitting.

## Magnetic resonance imaging

Magnetic resonance imaging (MRI) can be used to generate cross-sectional images of the heart, lungs and mediastinal structures. It provides better differentiation of soft tissue structures than CT but is poor at demonstrating calcification. MRI scans need to be 'gated' to the ECG, allowing the scanner to produce moving images of the heart and mediastinal structures throughout the cardiac cycle. MRI is very useful for imaging the aorta, including suspected dissection (see Fig. 16.72), and can define the anatomy of the heart and great vessels in patients with congenital heart disease. It is also useful for detecting infiltrative conditions affecting the heart and for evaluation of the RV that is difficult to image by echocardiography.

Physiological data can be obtained from the signal returned from moving blood, which allows quantification of blood flow across regurgitant or stenotic valves. It is also possible to analyse regional wall motion in patients with suspected coronary disease or cardiomyopathy.

Myocardial perfusion and viability can also be readily assessed by MRI. When enhanced by gadolinium-based contrast media, areas of myocardial hypoperfusion can be identified with better spatial resolution than nuclear medicine techniques. Later redistribution of this contrast, so-called delayed enhancement, can be used to identify

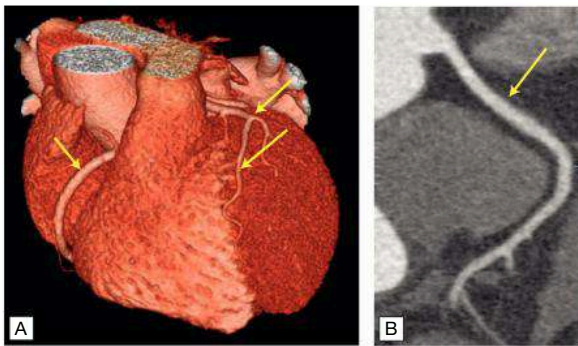

myocardial scarring and fibrosis: this is a particular strength of cardiac MRI (Fig. 16.14). This can help in selecting patients for revascularisation procedures, or in identifying those with myocardial infiltration, such as that seen with sarcoid heart disease and arrhythmogenic right ventricular cardiomyopathy.

## Cardiac catheterisation

This involves passing a specialised catheter through a peripheral vein or artery into the heart under X-ray guidance. Cardiac catheterisation allows BP and oxygen saturation to be measured in the cardiac chambers and great vessels, and is used to perform angiograms by injecting contrast media into a chamber or blood vessel.

Left heart catheterisation involves accessing the arterial circulation, usually through the radial artery, to allow catheterisation of the aorta, LV and coronary arteries. Coronary angiography is the most widely performed procedure, in which the left and right coronary arteries are selectively imaged, providing information about the extent and severity of coronary stenoses, thrombus and calcification (Fig. 16.15). Additional anatomical (intravascular ultrasound, optical coherence tomography) or functional (pressure wire) assessments are sometimes used to define plaque characteristics and severity more precisely. This permits planning of percutaneous coronary intervention and coronary artery bypass graft surgery. Left ventriculography can be performed during the procedure to determine the size and function of the LV (Fig. 16.16) and to demonstrate mitral regurgitation. Aortography defines the size of the aortic root and thoracic aorta, and can help quantify aortic regurgitation. Left heart catheterisation is a day-case procedure and is relatively safe, with serious complications occurring in only approximately 1 in 1000 cases.

Right heart catheterisation is used to assess right heart and pulmonary artery pressures, and to detect intracardiac shunts by measuring oxygen saturations in different chambers. For example, a step up in oxygen saturation from 65% in the RA to 80% in the pulmonary artery is indicative of a large left-to-right shunt that might be due to a ventricular septal defect. Cardiac output can also be measured using thermodilution techniques. Left atrial pressure can be measured directly by puncturing the interatrial septum from the RA with a special catheter. For most purposes, a satisfactory approximation to left atrial pressure can be obtained by 'wedging' an end-hole or balloon catheter in a branch of the pulmonary artery. Swan-Ganz balloon catheters are often used to monitor pulmonary 'wedge' pressure as a guide to left heart filling pressure in critically ill patients (see Fig. 9.25).

**Fig. 16.16** Left ventriculograms in diastole **A** and systole **B** in a patient with normal left ventricular contraction.

## Electrophysiology

Patients with known or suspected arrhythmia are investigated by percutaneous placement of electrode catheters into the heart via the femoral and neck veins. An electrophysiology study (EPS) is most commonly performed to evaluate patients for catheter ablation and is normally done at the same time as the ablation procedure. EPS is occasionally used for risk stratification of patients suspected of being at risk of ventricular arrhythmias.

## Radionuclide imaging

Radionuclide imaging can be used to evaluate cardiac function but is declining in popularity due to the availability of alternative techniques, such as MRI and CT, that either do not involve exposure to radiation or provide superior quality data to radionuclide imaging.

## Blood pool imaging

The patient is given an intravenous injection of radioisotope-labelled blood cells, and after 4–5 minutes, the distribution of isotope in the heart is evaluated by a gamma camera at different phases of the cardiac cycle,

thereby permitting the calculation of ventricular ejection fractions. It can also assess the size and 'shape' of the cardiac chambers.

## Myocardial perfusion scanning

The patient is given an intravenous injection of a radioactive isotope, such as <sup>99m</sup>technetium-tetrofosmin, and scintiscans of the myocardium are subsequently obtained by gamma camera at rest and during stress (see Fig. 16.57). Either exercise stress or pharmacological stress (using the inotrope dobutamine or the vasodilator dipyridamole) can be used. More sophisticated quantitative information can be obtained with positron emission tomography (PET), which can also be used to assess myocardial metabolism, but this is available in only a few centres.

## Presenting problems in cardiovascular disease

Cardiovascular disease gives rise to several symptoms, which may overlap those caused by pathologies of other systems. Making the correct diagnosis depends on careful analysis of the factors that provoke symptoms, the subtle differences in how they are described by the

i	16.5 New York Heart Association (NYHA) functional classification
<b>Class I</b>	
<ul style="list-style-type: none"> <li>• No limitation during ordinary activity</li> </ul>	
<b>Class II</b>	
<ul style="list-style-type: none"> <li>• Slight limitation during ordinary activity</li> </ul>	
<b>Class III</b>	
<ul style="list-style-type: none"> <li>• Marked limitation of normal activities without symptoms at rest</li> </ul>	
<b>Class IV</b>	
<ul style="list-style-type: none"> <li>• Unable to undertake physical activity without symptoms; symptoms may be present at rest</li> </ul>	

patient, the clinical findings and the results of investigations. A close relationship between symptoms and exertion is usually suggestive of heart disease. The New York Heart Association (NYHA) functional classification is used to grade the degree of disability caused by cardiac symptoms (Box 16.5).

### Chest pain on exertion

There are many other non-cardiac causes of chest pain, as discussed in Chapter 9. This section will focus on exertional chest pain (or discomfort), which is a typical presenting symptom of coronary artery disease.

#### Clinical assessment

Detailed history taking is crucial in determining the likely cause of chest pain. Chest pain on exertion suggests angina pectoris (Fig. 16.17). The reproducibility, predictability and relationship to physical exertion (and occasionally emotion) of the chest pain are the most important features. The duration of symptoms should be noted because patients with recent-onset angina are at greater risk than those with long-standing and unchanged symptoms. Physical examination is often normal but may reveal evidence of risk factors for cardiovascular disease, such as xanthoma or xanthelasma indicating hyperlipidaemia. Signs of anaemia or thyrotoxicosis may be identified, both of which can exacerbate angina. Cardiovascular examination may reveal evidence of left ventricular dysfunction or cardiac murmurs in patients with aortic valve disease and hypertrophic cardiomyopathy. Other manifestations of arterial disease, such as bruits and loss of peripheral pulses, may also be observed.

#### Investigations

A full blood count, fasting blood glucose, lipids, thyroid function tests and a 12-lead ECG are the most important baseline investigations. Stress testing, including exercise ECG, stress echocardiography and magnetic resonance perfusion imaging, can be helpful in confirming anginal symptoms and identifying high-risk patients who require further investigation and treatment but cannot reliably exclude the presence of coronary artery disease. However, CT coronary angiography is the first-line test of choice to diagnose angina due to coronary artery disease. If a murmur is found, echocardiography should be performed to check for valve disease or hypertrophic cardiomyopathy.

### Severe prolonged chest pain

Severe prolonged cardiac chest pain may be due to acute myocardial infarction or to unstable angina – known collectively as acute coronary syndrome.

#### Clinical assessment

Acute coronary syndrome is suggested by a previous history of stable angina but an episode of acute severe chest pain at rest can also be the

**Fig. 16.17** Typical ischaemic cardiac pain. Characteristic hand gestures used to describe cardiac pain. Typical radiation of pain is shown in the schematic.

first presentation of coronary artery disease. Making the correct diagnosis depends on analysing the character of the pain and its associated features. Physical examination may reveal signs of risk factors for coronary artery disease as described for exertional chest pain. There may also be pallor or sweating, which is indicative of autonomic disturbance and typical of acute coronary syndrome. Other features, such as arrhythmia, hypotension and heart failure, may occur. Patients presenting with symptoms consistent with an acute coronary syndrome require hospitalisation and urgent investigation, because there is a high risk of avoidable complications.

#### Investigations

A 12-lead ECG is mandatory and is the most useful method of initial triage, along with measurement of cardiac troponin I or T. The diagnosis of an acute coronary syndrome is supported by ST segment elevation or depression on ECG and an elevated level of troponin I or T, which demonstrates that there has been myocardial damage.

If the diagnosis remains unclear after initial investigation, repeat ECG recordings should be performed and are particularly useful if they can be obtained during an episode of pain. If the plasma troponin concentrations are normal at baseline, repeat measurements should be made 6–12 hours after the onset of symptoms or admission to hospital. New ECG changes or an elevated plasma troponin concentration usually confirm the diagnosis of an acute coronary syndrome. If the pain settles and does not recur, there are no new ECG changes and troponin concentrations remain normal, the patient can be discharged from hospital but further investigations may be indicated to look for evidence of coronary artery disease, as discussed on page 424.

#### Management

The differential diagnosis and management of acute coronary syndrome are described in more detail later in this chapter.

### Breathlessness

Cardiac causes of breathlessness include cardiac arrhythmias, acute and chronic heart failure, acute coronary syndrome, valvular disease, cardiomyopathy and constrictive pericarditis, all discussed later in this chapter. The differential diagnosis of breathlessness is wide, however, and has many other non-cardiac causes. These are discussed in more detail on pages 181 and 489.

### Syncope

The term 'syncope' refers to loss of consciousness due to reduced cerebral perfusion. The differential diagnosis, investigation and management of syncope are discussed on page 184.

## Palpitation

Palpitation is a common and sometimes frightening symptom that is usually due to a disorder of cardiac rhythm. Patients use the term to describe many sensations, including an unusually erratic, fast, slow or forceful heart beat, or even chest pain or breathlessness.

### Clinical assessment

Initial evaluation should concentrate on determining the likely mechanism of palpitation and whether or not there is significant underlying heart disease. A detailed description of the sensation is essential and patients should be asked to describe their symptoms clearly, or to demonstrate the sensation of rhythm by tapping with their hand. A provisional diagnosis can usually be made on the basis of the history (Box 16.6 and Fig. 16.18). Recurrent but short-lived bouts of an irregular heart rhythm are usually due to atrial or ventricular extrasystoles (ectopic beats). Some patients will describe the experience as a 'flip' or a 'jump' in the chest, while others report dropped or missed beats. Extrasystoles are often more frequent during periods of stress or debility; they can be triggered by alcohol or nicotine.

Episodes of a pounding, forceful and relatively fast (90–120/min) heart beat are a common manifestation of anxiety. These may also reflect a hyperdynamic circulation, such as anaemia, pregnancy and thyrotoxicosis, and can occur in some forms of valve disease such as aortic regurgitation. Discrete bouts of more rapid (over 120/min) heart beats are more likely to be due to a paroxysmal supraventricular or ventricular tachycardia. In contrast, episodes of atrial fibrillation typically present with irregular and usually rapid palpitation.

### Investigation

If initial assessment suggests that the palpitation is due to an arrhythmia, the diagnosis should be confirmed by an ECG recording during an episode using an ambulatory ECG monitor. Smartphones and smart watches with additional hardware and apps are extremely helpful in capturing the ECG during episodes. Additional investigations may be required depending on the nature of the arrhythmia, as discussed later in this chapter.

### Management

Palpitation is usually benign and even if the patient's symptoms are due to an arrhythmia, the outlook is good if there is no underlying structural heart disease. Most cases are due to an awareness of the normal heart beat, a sinus tachycardia or benign extrasystoles, in which case an explanation and reassurance may be all that is required. Palpitation associated with pre-syncope or syncope (p. 184) may reflect more serious structural or electrical disease and should be investigated without delay. Other arrhythmias may require treatment, such as drugs or ablation, and are discussed in more detail in the section on cardiac arrhythmias

## Cardiac arrest

Cardiac arrest describes the sudden and complete loss of cardiac output due to asystole, ventricular tachycardia or ventricular fibrillation

### 16.6 How to evaluate palpitation

- Is the palpitation continuous or intermittent?
- Is the heart beat regular or irregular?
- What is the approximate heart rate?
- Do symptoms occur in discrete attacks?
  - Is the onset abrupt? How do attacks terminate?
- Are there any associated symptoms?
  - Chest pain, lightheadedness, polyuria (a feature of supraventricular tachycardia)
- Are there any precipitating factors, such as exercise or alcohol excess?
- Is there a history of structural heart disease, such as coronary artery disease or valvular heart disease?

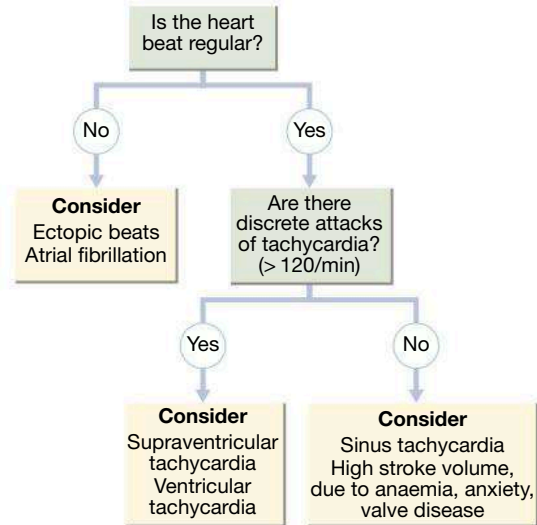

Fig. 16.18 A simple approach to the diagnosis of palpitation.

Fig. 16.19 Ventricular fibrillation. A bizarre chaotic rhythm, initiated in this case by two ventricular ectopic beats in rapid succession.

(Fig. 16.19), or loss of mechanical cardiac contraction (pulseless electrical activity). The causes of sudden arrhythmic death are summarised in Box 16.7. The clinical diagnosis is based on the victim being unconscious and pulseless; breathing may take some time to stop completely after cardiac arrest. Death is virtually inevitable, unless effective treatment is given promptly. Sudden cardiac death is usually caused by a catastrophic arrhythmia and accounts for 25%–30% of all deaths from cardiovascular disease, claiming an estimated 70 000 to 90 000 lives each year in the UK. Many of these deaths are potentially preventable. Management of cardiac arrest is further discussed in detail on page 202.

### 16.7 Causes of sudden arrhythmic death

#### Coronary artery disease (85%)

- Myocardial ischaemia
- Acute myocardial infarction
- Prior myocardial infarction with myocardial scarring

#### Structural heart disease (10%)

- Aortic stenosis
- Hypertrophic cardiomyopathy
- Dilated cardiomyopathy
- Arrhythmogenic right ventricular cardiomyopathy
- Congenital heart disease

#### No structural heart disease (5%)

- Long QT syndrome
- Brugada syndrome
- Wolff–Parkinson–White syndrome
- Adverse drug reactions (torsades de pointes)
- Severe electrolyte abnormalities

## Abnormal heart sounds

The first indication of heart disease may be the discovery of an abnormal sound on auscultation (Box 16.8). This may be incidental – for example, during a routine examination – or may be prompted by symptoms of heart disease.

### Clinical assessment

The aims of clinical assessment are, first, to determine if the abnormal sound is cardiac; second, to determine if it is pathological; and third, to try to determine its cause.

#### Is the sound cardiac?

Additional heart sounds and murmurs demonstrate a consistent relationship to the cardiac cycle, whereas extracardiac sounds, such as a pleural rub or venous hum, do not. Pericardial friction produces a characteristic scratching noise termed a pericardial rub, which may have two components corresponding to atrial and ventricular systole, and may vary with posture and respiration.

#### Is the sound pathological?

Pathological sounds and murmurs are the product of turbulent blood flow or rapid ventricular filling due to abnormal loading conditions. Some added sounds are physiological but may also occur in pathological conditions; for example, a third sound is common in young people and in pregnancy but is also a feature of heart failure (see Box 16.8). Similarly, a systolic murmur due to turbulence across the right ventricular outflow tract may occur in hyperdynamic states such as anaemia or pregnancy, but may also be due to pulmonary stenosis or an intracardiac shunt leading to volume overload of the RV, such as an atrial septal defect. Benign murmurs do not occur in diastole (Box 16.9), and systolic murmurs that radiate or are associated with a thrill are almost always pathological.

## 16.9 Features of a benign or innocent heart murmur

- Soft
- Mid-systolic
- Heard at left sternal border
- No radiation
- No other cardiac abnormalities

### What is the origin of the sound?

Timing, intensity, location, radiation and quality are all useful clues to the origin and nature of an additional sound or murmur (Box 16.10). Radiation of a murmur is determined by the direction of turbulent blood flow and is detectable only when there is a high-velocity jet, such as in mitral regurgitation (radiation from apex to axilla) or aortic stenosis (radiation from base to neck). Similarly, the pitch and quality of the sound can help to distinguish the murmur, such as the ‘blowing’ murmur of mitral regurgitation or the ‘rasping’ murmur of aortic stenosis. The position of a murmur in relation to the cardiac cycle is crucial and should be assessed by timing it with the heart sounds, carotid pulse and apex beat (Figs. 16.20 and 16.21).

### Systolic murmurs

Ejection systolic murmurs are associated with ventricular outflow tract obstruction and occur in mid-systole with a crescendo–decrescendo pattern, reflecting the changing velocity of blood flow (Box 16.11). Pansystolic murmurs maintain a constant intensity and extend from the first heart sound throughout systole to the second heart sound, sometimes obscuring it. They occur when blood leaks from a ventricle into a low-pressure chamber at an even or constant velocity. Mitral regurgitation, tricuspid regurgitation and ventricular septal defect are the only causes of a pansystolic murmur. Late systolic murmurs are unusual but may occur in mitral valve prolapse, if the mitral regurgitation is confined to late systole, and hypertrophic obstructive cardiomyopathy, if dynamic obstruction occurs late in systole.

## 16.8 Normal and abnormal heart sounds

Sound	Timing	Characteristics	Mechanisms	Variable features
<b>First heart sound (S1)</b>	Onset of systole	Usually single or narrowly split	Closure of mitral and tricuspid valves	Loud: hyperdynamic circulation (anaemia, pregnancy, thyrotoxicosis); mitral stenosis Soft: heart failure; mitral regurgitation
<b>Second heart sound (S2)</b>	End of systole	Split on inspiration Single on expiration	Closure of aortic and pulmonary valve  A <sub>2</sub> first  P <sub>2</sub> second	Fixed wide splitting with atrial septal defect  Wide but variable splitting with delayed right heart emptying (right bundle branch block)  Reversed splitting due to delayed left heart emptying (left bundle branch block)
<b>Third heart sound (S3)</b>	Early in diastole, just after S2	Low pitch, often heard as ‘gallop’	From ventricular wall due to abrupt cessation of rapid filling	Physiological: young people, pregnancy Pathological: heart failure, mitral regurgitation
<b>Fourth heart sound (S4)</b>	End of diastole, just before S1	Low pitch	Ventricular origin (stiff ventricle and augmented atrial contraction) related to atrial filling	Absent in atrial fibrillation A feature of severe left ventricular hypertrophy
<b>Systolic clicks</b>	Early or mid-systole	Brief, high-intensity sound	Valvular aortic stenosis Valvular pulmonary stenosis Floppy mitral valve Prosthetic heart sounds from opening and closing of normally functioning mechanical valves	Click may be lost when stenotic valve becomes thickened or calcified  Prosthetic clicks lost when valve obstructed by thrombus or vegetations
<b>Opening snap (OS)</b>	Early in diastole	High pitch, brief duration	Opening of stenosed leaflets of mitral valve Prosthetic heart sounds	Moves closer to S2 as mitral stenosis becomes more severe. May be absent in calcific mitral stenosis

**16.10 How to assess a heart murmur**

**When does it occur?**

- Time the murmur using heart sounds, carotid pulse and the apex beat. Is it systolic or diastolic?
- Does the murmur extend throughout systole or diastole or is it confined to a shorter part of the cardiac cycle?

**How loud is it?**

- Grade 1: very soft (audible only in ideal conditions)
- Grade 2: soft
- Grade 3: moderate
- Grade 4: loud with associated thrill
- Grade 5: very loud
- Grade 6: heard without stethoscope

Note: Diastolic murmurs are very rarely above grade 4

**Where is it heard best?**

- Listen over the apex and base of the heart, including the aortic and pulmonary areas

**Where does it radiate?**

- Listen at the neck, axilla or back

**What does it sound like?**

- Pitch is determined by flow (high pitch indicates high-velocity flow)
- Is the intensity constant or variable?

**Fig. 16.20** The relationship of the cardiac cycle to the ECG, the left ventricular pressure wave and the position of heart sounds.

Ejection systolic murmur  
(aortic stenosis, pulmonary stenosis, aortic or pulmonary flow murmurs)

Pansystolic murmur  
(mitral regurgitation, tricuspid regurgitation, ventricular septal defect)

Late systolic murmur  
(mitral valve prolapse)

Early diastolic murmur  
(aortic or pulmonary regurgitation)

Mid-diastolic murmur  
(mitral stenosis, tricuspid stenosis, mitral or tricuspid flow murmurs)

**Fig. 16.21** The timing and pattern of cardiac murmurs.

### Diastolic murmurs

These are due to accelerated or turbulent flow across the mitral or tricuspid valves. They are low-pitched noises that are often difficult to hear and should be evaluated with the bell of the stethoscope. A mid-diastolic murmur may be due to mitral stenosis (located at the apex and axilla), tricuspid stenosis (located at the left sternal border), increased flow across the mitral valve (for example, the to-and-fro murmur of severe mitral regurgitation) or increased flow across the tricuspid valve (for example, a left-to-right shunt through a large atrial septal defect). Early diastolic murmurs have a soft, blowing quality with a decrescendo pattern and should be evaluated with the diaphragm of the stethoscope. They are due to regurgitation across the aortic or pulmonary valves and are best heard at the left sternal border, with the patient sitting forwards in held expiration.

### Continuous murmurs

These result from a combination of systolic and diastolic flow, such as occurs with a persistent ductus arteriosus, and must be distinguished from extracardiac noises such as bruits from arterial shunts, venous hums (high rates of venous flow in children) and pericardial friction rubs.

### Investigations

If clinical evaluation suggests that the additional sound is cardiac and likely to be pathological, then echocardiography is indicated to determine the underlying cause.

### Management

Management of patients with additional heart sounds or murmurs depends on the underlying cause. More details are provided in the sections on specific valve defects and congenital anomalies later in this chapter.

## Heart failure

Heart failure describes the clinical syndrome that develops when the heart cannot maintain adequate output, or can do so only at the expense of elevated ventricular filling pressure. In mild to moderate forms of heart failure, symptoms occur only when the metabolic demand increases during exercise or some other form of stress. In severe heart failure, symptoms may be

### 16.11 Features of some common systolic murmurs

Condition	Timing and duration	Quality	Location and radiation	Associated features
<b>Aortic stenosis</b>	Mid-systolic	Loud, rasping	Base and left sternal border, radiating to suprasternal notch and carotids	Single second heart sound Ejection click (in young patients) Slow-rising pulse Left ventricular hypertrophy (pressure overload)
<b>Mitral regurgitation</b>	Pansystolic	Blowing	Apex, radiating to axilla	Soft first heart sound Third heart sound Left ventricular hypertrophy (volume overload)
<b>Ventricular septal defect</b>	Pansystolic	Harsh	Lower left sternal border, radiating to whole precordium	Thrill Biventricular hypertrophy
<b>Benign</b>	Mid-systolic	Soft	Left sternal border, no radiation	No other signs of heart disease

present at rest. In clinical practice, heart failure may be diagnosed when a patient with significant heart disease develops the signs or symptoms of a low cardiac output, pulmonary congestion or systemic venous congestion at rest or on exercise. Three types of heart failure are recognised.

#### Left heart failure

This is characterised by a reduction in left ventricular output and an increase in left atrial and pulmonary venous pressure. If left heart failure occurs suddenly – for example, as the result of an acute MI – the rapid increase in left atrial pressure causes pulmonary oedema. If the rise in atrial pressure is more gradual, as occurs with mitral stenosis, there is reflex pulmonary vasoconstriction, which protects the patient from pulmonary oedema. However, the resulting increase in pulmonary vascular resistance causes pulmonary hypertension, which in turn impairs right ventricular function.

#### Right heart failure

This is characterised by a reduction in right ventricular output and an increase in right atrial and systemic venous pressure. The most common causes are chronic lung disease, pulmonary embolism and pulmonary valvular stenosis. The term ‘cor pulmonale’ is used to describe right heart failure that is secondary to chronic lung disease.

#### Biventricular heart failure

In biventricular failure, both sides of the heart are affected. This may occur because the disease process, such as dilated cardiomyopathy or coronary heart disease, affects both ventricles or because disease of the left heart leads to chronic elevation of the left atrial pressure, pulmonary hypertension and right heart failure.

#### Epidemiology

Heart failure predominantly affects older people; the prevalence is 1.6% in the UK adult population but affects more than 10% in those aged 80–89 years. In the UK, most patients admitted to hospital with heart failure are more than 70 years old; they typically remain hospitalised for a week or more and may be left with chronic disability. Although the outlook depends, to some extent, on the underlying cause of the problem, untreated heart failure generally carries a poor prognosis; approximately 50% of patients with severe heart failure due to left ventricular dysfunction will die within 2 years because of either pump failure or malignant ventricular arrhythmias. The most common causes are coronary artery disease and myocardial infarction but almost all forms of heart disease can lead to heart failure, as summarised in [Box 16.12](#). An accurate diagnosis is important because treatment of the underlying cause may reverse heart failure or prevent its progression.

#### Pathogenesis

Heart failure occurs when cardiac output fails to meet the demands of the circulation. Cardiac output is determined by preload (the volume and

**Fig. 16.22 Starling's Law.** Normal (A), mild (B), moderate (C) and severe (D) heart failure. Ventricular performance is related to the degree of myocardial stretching. An increase in preload (end-diastolic volume, end-diastolic pressure, filling pressure or atrial pressure) will therefore enhance function; however, overstretching causes marked deterioration. In heart failure, the curve moves to the right and becomes flatter. An increase in myocardial contractility or a reduction in afterload will shift the curve upwards and to the left (green arrow).

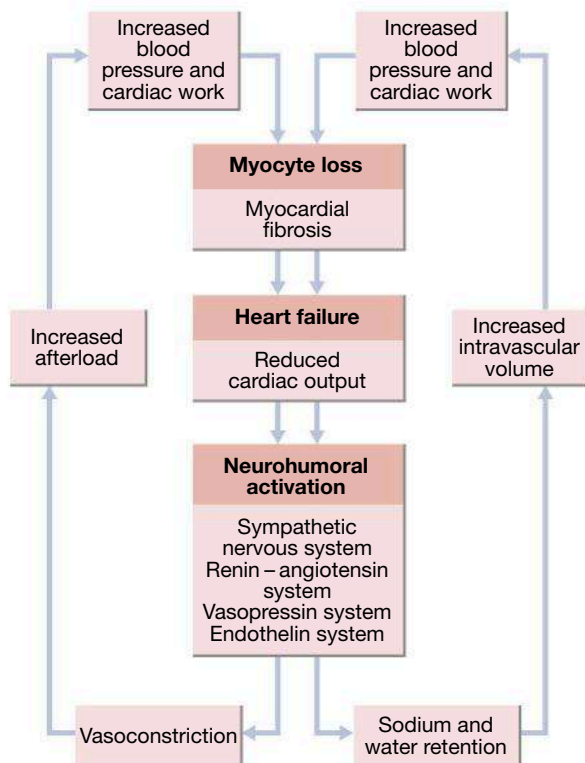

pressure of blood in the ventricles at the end of diastole), afterload (the volume and pressure of blood in the ventricles during systole) and myocardial contractility, forming the basis of Starling's Law ([Fig. 16.22](#)). The causes of heart failure are discussed below.

#### Ventricular dysfunction

Ventricular dysfunction is the most common cause of heart failure. This can occur because of impaired systolic contraction due to myocardial disease, or diastolic dysfunction where there is abnormal ventricular relaxation due to a stiff, non-compliant ventricle. This is most commonly found in patients with left ventricular hypertrophy. Systolic dysfunction and diastolic dysfunction often coexist, particularly in patients with coronary artery disease. Ventricular dysfunction reduces cardiac output, which, in turn, activates the sympathetic nervous system (SNS) and renin-angiotensin-aldosterone system (RAAS). Under normal circumstances, activation of the SNS and RAAS supports cardiac function but, in the setting of impaired ventricular function, the consequences are negative and lead to an increase in both afterload and preload ([Fig. 16.23](#)). A vicious circle may then be established because any additional fall in cardiac output causes further activation of the SNS and RAAS, and an additional increase in peripheral vascular resistance.

Activation of the RAAS causes vasoconstriction and sodium and water retention. This is primarily mediated by angiotensin II, a potent constrictor of arterioles, in both the kidney and the systemic circulation (see [Fig. 16.23](#)). Activation of the SNS also occurs and can initially sustain cardiac output through increased myocardial contractility and heart

16.12 Mechanisms of heart failure		
Cause	Examples	Features
<b>Reduced ventricular contractility</b>	Myocardial infarction (segmental dysfunction)	In coronary artery disease, 'akinetic' or 'dyskinetic' segments contract poorly and may impede the function of normal segments by distorting their contraction and relaxation patterns
	Myocarditis/cardiomyopathy (global dysfunction)	Progressive ventricular dilatation
<b>Ventricular outflow obstruction (pressure overload)</b>	Hypertension, aortic stenosis (left heart failure)	Initially, concentric ventricular hypertrophy allows the ventricle to maintain a normal output by generating a high systolic pressure. Later, secondary changes in the myocardium and increasing obstruction lead to failure with ventricular dilatation and rapid clinical deterioration
	Pulmonary hypertension, pulmonary valve stenosis (right heart failure)	
<b>Ventricular inflow obstruction</b>	Mitral stenosis, tricuspid stenosis	Small, vigorous ventricle; dilated, hypertrophied atrium. Atrial fibrillation is common and often causes marked deterioration because ventricular filling depends heavily on atrial contraction
<b>Ventricular volume overload</b>	Left ventricular volume overload (mitral or aortic regurgitation)	Dilatation and hypertrophy allow the ventricle to generate a high stroke volume and help to maintain a normal cardiac output. However, secondary changes in the myocardium lead to impaired contractility and worsening heart failure
	Ventricular septal defect	
	Right ventricular volume overload (atrial septal defect)	
	Increased metabolic demand (high output)	
<b>Arrhythmia</b>	Atrial fibrillation	Tachycardia does not allow for adequate filling of the heart, resulting in reduced cardiac output and back pressure
	Tachycardia	Prolonged tachycardia causes myocardial fatigue
	Complete heart block	Bradycardia limits cardiac output, even if stroke volume is normal
<b>Diastolic dysfunction</b>	Constrictive pericarditis	Marked fluid retention and peripheral oedema, ascites, pleural effusions and elevated jugular veins
	Restrictive cardiomyopathy	Bi-atrial enlargement (restrictive filling pattern and high atrial pressures). Atrial fibrillation may cause deterioration
	Left ventricular hypertrophy and fibrosis	Good systolic function but poor diastolic filling
	Cardiac tamponade	Hypotension, elevated jugular veins, pulsus paradoxus, poor urine output

**Fig. 16.23** Neurohumoral activation and compensatory mechanisms in heart failure. There is a vicious circle in progressive heart failure.

rate. Prolonged sympathetic stimulation has negative effects, however, causing cardiac myocyte apoptosis, cardiac hypertrophy and focal myocardial necrosis. Sympathetic stimulation also contributes to vasoconstriction and predisposes to arrhythmias. Sodium and water retention is further enhanced by the release of aldosterone, endothelin-1 (a potent vasoconstrictor peptide with marked effects on the renal vasculature) and, in severe heart failure, vasopressin (antidiuretic hormone, ADH). Natriuretic peptides are released from the atria in response to atrial dilatation and compensate to an extent for the sodium-conserving effect of aldosterone, but this mechanism is overwhelmed in heart failure. Pulmonary and peripheral oedema occur because of high left and right atrial pressures, and are compounded by sodium and water retention, caused by impairment of renal perfusion and by secondary hyperaldosteronism. If the underlying cause is a myocardial infarction, cardiac contractility is impaired and SNS and RAAS activation causes hypertrophy of non-infarcted segments, with thinning, dilatation and expansion of the infarcted segment (see Fig. 16.63). This leads to further deterioration in ventricular function and worsening heart failure.

#### High-output failure

Sometimes cardiac failure can occur in patients without heart disease due to a large arteriovenous shunt, or where there is an excessively high cardiac output due to beri-beri, severe anaemia or thyrotoxicosis.

#### Valvular disease

Heart failure can also be caused by valvular disease in which there is impaired filling of the ventricles due to mitral or tricuspid stenosis; where there is obstruction to ventricular outflow, as occurs in aortic and pulmonary stenosis and hypertrophic cardiomyopathy; or as the result of ventricular overload secondary to valvular regurgitation.

### Clinical assessment

Heart failure may develop suddenly, as in MI, or gradually, as in valvular heart disease. When there is gradual impairment of cardiac function, several compensatory changes take place. The term compensated heart failure is sometimes used to describe the condition of those with impaired cardiac function, in whom adaptive changes have prevented the development of overt heart failure. However, a minor event, such as an intercurrent infection or development of atrial fibrillation, may precipitate acute heart failure in these circumstances (Box 16.13). Similarly, acute heart failure sometimes supervenes as the result of a decompensating episode, on a background of chronic heart failure; this is called acute-on-chronic heart failure.

### Acute left heart failure

Acute left heart failure presents with a sudden onset of dyspnoea at rest that rapidly progresses to acute respiratory distress, orthopnoea and ultimately respiratory failure. Often there is a clear precipitating factor, such as an acute MI, which may be apparent from the history. The patient appears agitated, pale and clammy. The peripheries are cool to the touch and the pulse is rapid, but in some cases there may be an inappropriate bradycardia that aggravates the acute episode of heart failure. The BP is usually high because of SNS activation, but may be normal or low if the patient is in cardiogenic shock.

The jugular venous pressure (JVP) is usually elevated, particularly with associated fluid overload or right heart failure. In acute heart failure, there has been no time for ventricular dilatation and the apex is not displaced. A 'gallop' rhythm, with a third heart sound, is heard quite early in the development of acute left-sided heart failure. A new systolic murmur may signify acute mitral regurgitation or ventricular septal rupture. Chest examination may reveal crepitations at the lung bases if there is pulmonary oedema, or

#### 16.13 Factors that may precipitate or aggravate heart failure in pre-existing heart disease

- Myocardial ischaemia or infarction
- Intercurrent illness
- Arrhythmia
- Inappropriate reduction of therapy
- Administration of a drug with negative inotropic ( $\beta$ -blocker) or fluid-retaining properties (non-steroidal anti-inflammatory drugs, glucocorticoids)
- Pulmonary embolism
- Conditions associated with increased metabolic demand (pregnancy, thyrotoxicosis, anaemia)
- Intravenous fluid overload

crepitations throughout the lungs if this is severe. There may be expiratory wheeze. Patients with acute-on-chronic heart failure may have additional features of chronic heart failure (see below). Potential precipitants, such as an upper respiratory tract infection or inappropriate cessation of diuretic medication, may be identified on clinical examination or history-taking.

### Chronic heart failure

Patients with chronic heart failure commonly follow a relapsing and remitting course, with periods of stability and episodes of decompensation, leading to worsening symptoms that may necessitate hospitalisation. The clinical picture depends on the nature of the underlying heart disease, the type of heart failure that it has evoked, and the changes in the SNS and RAAS that have developed (see Box 16.12 and Fig. 16.24).

Low cardiac output causes fatigue and poor effort tolerance; the peripheries are cold and the BP is low. To maintain perfusion of vital organs, blood flow is diverted away from skeletal muscle and this may contribute to fatigue and weakness. Poor renal perfusion leads to oliguria and uraemia.

Pulmonary oedema due to left heart failure presents with dyspnoea and inspiratory crepitations over the lung bases. In contrast, right heart

failure produces a high JVP with hepatic congestion and dependent peripheral oedema. In ambulant patients the oedema affects the lower legs, whereas in bed-bound patients it collects around the thighs and sacrum. Ascites or pleural effusion may occur (Fig. 16.24). Heart failure is not the only cause of oedema (see Box 16.14).

Chronic heart failure is sometimes associated with marked weight loss (cardiac cachexia), caused by a combination of anorexia and impaired absorption due to gastrointestinal congestion, poor tissue perfusion due to a low cardiac output, and skeletal muscle atrophy due to immobility.

### Complications of heart failure

Several complications may occur in advanced heart failure, as described below.

- *Renal failure* is caused by poor renal perfusion due to low cardiac output and may be exacerbated by diuretic, ACE inhibitor and angiotensin receptor blocker (ARB) therapies.
- *Hypokalaemia* may be caused by potassium-losing diuretics, and also by hyperaldosteronism due to activation of the renin-angiotensin system and impairment of aldosterone metabolism from hepatic congestion. Most of the body's potassium is intracellular and there may be substantial depletion of potassium stores, even when the plasma concentration is in the reference range.
- *Hyperkalaemia* may be due to the effects of drugs that promote renal resorption of potassium, in particular the combination of ACE inhibitors, ARBs and mineralocorticoid receptor antagonists. These effects are amplified if there is renal dysfunction due to low cardiac output or atherosclerotic renal vascular disease.
- *Hyponatraemia* is a feature of severe heart failure and is a poor prognostic sign. It may be caused by diuretic therapy, inappropriate water retention due to high vasopressin secretion, or failure of the cell membrane ion pump due to intracellular energy depletion.

Fig. 16.24 Clinical features of left and right heart failure. (JVP = jugular venous pressure)

#### 16.14 Differential diagnosis of peripheral oedema

- Cardiac failure: right or combined left and right heart failure, pericardial constriction, cardiomyopathy
- Chronic venous insufficiency: varicose veins
- Hypoalbuminaemia: nephrotic syndrome, liver disease, protein-losing enteropathy; often widespread, can affect arms and face
- Drugs:
  - Sodium retention: fludrocortisone, non-steroidal anti-inflammatory drugs
  - Increasing capillary permeability: nifedipine, amlodipine
- Idiopathic: women > men
- Chronic lymphatic obstruction

- *Impaired liver function* is caused by hepatic venous congestion and poor arterial perfusion, which frequently cause mild jaundice and abnormal liver function tests; reduced synthesis of clotting factors can make anticoagulant control difficult.
- *Thromboembolism*. Deep vein thrombosis and pulmonary embolism may occur due to the effects of low cardiac output and enforced immobility. Systemic embolism, including stroke, occurs in patients with atrial fibrillation or flutter, or with intracardiac thrombus complicating mitral stenosis, MI or left ventricular aneurysm.
- *Atrial and ventricular arrhythmias* are very common and may be related to electrolyte changes such as hypokalaemia and hypomagnesaemia, myocardial fibrosis and the pro-arrhythmic effects of sympathetic activation. Atrial fibrillation occurs in approximately 20% of patients with heart failure and causes further impairment of cardiac function. Ventricular ectopic beats and non-sustained ventricular tachycardia are common findings in patients with heart failure and are associated with an adverse prognosis.
- *Sudden death* occurs in up to 50% of patients with heart failure and is most often due to ventricular fibrillation.

### Investigations

An erect chest X-ray should be performed in all cases. This may show abnormal distension of the upper lobe pulmonary veins (Fig. 16.25). Vascularity of the lung fields becomes more prominent and the pulmonary arteries dilate. Subsequently, interstitial oedema causes thickened interlobular septa and dilated lymphatics. These are evident as horizontal lines in the costophrenic angles (septal or 'Kerley B' lines). More advanced changes due to alveolar oedema cause a hazy opacification spreading from the hila, and pleural effusions. Echocardiography should be considered in all patients with heart failure in order to:

- determine the aetiology
- detect valvular heart disease, such as occult mitral or aortic stenosis, and other conditions that may be amenable to treatment
- identify patients who will benefit from long-term drug therapy and cardiac device implantation.

Serum urea, creatinine and electrolytes, haemoglobin and thyroid function may help to establish the nature and severity of the underlying heart disease and detect any complications. BNP is elevated in heart failure and is a prognostic marker, as well as being useful in differentiating heart failure from other causes of breathlessness or peripheral oedema.

### Management of acute heart failure

Acute heart failure with pulmonary oedema is a medical emergency that should be treated urgently. The patient should initially be kept rested upright, with continuous monitoring of cardiac rhythm, BP and pulse oximetry. Intravenous opiates can be of value in distressed patients but must be used sparingly, as they may cause respiratory depression and exacerbation of hypoxaemia and hypercapnia. The key elements of management are summarised in Box 16.15.

If these measures prove ineffective, inotropic agents such as dobutamine (2.5–10 µg/kg/min) may be required to augment cardiac output, particularly in hypotensive patients. An intra-aortic balloon pump may be beneficial in patients with acute cardiogenic pulmonary oedema and shock. Following management of the acute episode, additional measures must be used to control heart failure in the longer term, as discussed below.

### Management of chronic heart failure

The aims of treatment in chronic heart failure are to improve cardiac function by increasing contractility and coordination of the myocardium, by optimising preload or decreasing afterload, and controlling cardiac rate and rhythm (see Fig. 16.23). This can be achieved by using drug treatments, implantable device therapy, coronary revascularisation, and in resistant cases, mechanical assist devices or cardiac transplantation.

**Fig. 16.25** Radiological features of heart failure. **A** Chest X-ray of a patient with pulmonary oedema. **B** Enlargement of lung base showing septal or 'Kerley B' lines (arrow).

16.15 Management of acute pulmonary oedema	
Action	Effect
Sit the patient up	Reduces preload
Give high-flow oxygen	Corrects hypoxia
Ensure continuous positive airway pressure (CPAP) of 5–10 mmHg by tight-fitting mask	Reduces preload and pulmonary capillary hydraulic gradient
Administer nitrates: * IV glyceryl trinitrate (10–200 µg/min) Buccal glyceryl trinitrate 2–5 mg	Reduces preload and afterload
Administer a loop diuretic: Furosemide (50–100 mg IV)	Combats fluid overload

\*The dose of nitrate should be titrated upwards every 10 minutes until there is an improvement or systolic blood pressure is < 110 mmHg. (IV = intravenous)

### Education

Education of patients and their relatives about the causes and treatment of heart failure can improve adherence to a management plan (Box 16.16). Some patients may need to weigh themselves daily, as a measure of fluid load, and adjust their diuretic therapy accordingly.

## i

## 16.16 General measures for the management of heart failure

## Education

- Explanation of nature of disease, treatment and self-help strategies

## Diet

- Good general nutrition and weight reduction for the obese
- Avoidance of high-salt foods and added salt, especially for patients with severe congestive heart failure

## Alcohol

- Moderation or elimination of alcohol consumption; alcohol-induced cardiomyopathy requires abstinence

## Smoking

- Cessation

## Exercise

- Regular moderate aerobic exercise within limits of symptoms

## Vaccination

- Consideration of influenza and pneumococcal vaccination

## 16.17 Congestive cardiac failure in old age

- **Incidence:** rises with age and affects 5%–10% of those in their eighties.
- **Common causes:** coronary artery disease, hypertension and calcific degenerative valvular disease.
- **Diastolic dysfunction:** often prominent, particularly in those with a history of hypertension.
- **ACE inhibitors and ARBs:** improve symptoms and mortality but are more frequently associated with postural hypotension and renal impairment than in younger patients.
- **Loop diuretics:** usually required but may be poorly tolerated in those with urinary incontinence and men with prostate enlargement.

## Drug treatment

Many drug treatments are now available for heart failure. Drugs that reduce preload are appropriate in patients with high end-diastolic filling pressures and evidence of pulmonary or systemic venous congestion, whereas those that reduce afterload or increase myocardial contractility are more useful in patients with signs and symptoms of a low cardiac output. Some considerations specific to management of older patients are given in [Box 16.17](#).

**Diuretics** Diuretics promote urinary sodium and water excretion, leading to a reduction in blood plasma volume, which in turn reduces preload and improves pulmonary and systemic venous congestion. They may also reduce afterload and ventricular volume, leading to a fall in ventricular wall tension and increased cardiac efficiency. Although a fall in preload (ventricular filling pressure) normally reduces cardiac output, patients with heart failure are beyond the apex of the Starling curve, so there may be a substantial and beneficial fall in filling pressure with either no change or an improvement in cardiac output (see [Figs. 16.22](#) and [16.26](#)). Over-diuresis can cause excessive volume depletion, resulting in a fall in cardiac output with hypotension, lethargy and renal failure. This is especially likely in patients with a marked diastolic component to their heart failure.

Oedema may persist, despite oral loop diuretic therapy, in some patients with severe chronic heart failure, particularly if there is renal impairment. Under these circumstances an intravenous infusion of a loop diuretic, such as furosemide (5–10 mg/hr), may initiate a diuresis. Combining this with a thiazide diuretic, such as bendroflumethiazide (5 mg daily), may augment the diuresis but care must be taken to avoid an excessive fluid loss, hyponatraemia and hypokalaemia.

**Fig. 16.26** The effect of treatment on ventricular performance curves in heart failure. Diuretics and venodilators (A), angiotensin-converting enzyme (ACE) inhibitors and mixed vasodilators (B), and positive inotropic agents (C).

Mineralocorticoid receptor antagonists, such as spironolactone and eplerenone, are potassium-sparing diuretics that are of particular benefit in patients with heart failure with severe left ventricular systolic dysfunction. They improve long-term clinical outcome in individuals with severe heart failure or heart failure following acute MI but may cause hyperkalaemia, particularly when used with an ACE inhibitor.

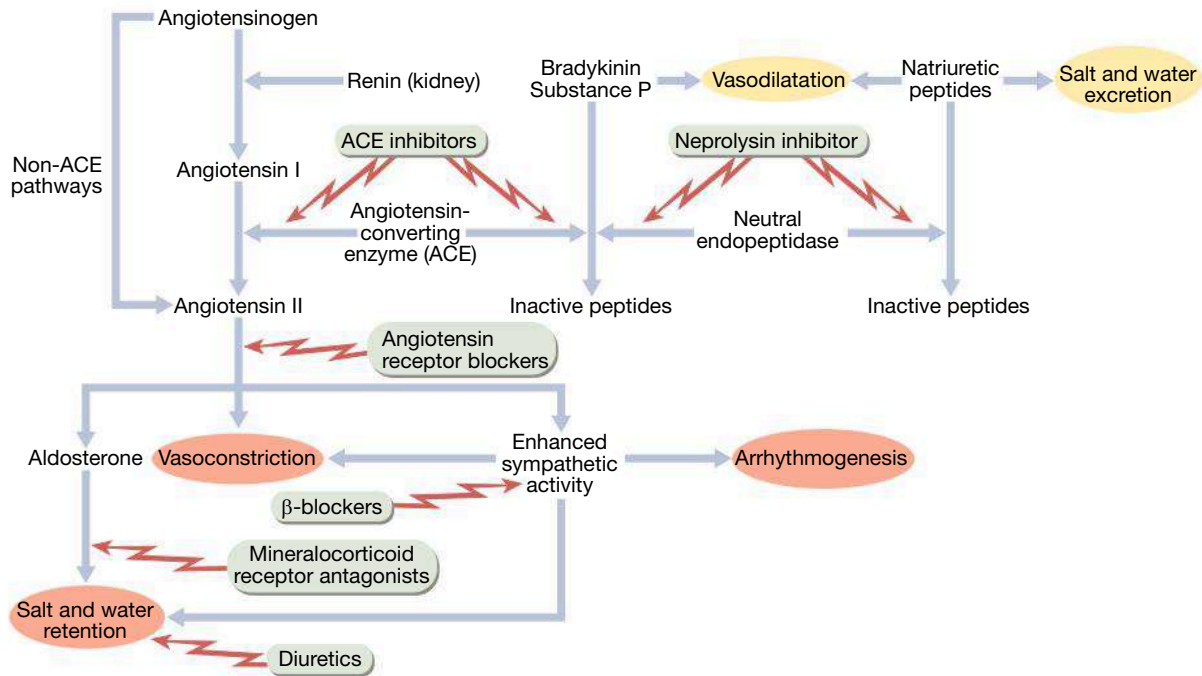

Originally developed as a treatment for type 2 diabetes mellitus, sodium-glucose co-transporter 2 (SGLT-2) inhibitors block the resorption of glucose in the nephron of the kidney to cause an osmotic diuresis. Their use is associated with reduced hospitalisations for heart failure and lower mortality in patients with heart failure irrespective of the presence of diabetes. However, they are associated with an increased risk of genitourinary tract infections and diabetic ketoacidosis.

**Angiotensin-converting enzyme inhibitors** Angiotensin-converting enzyme (ACE) inhibitors play a central role in the management of heart failure since they interrupt the vicious circle of neurohumoral activation that is characteristic of the disease by preventing the conversion of angiotensin I to angiotensin II. This, in turn, reduces peripheral vasoconstriction, activation of the sympathetic nervous system ([Fig. 16.27](#)), and salt and water retention due to aldosterone release, as well as preventing the activation of the renin–angiotensin system caused by diuretic therapy.

In moderate and severe heart failure, ACE inhibitors can produce a substantial improvement in effort tolerance and in mortality. They can also improve outcome and prevent the onset of overt heart failure in patients with poor residual left ventricular function following MI.

Adverse effects of ACE inhibitors include hypotension and renal impairment, especially in patients with bilateral renal artery stenosis or those with pre-existing renal disease. An increase in serum potassium concentration may also occur, which can be beneficial in offsetting the hypokalaemia associated with loop diuretic therapy. In stable patients without hypotension (systolic BP over 100 mmHg), ACE inhibitors can usually be safely started in the community. In other patients, however, it is usually advisable to withhold diuretics for 24 hours before starting treatment with a small dose of a long-acting agent, preferably given at night ([Box 16.18](#)). Renal function and serum potassium must be monitored and should be checked 1–2 weeks after starting therapy.

**Angiotensin receptor blockers** Angiotensin receptor blockers (ARBs) act by blocking the action of angiotensin II on the heart, peripheral vasculature and kidneys. In heart failure they produce beneficial haemodynamic changes similar to those of ACE inhibitors (see [Fig. 16.27](#)) but are generally better tolerated. They have comparable effects on mortality and are a useful alternative for patients who cannot tolerate ACE inhibitors. They should be started at a low dose and titrated upwards, depending on response (see [Box 16.18](#)). Unfortunately, they share all the more

**Fig. 16.27** Neurohumoral activation of the renin–angiotensin and sympathetic nervous systems have adverse (red) effects on the cardiovascular system which are counterbalanced by beneficial effects of endogenous natriuretic and vasoactive peptide systems (yellow). Heart failure treatments are targeted at inhibiting the detrimental pathways and enhancing the beneficial compensatory systems.

### 16.18 Dosages of ACE inhibitors, angiotensin receptor blockers, $\beta$ -blockers and neprilysin inhibitors in heart failure

	Starting dose	Target dose
<b>ACE inhibitors</b>		
Enalapril	2.5 mg twice daily	10 mg twice daily
Lisinopril	2.5 mg daily	20 mg daily
Ramipril	1.25 mg daily	10 mg daily
<b>Angiotensin receptor blockers</b>		
Losartan	25 mg daily	100 mg daily
Candesartan	4 mg daily	32 mg daily
Valsartan	40 mg daily	160 mg daily
<b><math>\beta</math>-blockers</b>		
Bisoprolol	1.25 mg daily	10 mg daily
Metoprolol	25 mg twice daily	100 mg twice daily
Carvedilol	3.125 mg twice daily	25 mg twice daily
<b>Neprilysin inhibitor-ARB</b>		
Sacubitril–valsartan	24/26 mg twice daily	97/103 mg twice daily

serious adverse effects of ACE inhibitors, including renal dysfunction and hyperkalaemia. While ARB are normally used as an alternative to ACE inhibitors, they can be combined in patients with resistant or recurrent heart failure.

**Neprilysin inhibitors** The only drug currently in this class is sacubitril, a small-molecule inhibitor of neutral endopeptidase, or neprilysin, which is responsible for the breakdown of the endogenous diuretics ANP and BNP as well as vasoactive peptides such as bradykinin and substance P (see Fig. 16.27). If used in combination with the ARB in an initial oral dose of 24 mg sacubitril and 26 mg valsartan daily, it produces additional symptomatic and mortality benefit over ACE inhibition and is increasingly being used in preference to ACE inhibitors in patients with chronic heart failure.

**Vasodilators** These drugs are valuable in chronic heart failure, when ACE inhibitors or ARBs are contraindicated. Venodilators, such as nitrates, reduce preload. Arterial dilators, such as hydralazine, reduce afterload (see Fig. 16.26). Their use is limited by pharmacological tolerance and hypotension.

**Beta-adrenoceptor antagonists ( $\beta$ -blockers)** Beta-blockade helps to counteract the deleterious effects of enhanced sympathetic stimulation and reduces the risk of arrhythmias and sudden death. When initiated in standard doses  $\beta$ -blockers may precipitate acute-on-chronic heart failure, but when given in small incremental doses they can increase ejection fraction, improve symptoms, reduce the frequency of hospitalisation and reduce mortality in patients with chronic heart failure. A typical regimen is bisoprolol, starting at 1.25 mg daily and increased gradually over 12 weeks to a target maintenance dose of 10 mg daily. Beta-blockers are more effective at reducing mortality than ACE inhibitors, with a relative risk reduction of 33% versus 20%, respectively.

**Ivabradine** Ivabradine acts on the  $I_f$  inward current in the SA node, resulting in reduction of heart rate. Typical dosages are 2.5–5 mg twice daily, increasing to 7.5 mg twice daily if necessary. It reduces hospital admission and mortality rates in patients with heart failure due to moderate or severe left ventricular systolic impairment. In trials, its effects were most marked in patients with a relatively high heart rate (over 77/min), so ivabradine is best suited to patients who cannot take  $\beta$ -blockers or whose heart rate remains high despite  $\beta$ -blockade. It is ineffective in patients with atrial fibrillation.

**Digoxin** Digoxin in maintenance doses of 0.0625–0.25 mg daily can be used to provide rate control in patients with heart failure and atrial fibrillation. In patients with severe heart failure (NYHA class III–IV, see Box 16.5), digoxin reduces the likelihood of hospitalisation for heart failure, although it has no effect on long-term survival.

**Amiodarone** This is a potent anti-arrhythmic drug that has little negative inotropic effect and may be valuable in patients with poor left ventricular function. It is effective only in the treatment of symptomatic

arrhythmias and should not be used as a preventative agent in asymptomatic patients. Amiodarone is used for prevention of symptomatic atrial arrhythmias and of ventricular arrhythmias when other pharmacological options have been exhausted.

### Non-pharmacological treatments

**Implantable cardiac defibrillators** These devices are indicated in patients with heart failure who have had, or who are at high risk of, life-threatening ventricular arrhythmias, since they reduce the risk of sudden death.

**Cardiac resynchronisation therapy devices** In patients with marked conduction system disease, especially left bundle branch block, there is uncoordinated left ventricular contraction which exacerbates heart failure. Cardiac resynchronisation therapy (CRT) uses pacemaker technology to overcome dyssynchronous contraction by pacing the LV and RV simultaneously (Fig. 16.28). This improves cardiac output and is associated with improved symptoms and reduced mortality.

**Coronary revascularisation** Coronary artery bypass surgery or percutaneous coronary intervention may improve function in areas of the myocardium that are 'hibernating' because of inadequate blood supply, and can be used to treat carefully selected patients with heart failure and coronary artery disease. If necessary, 'hibernating' myocardium can be identified by stress echocardiography and specialised nuclear or magnetic resonance imaging.

**Cardiac transplantation** Cardiac transplantation is an established and successful treatment for patients with intractable heart failure. Coronary artery disease and dilated cardiomyopathy are the most common indications. The use of transplantation is limited by the efficacy of modern drug and device therapies, as well as the availability of donor hearts, so it is generally reserved for young patients with severe symptoms despite optimal therapy.

Conventional heart transplantation is contraindicated in patients with pulmonary vascular disease due to long-standing left heart failure, complex congenital heart disease such as Eisenmenger syndrome, or primary pulmonary hypertension because the RV of the donor heart may fail in the face of high pulmonary vascular resistance. However, heart–lung transplantation can be successful in patients with Eisenmenger syndrome, and lung transplantation has been used for primary pulmonary hypertension.

**Fig. 16.28** Chest X-ray of a biventricular pacemaker and defibrillator (cardiac resynchronisation therapy). The right ventricular lead (RV) is in position in the ventricular apex and is used for both pacing and defibrillation. The left ventricular lead (LV) is placed via the coronary sinus, and the right atrial lead (RA) is placed in the right atrial appendage; both are used for pacing only.

Although cardiac transplantation usually produces a dramatic improvement in the recipient's quality of life, serious complications may occur:

- **Rejection.** In spite of routine therapy with ciclosporin A, azathioprine and corticosteroids, episodes of rejection are common and may present with heart failure, arrhythmias or subtle ECG changes. Cardiac biopsy is often used to confirm the diagnosis before starting treatment with high-dose corticosteroids.
- **Accelerated atherosclerosis.** Recurrent heart failure is often due to progressive atherosclerosis in the coronary arteries of the donor heart. This is not confined to patients who underwent transplantation for coronary artery disease and is probably a manifestation of chronic rejection. Angina is rare because the heart has been denervated.
- **Infection.** Opportunistic infection with organisms such as cytomegalovirus or *Aspergillus* remains a major cause of death in transplant recipients.

**Ventricular assist devices** Because of the limited supply of donor organs, ventricular assist devices (VAD) may be employed as a bridge to cardiac transplantation and as short-term restoration therapy following a potentially reversible insult such as viral myocarditis. In some patients, VADs may be used as a long-term therapy if no other options exist.

These devices assist cardiac output by using a roller, centrifugal or pulsatile pump that, in some cases, is implantable and portable. They withdraw blood through cannulae inserted in the atria or ventricular apex and pump it into the pulmonary artery or aorta. They are designed not only to unload the ventricles but also to provide support to the pulmonary and systemic circulations. Their more widespread application is limited by high complication rates (haemorrhage, systemic embolism, infection, neurological and renal sequelae), although some improvements in survival and quality of life have been demonstrated in patients with severe heart failure.

## Cardiac arrhythmias

A cardiac arrhythmia is defined as a disturbance of the electrical rhythm of the heart. Arrhythmias are often a manifestation of structural heart disease but may also occur because of abnormal conduction or depolarisation in an otherwise healthy heart. There are many types of cardiac arrhythmia, as discussed later in this section. By convention, however, a heart rate of more than 100/min is a tachycardia, and a heart rate of less than 60/min is a bradycardia.

### Pathogenesis

Arrhythmias usually occur as the result of pathology affecting the conduction system of the heart. The cardiac cycle is normally initiated by spontaneous depolarisation in the SA node. The atria and ventricles then activate sequentially as the depolarisation wave passes through specialised conducting tissues (see Fig. 16.4). The SA node acts as a pacemaker and its intrinsic rate is regulated by the autonomic nervous system; parasympathetic (vagal) activity decreases the heart rate and sympathetic activity increases it via cardiac sympathetic nerves and circulating catecholamines.

There are three main mechanisms of tachycardia:

- **Increased automaticity.** The tachycardia is produced by spontaneous depolarisation of an ectopic focus in the atria, atrioventricular junction or ventricles, often in response to catecholamines. Single depolarisations lead to atrial, junctional or ventricular premature (ectopic) beats. Repeated depolarisation leads to atrial, junctional or ventricular tachycardia.
- **Re-entry.** The tachycardia is initiated by an ectopic beat and sustained by a re-entry circuit (Fig. 16.29). Most tachyarrhythmias are caused by re-entry.
- **Triggered activity.** This can cause ventricular arrhythmias in patients with coronary artery disease. It is a form of secondary depolarisation

**Fig. 16.29** The mechanism of re-entry. Re-entry can occur when there are two alternative pathways with different conducting properties, such as the atrioventricular node and an accessory pathway, or an area of normal and an area of ischaemic tissue. Here, pathway A conducts slowly and recovers quickly, while pathway B conducts rapidly and recovers slowly. (1) In sinus rhythm, each impulse passes down both pathways before entering a common distal pathway. (2) As the pathways recover at different rates, a premature impulse may find pathway A open and B closed. (3) Pathway B may recover while the premature impulse is travelling selectively down pathway A. The impulse can then travel retrogradely up pathway B, setting up a closed loop or re-entry circuit. (4) This may initiate a tachycardia that continues until the circuit is interrupted by a change in conduction rates or electrical depolarisation.

arising from an incompletely repolarised cell membrane. Arrhythmias may be supraventricular (sinus, atrial or junctional) or ventricular in origin.

Supraventricular rhythms usually produce narrow QRS complexes because the ventricles are depolarised in their normal sequence via the AV node, the bundle of His, bundle branches and Purkinje fibres. In contrast, ventricular arrhythmias often produce broad, bizarre QRS complexes because the ventricles are activated in sequence rather than in parallel, and activation occurs via myocardial cells rather than the rapidly conducting Purkinje fibres. Occasionally, supraventricular tachycardia can mimic ventricular tachycardia and present as a broad-complex tachycardia due to coexisting bundle branch block or the presence of an additional atrioventricular connection (accessory pathway, see below).

Bradycardia is caused by either reduced automaticity of the SA node or impaired conduction through the AV node or His–Purkinje system. If the sinus rate becomes unduly slow, another, more distal part of the conducting system may assume the role of pacemaker. This is known as an escape rhythm and may arise in the AV node or His bundle (junctional rhythm) or in the ventricles (idioventricular rhythm).

### Clinical features

Many arrhythmias are asymptomatic but sustained tachycardias typically present with rapid palpitation. Dizziness, chest discomfort or breathlessness may also occur. Extreme tachycardias can also cause syncope because the heart is unable to fill properly at extreme rates. Bradycardias tend to cause symptoms of low cardiac output, including fatigue, lightheadedness and syncope. Extreme bradycardias or tachycardias can precipitate sudden death or cardiac arrest.

### Investigations

The first-line investigation is a 12-lead ECG, which can be diagnostic in many cases. If arrhythmias are intermittent and the resting ECG is normal, an attempt should be made to capture the abnormal rhythm using an ambulatory ECG or a patient-activated ECG.

### Management

Features of individual arrhythmias are discussed below. Management depends on the nature of the arrhythmia and the general principles of medical management are discussed later in this chapter.

## Sinus arrhythmia

This is defined as a cyclical alteration of the heart rate during respiration, with an increase during inspiration and a decrease during expiration. Sinus arrhythmia is a normal phenomenon and can be quite pronounced in children. Absence of heart rate variation with breathing or with changes in

posture may be a feature of diabetic neuropathy autonomic neuropathy or increased sympathetic drive. Sinus arrhythmia does not require treatment.

## Sinus bradycardia

This may occur in healthy people at rest and is a common finding in athletes. Some pathological causes are listed in [Box 16.19](#). If sinus bradycardia is asymptomatic, then no treatment is required. Symptomatic sinus bradycardia may occur acutely during an MI and can be treated with intravenous atropine (0.6–1.2 mg). Patients with recurrent or persistent symptomatic sinus bradycardia should be considered for permanent pacemaker implantation.

## Sinus tachycardia

Sinus tachycardia is usually due to an increase in sympathetic activity associated with exercise or emotion. Healthy young adults can produce a rapid sinus rate, up to 200/min, during intense exercise. Sinus tachycardia usually does not require treatment but sometimes may reflect an underlying disease, as summarised in [Box 16.19](#).

## Sinoatrial disease

Sinoatrial disease or 'sick sinus syndrome' can occur at any age but is most common in older people. It is caused by degenerative changes in the SA node and is characterised by a variety of arrhythmias ([Box 16.20](#)). The typical presentation is with palpitation, dizzy spells or syncope, due to intermittent tachycardia, bradycardia, or pauses in sinus rhythm with no atrial or ventricular activity ([Fig. 16.30](#)).

In sinoatrial disease, a permanent pacemaker improves symptoms but not prognosis so is not indicated in asymptomatic patients. It is used in

### 16.19 Some pathological causes of sinus bradycardia and tachycardia

#### Sinus bradycardia

- Myocardial infarction
- Sinus node disease (sick sinus syndrome)
- Hypothermia
- Hypothyroidism
- Cholestatic jaundice
- Raised intracranial pressure
- Drugs ( $\beta$ -blockers, digoxin, verapamil)

#### Sinus tachycardia

- Anxiety
- Fever
- Anaemia
- Heart failure
- Thyrotoxicosis
- Pheochromocytoma
- Drugs ( $\beta$ -agonists)

**Fig. 16.30 Sinoatrial disease (sick sinus syndrome).** A continuous rhythm strip from a 24-hour ECG tape recording illustrating periods of sinus rhythm, atrial ectopics, junctional beats, sinus bradycardia, sinus arrest and paroxysmal atrial fibrillation.

### i

#### 16.20 Common features of sinoatrial disease

- Sinus bradycardia
- Sinoatrial block (sinus arrest)
- Paroxysmal atrial fibrillation
- Paroxysmal atrial tachycardia
- Atrioventricular block

patients with symptomatic bradycardia, including bradycardia induced by drugs required to prevent tachyarrhythmias. A dual-chamber pacemaker is normally used (see p. 422). The right atrial lead is used to assist the SA node, and the right ventricular lead is a backup in case AV nodal block occurs later on.

### Atrioventricular block

This usually occurs as the result of disease affecting the AV node. AV block can be intermittent, however, and may become evident only when the conducting tissue is stressed by a rapid atrial rate. Reflecting this fact, atrial tachyarrhythmias are often associated with AV block (see Fig. 16.36). Episodes of ventricular asystole may also complicate complete heart block or Mobitz type II second-degree AV block. Several types of AV block are recognised.

#### First-degree atrioventricular block

In this condition, AV conduction is delayed and so the PR interval is prolonged ( $>0.20$  sec; Fig. 16.31). It rarely causes symptoms and does not usually require treatment.

#### Second-degree atrioventricular block

Here dropped beats occur because some impulses from the atria fail to conduct to the ventricles. Two subtypes are recognised. In Mobitz type I second-degree AV block (Fig. 16.32), there is progressive lengthening of successive PR intervals, culminating in a dropped beat. The cycle then repeats itself. This is known as the Wenckebach phenomenon and is usually due to impaired conduction in the AV node itself. The phenomenon may be physiological and is sometimes observed at rest or during sleep in athletic young adults with high vagal tone.

In Mobitz type II second-degree AV block (Fig. 16.33), the PR interval of the conducted impulses remains constant but some P waves are not conducted. This is usually caused by disease of the His–Purkinje system and carries a risk of asystole.

**Fig. 16.31 First-degree atrioventricular block.** The PR interval is prolonged and measures 0.32 sec.

In 2:1 AV block (Fig. 16.34), alternate P waves are not conducted, so it is impossible to distinguish between Mobitz type I and type II block.

#### Third-degree atrioventricular block

In third-degree AV block, conduction fails completely and the atria and ventricles beat independently. This is known as AV dissociation, as shown in Fig. 16.35. Ventricular activity is maintained by an escape rhythm arising in the AV node or bundle of His (narrow QRS complexes) or the distal Purkinje tissues (broad QRS complexes). Distal escape rhythms tend to be slower and less reliable. Complete AV block (Box 16.21) produces a slow (25–50/min), regular pulse that does not vary with exercise, except in the case of congenital complete AV block. There is usually a compensatory increase in stroke volume, producing a large-volume pulse. Cannon waves may be visible in the neck and the intensity of the first heart sound varies due to the loss of AV synchrony.

#### Clinical features

The typical presentation is with recurrent syncope or ‘Stokes–Adams’ attacks. These episodes are characterised by sudden loss of consciousness that occurs without warning and results in collapse. A brief anoxic seizure (due to cerebral ischaemia) may occur if there is prolonged asystole. There is pallor and a death-like appearance during the attack, but when the heart starts beating again there is a characteristic flush. In distinction to epilepsy, recovery is rapid. Sinoatrial disease and neurocardiogenic syncope (p. 184) may cause similar symptoms.

#### Management

This depends on the clinical circumstances. Inferior ST elevation MI is sometimes complicated by transient AV block because the right coronary artery (RCA) supplies the AV node. There is usually a reliable

**Fig. 16.32** Second-degree atrioventricular block (Mobitz type I – the Wenckebach phenomenon). The PR interval progressively increases until a P wave is not conducted. The cycle then repeats itself. In this example, conduction is at a ratio of 4:3, leading to groupings of three ventricular complexes in a row.

**Fig. 16.33** Second-degree atrioventricular block (Mobitz type II). The PR interval of conducted beats is normal but some P waves are not conducted. The constant PR interval distinguishes this from the Wenckebach phenomenon.

**Fig. 16.34** Second-degree atrioventricular block with fixed 2:1 block. Alternate P waves are not conducted. This may be due to Mobitz type I or II block.

**Fig. 16.35** Complete (third-degree) atrioventricular block. There is complete dissociation of atrial and ventricular complexes. The atrial rate is 80/min and the ventricular rate is 38/min.

## 16.21 Causes of complete atrioventricular block

### Congenital Acquired

- Idiopathic fibrosis
- Myocardial infarction/ischaemia
- Inflammation:
  - Infective endocarditis
  - Sarcoidosis
  - Chagas' disease
- Trauma
- Drugs:
  - Digoxin
  - $\beta$ -blockers
  - Calcium antagonists

escape rhythm and, if the patient remains well, no treatment is required. Symptomatic second- or third-degree AV block may respond to atropine (0.6 mg IV, repeated as necessary) or, if this fails, a temporary pacemaker. In most cases, the AV block will resolve within 7–10 days.

Second- or third-degree AV heart block complicating acute anterior MI indicates extensive ventricular damage involving both bundle branches and carries a poor prognosis. Asystole may ensue and a temporary pacemaker should be inserted promptly. If the patient presents with asystole, intravenous atropine (3 mg) or intravenous isoprenaline (2 mg in 500 mL 5% dextrose, infused at 10–60 mL/hr) may help to maintain the circulation until a temporary pacing electrode can be inserted. Temporary pacing can provide effective rhythm support in the short term.

Patients with symptomatic bradyarrhythmias associated with AV block should be treated with a permanent pacemaker. Asymptomatic first-degree or Mobitz type I second-degree AV block (Wenckebach phenomenon) does not require treatment but may be an indication of underlying heart disease. A permanent pacemaker is usually indicated in patients with asymptomatic Mobitz type II second-degree AV block or third-degree AV heart block because of the risk of asystole and sudden death. Pacing improves prognosis.

## Bundle branch block

Damage to the right or left bundle branch of the conducting system can occur as a result of many pathologies, including ischaemic heart disease, hypertensive heart disease and cardiomyopathy. However, right bundle branch block (RBBB) can occur as a normal variant in healthy individuals (Box 16.22). In left bundle branch block (LBBB) and RBBB, depolarisation proceeds through a slow myocardial route in the affected ventricle rather than through the rapidly conducting Purkinje tissues that constitute the bundle branches. This causes delayed conduction into the LV or RV, broadens the QRS complex ( $\geq 0.12$  sec) and produces characteristic alterations in QRS morphology (Figs. 16.36 and 16.37). Damage to the left bundle can also occur after it divides into anterior and posterior fascicles, when it is called hemiblock. In this case, the QRS complex is not broad but the direction of ventricular depolarisation is changed, causing left axis deviation in left anterior hemiblock and right axis deviation in left posterior hemiblock (see Fig. 16.7). The combination of RBBB and left anterior or posterior hemiblock is known as bifascicular block. LBBB usually signifies important underlying heart disease and also causes ventricular incoordination, which may aggravate symptoms in patients with heart failure. This can be treated in selected patients by cardiac resynchronisation therapy.

## Atrial ectopic beats

Atrial ectopic beats usually cause no symptoms but can give the sensation of a missed beat or an abnormally strong beat. The ECG (Fig. 16.39)

## 16.22 Common causes of bundle branch block

### Right bundle branch block

- Normal variant
- Right ventricular hypertrophy or strain, e.g. pulmonary embolism
- Congenital heart disease, e.g. atrial septal defect
- Coronary artery disease

### Left bundle branch block

- Coronary artery disease
- Hypertension
- Aortic valve disease
- Cardiomyopathy

**Fig. 16.36 Right bundle branch block.** Note the wide QRS complexes with 'M'-shaped configuration in leads  $V_1$  and  $V_2$  and a wide S wave in lead I.

shows a premature but otherwise normal QRS complex; if visible, the preceding P wave has a different morphology because the atria activate from an abnormal site. In most cases these are of no consequence, although very frequent atrial ectopic beats may herald the onset of atrial fibrillation. Treatment is rarely necessary but  $\beta$ -blockers can be used if symptoms are intrusive.

### Atrial tachycardia

Atrial tachycardia may be a manifestation of increased atrial automaticity, sinoatrial disease or digoxin toxicity. It produces a narrow-complex tachycardia with abnormal P-wave morphology, sometimes associated with AV block if the atrial rate is rapid. It may respond to  $\beta$ -blockers, which reduce automaticity, or class I or III anti-arrhythmic drugs (see Box 16.30). The ventricular response in rapid atrial tachycardias may be controlled by AV node-blocking drugs. Catheter ablation (p. 423) can be used to target the ectopic site and should be offered as an alternative to anti-arrhythmic drugs in patients with recurrent atrial tachycardia.

### Atrial flutter

Atrial flutter is characterised by a large (macro) re-entry circuit, usually within the right atrium encircling the tricuspid annulus. The atrial rate is approximately 300/min, and is usually associated with 2:1, 3:1 or 4:1 AV

**Fig. 16.37 Left bundle branch block.** Note the wide QRS complexes with loss of the Q wave or septal vector in lead I and 'M'-shaped QRS complexes in  $V_5$  and  $V_6$ .

**Fig. 16.38 Atrial ectopic beats.** The first, second and fifth complexes are normal sinus beats. The third, fourth and sixth complexes are atrial ectopic beats with identical QRS complexes and abnormal (sometimes barely visible) P waves.

**Fig. 16.39 Atrial flutter.** Simultaneous recording showing atrial flutter with 4:1 atrioventricular block. Flutter waves are visible only in leads II and III.

block (with corresponding heart rates of 150, 100 or 75/min). Rarely, in young patients, every flutter wave is conducted, producing a rate of 300/min and, potentially, haemodynamic compromise. The ECG shows sawtooth flutter waves (Fig. 16.39). When there is regular 2:1 AV block, it may be difficult to identify flutter waves that are buried in QRS complexes and T waves. Atrial flutter should be suspected when there is a narrow-complex tachycardia of 150/min. Carotid sinus pressure or intravenous adenosine may help to establish the diagnosis by temporarily increasing the degree of AV block and revealing flutter waves (Fig. 16.40).

**Fig. 16.40** Carotid sinus pressure in atrial flutter: continuous trace. The diagnosis of atrial flutter with 2:1 block was established when carotid sinus pressure produced temporary atrioventricular block, revealing the flutter waves.

### Management

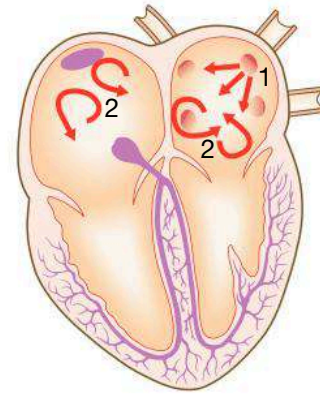

Atrial flutter can be managed by either 'rate control' or 'rhythm control'. Rate control uses AV node-blocking drugs, such as  $\beta$ -blockers, verapamil or digoxin at the dosages shown in [Box 16.30](#), to control the ventricular rate. In most cases rhythm control is preferable. This can be achieved by either direct current (DC) cardioversion, or catheter ablation. DC cardioversion is associated with a high recurrence rate even when drugs, such as  $\beta$ -blockers or amiodarone, are used afterwards. Class Ic anti-arrhythmic drugs, such as flecainide, are contraindicated because they can produce a paradoxical extreme tachycardia and haemodynamic compromise. Catheter ablation offers a greater than 90% chance of permanent cure and is the treatment of choice for patients with persistent symptoms. Anticoagulant management in patients with atrial flutter, including management around cardioversion, is identical to that of patients with atrial fibrillation.

### Atrial fibrillation

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, with an overall prevalence of 0.5% in the adult population of the UK. The prevalence rises with age, affecting 1% of those aged 60–64 years, increasing to 9% of those aged over 80 years. It is associated with significant morbidity and a twofold increase in mortality. This is mainly because of its association with underlying heart disease but also because of its association with systemic embolism and stroke.

### Pathogenesis

AF is a complex arrhythmia characterised by both abnormal automatic firing and the presence of multiple interacting re-entry circuits within the atria. Episodes of AF are initiated by rapid bursts of ectopic beats arising from conducting tissue in the pulmonary veins or from diseased atrial tissue. It becomes sustained because of re-entrant conduction within the atria or sometimes because of continuous ectopic firing ([Fig. 16.41](#)). Re-entry is more likely to occur in atria that are enlarged or in which conduction is slow, as is the case in many forms of heart disease. During episodes of AF, the atria beat rapidly but in an uncoordinated and ineffective manner. The ventricles are activated irregularly at a rate determined by conduction through the AV node. This produces the characteristic 'irregularly irregular' pulse. The ECG ([Fig. 16.42](#)) shows normal but irregular QRS complexes; there are no P waves but the baseline may show irregular fibrillation waves. Commonly, AF is classified as paroxysmal (intermittent episodes that self-terminate within 7 days), persistent (prolonged episodes that can be terminated by electrical or pharmacological cardioversion) or permanent. It can be difficult to identify what type of AF patients have at first presentation but this usually becomes clearer as time progresses. Unfortunately for many patients, paroxysmal AF becomes permanent as the underlying disease process progresses. This is partly because of electrophysiological changes that occur in the atria within a few hours of the onset of AF and which tend to maintain fibrillation: a

**Fig. 16.41** Mechanisms initiating atrial fibrillation. (1) Ectopic beats, often arising from the pulmonary veins, trigger atrial fibrillation. (2) Re-entry within the atria maintains atrial fibrillation, with multiple interacting re-entry circuits operating simultaneously.

**Fig. 16.42** Two examples of atrial fibrillation. The QRS complexes are irregular and there are no P waves. **A** There is usually a fast ventricular rate, between 120 and 160/min, at the onset of atrial fibrillation. **B** In chronic atrial fibrillation, the ventricular rate may be much slower, due to the effects of medication and AV nodal fatigue.

process called electrical remodelling. When AF persists for a period of months, structural remodelling also occurs, leading to atrial fibrosis and dilatation that predispose to chronicity of the AF. Early treatment of AF can sometimes prevent the arrhythmia from becoming persistent.

Many forms of heart disease can present with AF ([Box 16.23](#)), particularly those that are associated with enlargement or dilatation of the atria. Alcohol excess, hyperthyroidism and chronic lung disease are also common causes of AF, although multiple predisposing factors may coexist, such as the combination of alcohol, hypertension and coronary artery disease. About 50% of all patients with paroxysmal AF and 20% of patients with persistent or permanent AF have structurally normal hearts; this is known as 'lone atrial fibrillation'. Aspects of atrial fibrillation that pertain particularly to old age are listed in [Box 16.24](#).

### Clinical features

The typical presentation is with palpitation, breathlessness and fatigue. In patients with poor ventricular function or valve disease, AF may precipitate or aggravate cardiac failure because of loss of atrial function and heart rate control. A fall in BP may cause lightheadedness, and chest pain may occur with underlying coronary artery disease, sometimes accompanied by ST segment and T-wave abnormalities on the ECG, and troponin elevation. In older patients, AF may not be associated with a rapid ventricular rate and may be asymptomatic, only to be discovered as a result of a routine examination or an ECG. Asymptomatic AF may also present with systemic embolism and is a major cause of stroke in older people.

### Investigations

Assessment of patients with newly diagnosed AF should include a full history, physical examination, a 12-lead ECG, echocardiogram and thyroid function tests to exclude thyrotoxicosis. The echocardiogram is used to identify any structural heart disease, particularly mitral valve disease.

**16.23 Common causes of atrial fibrillation**

- Coronary artery disease (including acute MI)
- Valvular heart disease, especially rheumatic mitral valve disease
- Hypertension
- Sinoatrial disease
- Hyperthyroidism
- Alcohol
- Cardiomyopathy
- Congenital heart disease
- Chest infection
- Pulmonary embolism
- Pericardial disease
- Idiopathic (lone atrial fibrillation)

**16.24 Atrial fibrillation in old age**

- **Prevalence:** rises with age, reaching 9% in those over 80 years.
- **Symptoms:** sometimes asymptomatic but often accompanied by diastolic heart failure.
- **Hyperthyroidism:** atrial fibrillation may emerge as the dominant feature of otherwise silent or occult hyperthyroidism.
- **Cardioversion:** followed by high rates (~70% at 1 year) of recurrent atrial fibrillation.
- **Stroke:** atrial fibrillation is an important cause of cerebral embolism, found in 15% of all stroke patients and 2%–8% of those with transient ischaemic attacks (TIAs).
- **Anticoagulation:** although the risk of thromboembolism rises, the hazards of anticoagulation also become greater with age because of increased comorbidity, particularly cognitive impairment and falls.
- **Direct oral anticoagulants:** alternatives to warfarin. No blood monitoring is required, there are fewer drug interactions, and fixed dosing may aid adherence. Renal impairment affects dosing, for example apixaban dose is reduced from 5 mg twice daily to 2.5 mg twice daily if two or more of the following apply: serum creatinine more than 132 µmol/L, age 80 years or greater, weight 60 kg or less.
- **Warfarin:** in those over 75 years, care should be taken to maintain an INR (International Normalised Ratio) below 3.0 because of the increased risk of intracranial haemorrhage.

**Management**

Management depends on whether the AF is transient or persistent and whether there is a clear precipitating factor. When AF complicates an acute illness such as a chest infection or pulmonary embolism, treatment of the underlying disorder will often restore sinus rhythm. Where AF does not resolve, the choice lies between rate control or rhythm control. Stroke risk stratification and prevention are the most important issues in managing atrial fibrillation. Management of paroxysmal and persistent AF is discussed below.

**Paroxysmal atrial fibrillation**

Occasional attacks of AF that are well tolerated do not require treatment. Beta-blockers are normally used as first-line therapy if symptoms are troublesome, since they reduce the ectopic firing that normally initiates the arrhythmia. They are particularly useful for treating patients with AF associated with coronary artery disease, hypertension and cardiac failure. Class Ic drugs (see [Box 16.30](#)), such as propafenone or flecainide, are also effective at preventing episodes but should not be given to patients with coronary artery disease or left ventricular dysfunction. Flecainide is seldom used alone, since it can precipitate atrial flutter, and is usually prescribed with a rate-limiting  $\beta$ -blocker. Class III drugs can also be used; amiodarone is the most effective agent for preventing AF but side-effects restrict its use to when other measures fail. Dronedarone is an effective alternative but is contraindicated in patients with heart failure or significant left ventricular impairment. Calcium channel blockers, such as diltiazem (200–400 mg daily), are sometimes used to prevent atrial fibrillation but they are not as effective.

Catheter ablation can be considered as an alternative to anti-arrhythmic drug therapy. Ablation targets the left atrial to pulmonary venous connections, preventing ectopic triggering of AF. In addition, lines of conduction block can be created within the atria to prevent re-entry. Ablation

prevents AF in approximately 75% of patients, although a repeat procedure is sometimes required before this is achieved. There is emerging evidence that ablation may improve prognosis in some patients with AF and heart failure. Ablation for AF is an attractive treatment but is not risk-free, and may be complicated by cardiac tamponade, stroke, phrenic nerve injury and, rarely, pulmonary vein stenosis.

**Persistent atrial fibrillation**

There are two options for treating persistent AF – rate control or rhythm control. With both options prophylaxis against thromboembolism is required on either a short-term or long-term basis.

**Rhythm control** Restoration of sinus rhythm is appropriate if the arrhythmia causes troublesome symptoms and if there is a treatable underlying cause. Electrical DC cardioversion or pharmacological cardioversion may be used. Cardioversion is initially successful in most patients but relapse is frequent (25%–50% at 1 month and 70%–90% at 1 year). Attempts to restore and maintain sinus rhythm are most successful if AF has been present for less than 3 months, the patient is young and there is no important structural heart disease.

Immediate cardioversion is appropriate if AF has been present for less than 48 hours. In stable patients with no history of structural heart disease, intravenous flecainide (2 mg/kg over 30 mins, maximum dose 150 mg) can be used and will restore sinus rhythm in 75% of patients within 8 hours. In patients with structural or ischaemic heart disease, intravenous amiodarone can be given through a central venous catheter. DC cardioversion may also be used but requires deep sedation or general anaesthesia. If AF has been present for 48 hours or longer, or if there is doubt about its duration, DC cardioversion should be deferred until the patient has been established on effective oral anticoagulation for a minimum of 4 weeks and any underlying problems, such as hypertension or alcohol excess, have been corrected. Prophylactic treatment with amiodarone can reduce the risk of recurrence. Catheter ablation is sometimes used to restore and to maintain sinus rhythm in persistent AF but is a less effective treatment than for paroxysmal AF.

**Rate control** If sinus rhythm cannot be restored, treatment should be directed at controlling the heart rate. Beta-blockers, rate-limiting calcium antagonists, such as verapamil or diltiazem (see [Box 16.29](#) and [Fig. 16.49](#)), and digoxin all reduce the ventricular rate by slowing AV conduction. This alone may produce a striking improvement in cardiac function, particularly in patients with mitral stenosis. Beta-blockers and rate-limiting calcium antagonists are more effective than digoxin at controlling the heart rate during exercise and have additional benefits in patients with hypertension or structural heart disease. Combination therapy with digoxin and a  $\beta$ -blocker can help with rate control but calcium channel antagonists should not be used with  $\beta$ -blockers because of the risk of bradycardia.

In exceptional cases, poorly controlled and symptomatic AF can be treated by implanting a permanent pacemaker and then deliberately inducing complete AV nodal block with catheter ablation. This is known as the ‘pace and ablate’ strategy.

**Prevention of thromboembolism and stroke** Loss of atrial contraction and left atrial dilatation cause stasis of blood in the LA and may lead to thrombus formation in the left atrial appendage. This predisposes patients to stroke and systemic embolism. Patients undergoing cardioversion for AF of greater than 48 hours’ duration require temporary anticoagulation to reduce these risks. Direct oral anticoagulants or warfarin may be used. Anticoagulation should be started for at least 4 weeks before cardioversion and should be maintained for at least 3 months following successful cardioversion.

In patients with AF, the annual risk of stroke is influenced by many factors and a decision has to be made in which the risk of stroke is balanced against the risk of bleeding with anticoagulation. Patients with AF secondary to mitral valve disease should always be anticoagulated

because the risk is so high. In other patients, clinical scoring systems can be used to assess the risk of stroke and bleeding. The risk of stroke is usually assessed by the CHA<sub>2</sub>DS<sub>2</sub>-VASc score (Box 16.25), and the HAS-BLED score can be used to estimate the bleeding risk (Box 16.26). Patients with a HAS-BLED score of 3 or more points may require more careful monitoring if anticoagulated.

In patients with paroxysmal AF, stroke risk is similar to that in patients with persistent AF when adjusted for CHA<sub>2</sub>DS<sub>2</sub>-VASc score. The risk of embolism is only weakly related to the frequency and duration of AF episodes, so stroke prevention guidelines do not distinguish between those with paroxysmal, persistent and permanent AF.

Several agents can be used to reduce stroke risk in AF. The factor Xa inhibitors rivaroxaban, apixaban and edoxaban, and the direct thrombin inhibitor dabigatran (collectively referred to as direct-acting oral anticoagulants, or DOACs) have largely replaced warfarin for stroke prevention in AF. These drugs are described in more detail in Chapter 25. They are at least as effective at preventing thrombotic stroke and are generally associated with a lower risk of intracranial haemorrhage. Other advantages include the lack of requirement for monitoring and the fact that they have fewer drug and food interactions. They should be considered in patients with AF and CHA<sub>2</sub>DS<sub>2</sub>-VASc score of 1 or more (male), or 2 or more (female). Stroke risk is reduced by around two-thirds, with an annual major bleeding risk of around 1%. Risk factors for bleeding include active peptic ulcer disease, uncontrolled hypertension, alcohol misuse and frequent falls. Agents that reverse the effects of DOACs have been developed. These include idarucizumab, which binds to dabigatran, and andexanet alfa, which binds to apixaban and rivaroxaban.

Warfarin can be used, adjusted to a target INR (International Normalised Ratio) of 2.0–3.0. If bleeding does occur in warfarin-treated patients, anticoagulation can be reversed by administering vitamin K or clotting factors.

Aspirin should not be used since it has little or no effect on embolic stroke and is associated with significant bleeding risk.

### Supraventricular tachycardia

The term supraventricular tachycardia (SVT) describes a group of regular tachycardias that have a similar appearance on ECG. These are usually narrow-complex tachycardias and are characterised by a re-entry circuit or automatic focus involving the atria. The three principal types are atrioventricular nodal re-entrant tachycardia (AVNRT), atrioventricular re-entrant tachycardia (AVRT) and atrial tachycardia. The term SVT is not strictly accurate as, in many cases, the ventricles also form part of the re-entry circuit.

### Atrioventricular nodal re-entrant tachycardia

Atrioventricular nodal re-entrant tachycardia (AVNRT) is a type of SVT caused by re-entry in a circuit involving the AV node and its two right atrial input pathways: a superior 'fast' pathway and an inferior 'slow' pathway (see Fig. 16.44A). This produces a regular tachycardia with a rate of 120–240/min. It tends to occur in the absence of structural heart disease and episodes may last from a few seconds to many hours. The patient is usually aware of a rapid, very forceful, regular heart beat and may experience chest discomfort, lightheadedness or breathlessness. Polyuria, mainly due to the release of ANP, is sometimes a feature. The ECG (Fig. 16.43) usually shows a tachycardia with normal QRS complexes but occasionally there may be rate-dependent bundle branch block.

### Management

Treatment is not always necessary. However, an acute episode may be terminated by carotid sinus pressure or by the Valsalva manoeuvre. Adenosine (3–12 mg rapidly IV in incremental doses until tachycardia stops) or verapamil (5 mg IV over 1 min) will restore sinus rhythm in most cases. Intravenous  $\beta$ -blocker or flecainide can also be used. In rare

HAS-BLED score of $\geq$ 3 points requires close patient monitoring	

cases, when there is severe haemodynamic compromise, the tachycardia should be terminated by DC cardioversion.

In patients with recurrent SVT, catheter ablation is the most effective therapy and will permanently prevent SVT in more than 90% of cases. Alternatively, prophylaxis with oral  $\beta$ -blocker, verapamil or flecainide may be used but commits predominantly young patients to long-term drug therapy and can create difficulty in female patients, as these drugs should be avoided during pregnancy where possible.

### Atrioventricular re-entrant tachycardia

In this condition there is an abnormal band of conducting tissue that connects the atria and ventricles. This so-called accessory pathway comprises rapidly conducting fibres that resemble Purkinje tissue,

in that they conduct very rapidly and are rich in sodium channels. In about 50% of cases, this pathway conducts only in the retrograde direction (from ventricles to atria) and thus does not alter the appearance of the ECG in sinus rhythm. This is known as a concealed accessory pathway. In the rest, the pathway also conducts in an antegrade direction (from atria to ventricles), so AV conduction in sinus rhythm is mediated via both the AV node and the accessory pathway, distorting the QRS complex. Premature ventricular activation via the pathway shortens the PR interval and produces a 'slurred' initial deflection of the QRS complex, called a delta wave (Fig. 16.44B). This is known as a manifest accessory pathway. As the AV node and accessory pathway have different conduction speeds and refractory periods, a re-entry circuit can develop, causing tachycardia (Fig. 16.44C); when associated with symptoms, the condition is known as Wolff–Parkinson–White (WPW) syndrome. The ECG during this tachycardia is almost indistinguishable from that of AVNRT (Fig. 16.44A).

### Management

Carotid sinus pressure or intravenous adenosine can terminate the tachycardia. If AF occurs, it may produce a dangerously rapid ventricular rate because the accessory pathway lacks the rate-limiting properties of

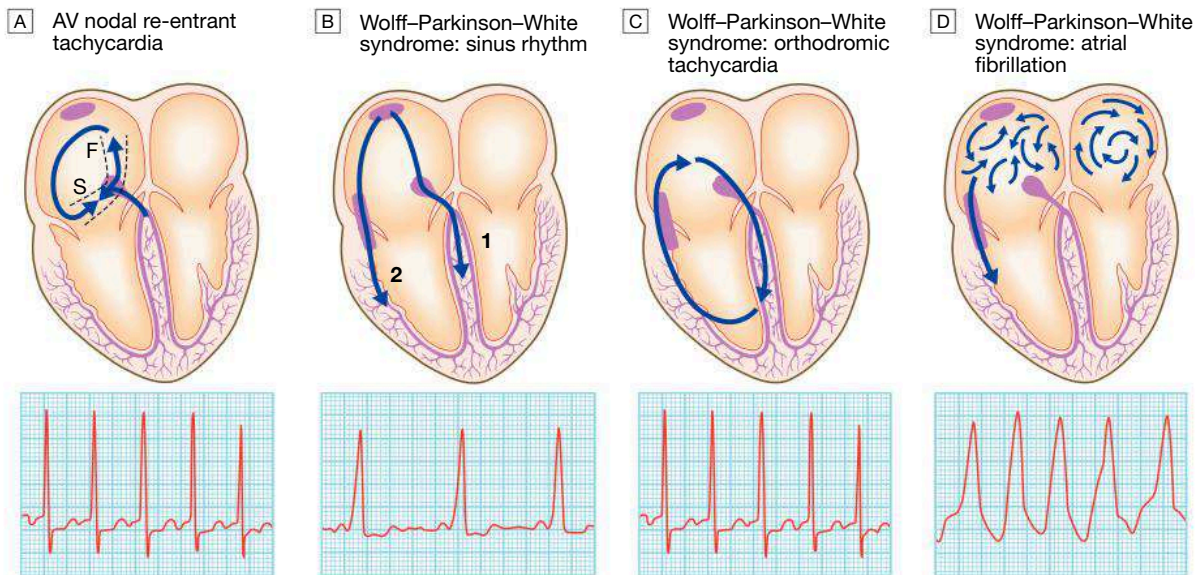

**Fig. 16.43** Supraventricular tachycardia. The rate is 180/min and the QRS complexes are normal.

the AV node (Fig. 16.44D). This is known as pre-excited atrial fibrillation and may cause collapse, syncope and even death. It should be treated as an emergency, usually with DC cardioversion.

Catheter ablation is first-line treatment in symptomatic patients and is nearly always curative. Alternatively, prophylactic anti-arrhythmic drugs, such as flecainide or propafenone (see Box 16.30) can be used to slow conduction in, and prolong the refractory period of, the accessory pathway. Long-term drug therapy is not the preferred treatment for most patients and amiodarone should not be used, as its side-effect profile cannot be justified and ablation is safer and more effective. Digoxin and verapamil shorten the refractory period of the accessory pathway and should not be used.

### Ventricular premature beats

Ventricular premature beats (VPBs) are frequently found in healthy people and their prevalence increases with age. Ectopic beats in patients with otherwise normal hearts are more prominent at rest and disappear with exercise. Sometimes VPBs are a manifestation of subclinical coronary artery disease or cardiomyopathy but also may occur in patients with established heart disease following an MI. Most patients with VPBs are asymptomatic but some present with an irregular heart beat, missed beats or abnormally strong beats, due to increased cardiac output of the post-ectopic sinus beat. On examination the pulse is irregular, with weak or missed beats as a result of the fact that the stroke volume is low because left ventricular contraction occurs before filling is complete (Fig. 16.45). The ECG shows broad and bizarre complexes because the ventricles are activated sequentially rather than simultaneously. The complexes may be unifocal (identical beats arising from a single ectopic focus) or multifocal (varying morphology with multiple foci, see Fig. 16.46). 'Couplet' and 'triplet' are the terms used to describe two or three successive ectopic beats. A run of alternating

**Fig. 16.44** Atrioventricular nodal re-entrant tachycardia (AVNRT) and Wolff–Parkinson–White (WPW) syndrome. **A** Atrioventricular (AV) nodal re-entrant tachycardia. The mechanism of AVNRT occurs via two right atrial AV nodal input pathways: the slow (S) and fast (F) pathways. Antegrade conduction occurs via the slow pathway; the wavefront enters the AV node and passes into the ventricles, at the same time re-entering the atria via the fast pathway. In WPW syndrome, there is a strip of accessory conducting tissue that allows electricity to bypass the AV node and spread from the atria to the ventricles rapidly and without delay. When the ventricles are depolarised through the AV node the ECG is normal, but when the ventricles are depolarised through the accessory conducting tissue the ECG shows a very short PR interval and a broad QRS complex. **B** Sinus rhythm. In sinus rhythm, the ventricles are depolarised through (1) the AV node and (2) the accessory pathway, producing an ECG with a short PR interval and broadened QRS complexes; the characteristic slurring of the upstroke of the QRS complex is known as a delta wave. The degree of pre-excitation (the proportion of activation passing down the accessory pathway) and therefore the ECG appearances may vary a lot, and at times the ECG can look normal. **C** Orthodromic tachycardia. This is the most common form of tachycardia in WPW. The re-entry circuit passes antegradely through the AV node and retrogradely through the accessory pathway. The ventricles are therefore depolarised in the normal way, producing a narrow-complex tachycardia that is indistinguishable from other forms of supraventricular tachycardia. **D** Atrial fibrillation. In this rhythm, the ventricles are largely depolarised through the accessory pathway, producing an irregular broad-complex tachycardia that is often more rapid than the example shown.

**Fig. 16.45 Ventricular ectopic beats.** **A** There are broad, bizarre QRS complexes (arrows) with no preceding P wave in between normal sinus beats. Their configuration varies, so these are multifocal ectopics. **B** A simultaneous arterial pressure trace is shown. The ectopic beats result in a weaker pulse (arrows), which may be perceived as a 'dropped beat'.

sinus and ventricular ectopic beats is known as ventricular 'bigeminy'. The significance depends on the presence or absence of underlying heart disease.

### Management

Treatment may not be necessary, unless the patient is highly symptomatic, in which case  $\beta$ -blockers or, in some situations, catheter ablation can be used. There is no evidence that anti-arrhythmic therapy improves prognosis but the discovery of very frequent VPBs in a patient not known to have heart disease should prompt further investigations with echocardiography and an exercise ECG to screen for structural heart disease and ischaemic heart disease. It is common for VPBs to occur during the course of an acute MI. Persistent, frequent VPBs (over 10/hr) in patients who have survived the acute phase of MI indicate a poorer long-term outcome. In this situation, anti-arrhythmic drugs do not improve and may even worsen prognosis. The exception is  $\beta$ -blockers, which should be prescribed for other reasons following MI. Similarly, heart failure of any cause is associated with VPBs. While they indicate an adverse prognosis, this is not improved by anti-arrhythmic drugs. Effective treatment of the heart failure may suppress the ectopic beats.

## Ventricular tachycardia

Ventricular tachycardia (VT) occurs most commonly in the settings of acute MI, chronic coronary artery disease and cardiomyopathy. It is associated with extensive ventricular disease, impaired left ventricular function and ventricular aneurysm. In these settings, VT may cause haemodynamic compromise or degenerate into ventricular fibrillation (see Fig. 16.19). VT is most often caused by re-entry within scarred ventricular tissue, and less often by abnormal automaticity or triggered activity in ischaemic tissue. Patients may experience palpitation, dyspnoea, lightheadedness and syncope. The ECG shows tachycardia and broad, abnormal QRS complexes with a rate of more than 120/min (Fig. 16.46). It may be difficult to distinguish VT from SVT with bundle branch block or pre-excitation (WPW syndrome) on ECG but features in favour of VT are listed in Box 16.27. A 12-lead ECG (Fig. 16.47) or electrophysiology study may help establish the diagnosis. When there is doubt, it is safer to manage the problem as VT.

Patients recovering from MI sometimes have periods of idioventricular rhythm ('slow' VT) at a rate only slightly above the preceding sinus rate and below 120/min. These episodes often reflect reperfusion of the infarct territory and may be a good sign. They are usually self-limiting and asymptomatic, and do not require treatment. Other forms of sustained VT require treatment, often as an emergency.

Occasionally, VT occurs in patients with otherwise healthy hearts ('normal heart VT'), usually because of abnormal automaticity in the right ventricular outflow tract or one of the fascicles of the left bundle branch.

**Fig. 16.46 Ventricular tachycardia: fusion beat.** In ventricular tachycardia, there is independent atrial and ventricular activity. Occasionally, a P wave is conducted to the ventricles through the AV node, producing a normal sinus beat in the middle of the tachycardia (a capture beat); more commonly, however, the conducted impulse fuses with an impulse from the tachycardia (a fusion beat, arrow). This can occur only when there is atrioventricular dissociation and is therefore diagnostic of ventricular tachycardia.

### i

#### 16.27 Features more in keeping with ventricular tachycardia

- History of myocardial infarction
- Atrioventricular dissociation (pathognomonic)
- Capture/fusion beats (pathognomonic; see Fig. 16.40)
- Extreme left axis deviation
- Very broad QRS complexes (> 140 msec)
- No response to carotid sinus massage or intravenous adenosine

### Management

Prompt action to restore sinus rhythm is required and should usually be followed by prophylactic therapy. Synchronised DC cardioversion is the treatment of choice if systolic BP is less than 90 mmHg. If the arrhythmia is well tolerated, intravenous amiodarone may be given as a bolus, followed by a continuous infusion (see Box 16.30). Intravenous lidocaine can also be used but may depress left ventricular function, causing hypotension or acute heart failure. Hypokalaemia, hypomagnesaemia, acidosis and hypoxia should be corrected if present.

Beta-blockers are effective at preventing VT by reducing ventricular automaticity. Amiodarone can be added if additional control is needed. Class Ic anti-arrhythmic drugs should not be used for prevention of VT in patients with coronary artery disease or heart failure because they depress myocardial function and can increase the likelihood of a dangerous arrhythmia. In patients with poor left ventricular function or where VT is associated with haemodynamic compromise, the use of an implantable cardiac defibrillator is recommended. In resistant cases of focal or infarct scar-mediated VT, catheter ablation can be used to interrupt the

arrhythmia focus or circuit. The treatment of choice for VT occurring in a normal heart is catheter ablation, which often can be curative.

## Torsades de pointes

This form of polymorphic VT is a complication of prolonged ventricular repolarisation (prolonged QT interval). The ECG shows rapid irregular complexes that seem to twist around the baseline as the mean QRS axis changes (Fig. 16.48). The arrhythmia is usually non-sustained and repetitive, but may degenerate into ventricular fibrillation. During periods of sinus rhythm, the ECG will usually show a prolonged QT interval ( $>0.44$  sec in men,  $>0.46$  sec in women when corrected to a heart rate of 60/min).

Some of the common causes are listed in Box 16.28. The arrhythmia is more common in women and is often triggered by a combination of factors, such as administration of QT-prolonging medications and hypokalaemia. The congenital long QT syndromes are a family of genetic

**Fig. 16.47** Ventricular tachycardia: 12-lead ECG. There are typically very broad QRS complexes and marked left axis deviation. There is also atrioventricular dissociation; some P waves are visible and others are buried in the QRS complexes (arrows).

disorders that are characterised by mutations in genes that code for cardiac potassium or sodium channels. Long QT syndrome subtypes have different triggers, which are important when counselling patients. Adrenergic stimulation through vigorous exercise is a common trigger in long QT type 1, and a sudden noise may trigger arrhythmias in long QT type 2. Arrhythmias are more common during sleep in type 3.

## Management

Intravenous magnesium (8 mmol over 15 mins, then 72 mmol over 24 hrs) should be given in all cases. If this is ineffective, atrial pacing should be tried, since it can suppress the arrhythmia through rate-dependent shortening of the QT interval. Intravenous isoprenaline is a reasonable alternative to pacing but should be avoided in patients with the congenital long QT syndromes. Once initial control has been achieved, efforts should be made to identify and treat the underlying cause or stop medications that predispose to the arrhythmia. If the underlying cause cannot be corrected or the arrhythmia is the result of an inherited syndrome, then long-term pharmacological therapy may be necessary. Beta-blockers are effective at preventing syncope in patients with congenital long QT syndrome. Some patients, particularly those with extreme QT interval prolongation ( $>500$  msec) or certain high-risk genotypes, should be considered for an implantable defibrillator. Left stellate ganglion block may be of value in patients with resistant arrhythmias.

Brugada syndrome is a related genetic disorder that may present with polymorphic VT or sudden death. It is most commonly caused by mutations in the *SCN5A* gene which encodes a sodium channel expressed in cardiac myocytes. It is characterised by an abnormal ECG (right bundle branch block and ST elevation in  $V_1$  and  $V_2$  but not usually prolongation of the QT interval). The only known effective treatment is an implantable defibrillator.

### 16.28 Causes of long QT interval and torsades de pointes

#### Bradycardia

- Bradycardia potentiates other factors that cause torsades de pointes

#### Electrolyte disturbance

- Hypokalaemia
- Hypomagnesaemia
- Hypocalcaemia

#### Drugs\*

- Disopyramide, flecainide and other class Ia, Ic anti-arrhythmic drugs (Box 16.29 and Fig. 16.49)
- Sotalol, amiodarone and other class III anti-arrhythmic drugs
- Amitriptyline and other tricyclic antidepressants
- Chlorpromazine and other phenothiazines
- Erythromycin and other macrolides
- Hydroxychloroquine and chloroquine

#### Congenital syndromes

- Long QT1: gene affected *KCNQ1*:  $K^+$  channel, 30%–35%
- Long QT2: gene affected *HERG*:  $K^+$  channel, 25%–30%
- Long QT3: gene affected *SCN5A*:  $Na^+$  channel, 5%–10%
- Long QT4–12: rare; various genes implicated

\*Many other drugs that are not shown can be associated with prolongation of the QT interval. See [www.crediblemeds.org](http://www.crediblemeds.org) for a complete list.

**Fig. 16.48** Torsades de pointes. A bradycardia with a long QT interval is followed by polymorphic ventricular tachycardia that is triggered by an R on T ectopic.

## Principles of management of cardiac arrhythmias

Cardiac arrhythmias can be managed with anti-arrhythmic drug therapy, cardiac implantable electronic devices (CIEDs), or catheter ablation.

### Anti-arrhythmic drugs

Traditionally, the Vaughan Williams system has been used to categorise anti-arrhythmic drugs based on their effects on the action potential. Increased understanding of the mechanisms of action has allowed further subclassification, based on the cardiac ion channels and receptors on which they act see (Box 16.29 and Fig. 16.49). The individual agents, dosages and most common side-effects are summarised in Box 16.30 and the general principles of use are summarised in Box 16.31.

#### Class I drugs

Class I drugs act principally by suppressing excitability and slowing conduction in atrial or ventricular muscle. They block sodium channels, of which there are several types in cardiac tissue. These drugs should generally be avoided in patients with heart failure because they depress myocardial function, and class Ia and Ic drugs are often pro-arrhythmic.

##### Class Ia drugs

These prolong cardiac action potential duration and increase the tissue refractory period. They are used to prevent both atrial and ventricular arrhythmias.

##### Disopyramide

This is an effective drug but causes anticholinergic side-effects, such as urinary retention, and can precipitate glaucoma. It can depress myocardial function and should be avoided in cardiac failure.

##### Quinidine

This drug is effective at preventing AF and is occasionally used in Brugada syndrome. It is strongly pro-arrhythmic and can cause gastrointestinal upset.

#### 16.29 Classification of anti-arrhythmic drugs by effect on the intracellular action potential\*

##### Class I: membrane-stabilising agents (sodium channel blockers)

###### (a) Block Na<sup>+</sup> channel and prolong action potential

- Quinidine, disopyramide

###### (b) Block Na<sup>+</sup> channel and shorten action potential

- Lidocaine, mexiletine

###### (c) Block Na<sup>+</sup> channel with no effect on action potential

- Flecainide, propafenone

##### Class II: $\beta$ -adrenoceptor antagonists ( $\beta$ -blockers)

- Atenolol, bisoprolol, metoprolol

##### Class III: drugs whose main effect is to prolong the action potential

- Amiodarone, dronedarone, sotalol

##### Class IV: slow calcium channel blockers

- Verapamil, diltiazem

\*Some drugs such as digoxin, ivabradine and adenosine have no place in this classification, while others such as amiodarone have properties in more than one class.

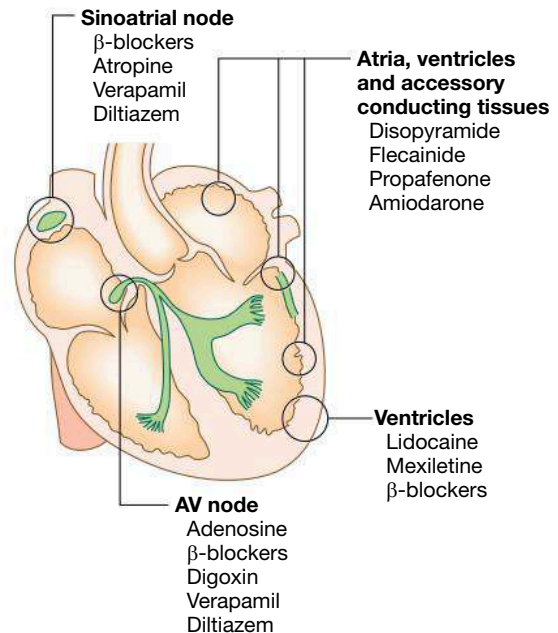

Fig. 16.49 Classification of anti-arrhythmic drugs by site of action. (AV = atrioventricular)

#### Class Ib drugs

These shorten the action potential and tissue refractory period. They act on channels found predominantly in ventricular myocardium and so are used to treat or prevent VT and VF.

##### Lidocaine

This must be given intravenously and has a very short plasma half-life.

##### Mexiletine

This can be given intravenously or orally but has many side-effects.

#### Class Ic drugs

These affect the slope of the action potential without altering its duration or refractory period. They are used mainly for prophylaxis of AF but are effective in prophylaxis and treatment of supraventricular or ventricular arrhythmias. They are useful for WPW syndrome because they block conduction in accessory pathways. They should not be used in patients with previous MI because they increase the risk of arrhythmia in this setting.

##### Flecainide

This is effective for prevention of AF, and an intravenous infusion may be used for pharmacological cardioversion of AF of less than 24 hours' duration. Since flecainide can cause slow atrial flutter with a paradoxically rapid ventricular rate, it should be prescribed along with an AV node-blocking drug such as a  $\beta$ -blocker to control the ventricular rate.

##### Propafenone

This also has some  $\beta$ -blocker (class II) properties. Important interactions with digoxin, warfarin and cimetidine have been described.

#### Class II drugs

This group comprises the  $\beta$ -adrenoceptor antagonists ( $\beta$ -blockers). These agents reduce the rate of SA node depolarisation and cause relative block in the AV node, making them useful for rate control in atrial flutter and AF. They can be used to prevent VT and SVT. They reduce myocardial excitability and the risk of arrhythmic death in patients with coronary artery disease and heart failure.

16.30 Uses, dosage and side-effects of anti-arrhythmic drugs				
Drug	Main uses	Route	Dosage (adult)	Important side-effects
<b>Class I</b>				
Disopyramide	Prevention and treatment of atrial and ventricular tachyarrhythmias	IV	2 mg/kg at 30 mg/min, then 0.4 mg/kg/hr (max 800 mg/day)	Myocardial depression, hypotension, dry mouth, urinary retention
Lidocaine	Treatment and short-term prevention of VT and VF	Oral IV	300–800 mg daily in divided dosage Bolus 50–100 mg, 4 mg/min for 30 mins, then 2 mg/min for 2 hrs, then 1 mg/min for 24 hrs	Myocardial depression, delirium, convulsions
Mexiletine	Prevention and treatment of ventricular tachyarrhythmias	IV	Loading dose: 100–250 mg at 25 mg/min, then 250 mg in 1 hr, then 250 mg in 2 hrs Maintenance therapy: 0.5 mg/min	Myocardial depression, gastrointestinal irritation, delirium, dizziness, tremor, nystagmus, ataxia
Flecainide	Prevention and treatment of atrial and ventricular tachyarrhythmias	Oral IV	167–500 mg daily 2 mg/kg over 10 mins, then if required 1.5 mg/kg/hr for 1 hr, then 0.1 mg/kg/hr	Myocardial depression, dizziness
Propafenone	Prevention and treatment of atrial and ventricular tachyarrhythmias	Oral	150 mg 3 times daily for 1 week, then 300 mg twice daily	Myocardial depression, dizziness
<b>Class II</b>				
Atenolol	Treatment and prevention of SVT and AF, prevention of VEs and exercise-induced VF	IV Oral	2.5 mg at 1 mg/min, repeated at 5-min intervals (max 10 mg) 25–100 mg daily	Myocardial depression, bradycardia, bronchospasm, fatigue, depression, nightmares, cold peripheries
Bisoprolol		Oral	2.5–10 mg daily	
Metoprolol		IV	5 mg over 2 mins to a maximum of 15 mg	
<b>Class III</b>				
Amiodarone	Serious or resistant atrial and ventricular tachyarrhythmias	IV Oral	5 mg/kg over 20–120 mins, then up to 15 mg/kg/24 hrs Initially 600–1200 mg/day, then 100–400 mg daily	Photosensitivity skin discoloration, corneal deposits, thyroid dysfunction, alveolitis, nausea and vomiting, hepatotoxicity, peripheral neuropathy, torsades de pointes; potentiates digoxin and warfarin
Dronedarone	Paroxysmal atrial fibrillation	Oral	400 mg twice daily	Renal and hepatic dysfunction requiring regular blood monitoring Can cause torsade de pointes
Sotalol*	AF, rarely ventricular tachyarrhythmias	IV Oral	10–20 mg slowly 40–160 mg twice daily	
<b>Class IV</b>				
Verapamil	Treatment of SVT, control of AF	IV Oral	5–10 mg over 30 secs 40–120 mg 3 times daily or 240 mg SR daily	Myocardial depression, hypotension, bradycardia, constipation
<b>Other</b>				
Atropine	Treatment of bradycardia and/or hypotension due to vagal over-activity (see Box 16.32)	IV	0.6–3 mg	Dry mouth, thirst, blurred vision, atrial and ventricular extrasystoles
Adenosine	Treatment of SVT, aid to diagnosis in unidentified tachycardia	IV	3 mg over 2 secs, followed if necessary by 6 mg, then 12 mg at intervals of 1–2 mins	Flushing, dyspnoea, chest pain Avoid in asthma
Digoxin	Rate control of AF	IV Oral	Loading dose: 0.5–1 mg (total), 0.5 mg over 30 mins, then 0.25–0.5 mg after 4–6 hrs 0.5 mg repeated after 6 hrs, then 0.0625–0.25 mg daily	Gastrointestinal disturbance, xanthopsia, arrhythmias

\*Sotalol also has class II activity as a  $\beta$ -blocker.

(AF = atrial fibrillation; IV = intravenous; SR = sustained-release formulation; SVT = supraventricular tachycardia; VE = ventricular ectopic; VF = ventricular fibrillation; VT = ventricular tachycardia)

### Non-selective $\beta$ -blockers

These act on both  $\beta_1$  and  $\beta_2$  receptors. Beta<sub>2</sub>-blockade causes side-effects, such as bronchospasm and peripheral vasoconstriction. Propranolol is non-selective and is subject to extensive first-pass metabolism in the liver. The effective oral dose is therefore unpredictable and must be titrated after treatment is started with a small dose. Other non-selective drugs include nadolol and carvedilol.

### Cardioselective $\beta$ -blockers

These act mainly on myocardial  $\beta_1$  receptors and are relatively well tolerated. Bisoprolol and metoprolol are examples of cardioselective  $\beta$ -blockers.

#### Sotalol

This is a racemic mixture of two isomers with non-selective  $\beta$ -blocker (mainly l-sotalol) and class III (mainly d-sotalol) activity. It may cause torsades de pointes.

### 16.31 Anti-arrhythmic drugs: principles of use

Anti-arrhythmic drugs are potentially toxic and should be used carefully according to the following principles:

- Many arrhythmias are benign and do not require specific treatment
- Precipitating or causal factors should be corrected if possible:
  - Alcohol excess
  - Myocardial ischaemia
  - Hyperthyroidism
  - Acidosis
  - Hypokalaemia
  - Hypomagnesaemia
- If drug therapy is required, it is best to use as few drugs as possible
- In difficult cases, programmed electrical stimulation (electrophysiological study) may help to identify the optimum therapy
- When managing life-threatening arrhythmias, it is essential to ensure that prophylactic treatment is effective. Ambulatory monitoring and exercise testing may be of value
- Patients on long-term anti-arrhythmic drugs should be reviewed regularly and attempts made to withdraw therapy if the factors that precipitated the arrhythmias are no longer operative
- For patients with recurrent supraventricular tachycardia or atrial flutter, radiofrequency ablation is the treatment of choice

### Class III drugs

Class III drugs act by prolonging the plateau phase of the action potential, thus lengthening the refractory period. These drugs are very effective at preventing atrial and ventricular tachyarrhythmias. They cause QT interval prolongation and can predispose to torsades de pointes and VT, especially in patients with other predisposing risk factors (see [Box 16.28](#)). Disopyramide and sotalol have some class III activity but the main drug in this class is amiodarone, as discussed below.

#### Amiodarone

While amiodarone is primarily considered a class III drug, it also has class I, II and IV activity. It is probably the most effective drug currently available for controlling paroxysmal AF. It is also used to prevent episodes of recurrent VT, particularly in patients with poor left ventricular function or those with implantable defibrillators (to prevent unnecessary DC shocks). Amiodarone has a very long tissue half-life (25–110 days). An intravenous or oral loading regime is often used to achieve therapeutic tissue concentrations. The drug's effects may last for weeks or months after treatment has been stopped. Side-effects are common (up to one-third of patients), numerous and potentially serious. Drug interactions are also common (see [Box 16.30](#)).

#### Dronedarone

Dronedarone is related to amiodarone but has a short tissue half-life and fewer side-effects. It has recently been shown to be effective at preventing episodes of atrial flutter and AF. It is contraindicated in patients with permanent AF, or if there is heart failure or left ventricular impairment, because it increases mortality. Regular liver and renal function test monitoring is required.

### Class IV drugs

These block the 'slow calcium channel', which is important for impulse generation and conduction in atrial and nodal tissue, although it is also present in ventricular muscle. Their main indications are prevention of SVT (by blocking the AV node) and rate control in patients with AF.

#### Verapamil

This is the most widely used drug in this class. Intravenous verapamil may cause profound bradycardia or hypotension, and should not be used in conjunction with  $\beta$ -blockers.

### 16.32 Response to intravenous adenosine

Arrhythmia	Response
Supraventricular tachycardia	Termination
Atrial fibrillation, atrial flutter, atrial tachycardia	Transient atrioventricular block
Ventricular tachycardia	No effect

#### Diltiazem

This has similar properties to verapamil.

### Other anti-arrhythmic drugs

#### Atropine sulphate

Atropine is a muscarinic receptor antagonist that increases the sinus rate and SA and AV conduction. It is the treatment of choice for severe bradycardia or hypotension due to vagal over-activity. It is used for initial management of symptomatic bradyarrhythmias complicating inferior MI, and in cardiac arrest due to asystole. The usual dose is 0.6 mg IV, repeated if necessary to a maximum of 3 mg. Repeat dosing may be necessary because the drug disappears rapidly from the circulation after parenteral administration. Side-effects are listed in [Box 16.30](#).

#### Adenosine

This works by binding to A1 receptors in conducting tissue, producing a transient AV block lasting a few seconds. It is used to terminate SVTs when the AV node is part of the re-entry circuit, or to help establish the diagnosis in difficult arrhythmias, such as atrial flutter with 2:1 AV block (see [Fig. 16.40](#)) or broad-complex tachycardia (see [Boxes 16.30](#) and [16.32](#)). Adenosine is given as an intravenous bolus, initially 3 mg over 2 seconds (see [Box 16.30](#)). If there is no response after 1–2 minutes, 6 mg should be given; if necessary, after another 1–2 minutes the maximum dose of 12 mg may be given. Patients should be warned to expect short-lived and sometimes distressing flushing, breathlessness and chest pain. Adenosine can cause bronchospasm and should be avoided in patients with asthma; its effects are greatly potentiated by dipyridamole and inhibited by theophylline and other xanthines.

#### Digoxin

Digoxin is a glycoside purified from the European foxglove, *Digitalis lanata*, which slows conduction and prolongs the refractory period in the AV node. This effect helps to control the ventricular rate in AF. Digoxin also shortens refractory periods and enhances excitability and conduction in other parts of the heart, including accessory pathways. It may therefore increase atrial and ventricular ectopic activity and can lead to more complex atrial and ventricular tachyarrhythmias. Digoxin is largely excreted by the kidneys, and the maintenance dose (see [Box 16.30](#)) should be reduced in children, older people and those with renal impairment. It is widely distributed and has a long tissue half-life (36 hours), so that effects may persist for several days. Measurement of plasma digoxin concentration helps identify digoxin toxicity or under-treatment ([Box 16.33](#)).

### Non-pharmacological treatments

#### Electrical cardioversion

Electrical cardioversion, also known as direct current (DC) cardioversion, is useful for terminating an organised rhythm, such as AF or VT. The shock depolarises the myocardium, interrupts the arrhythmia and produces a brief period of asystole, followed by the resumption of sinus rhythm. Cardioversion is usually carried out as an elective procedure under general anaesthesia. The shock is delivered immediately after the R wave because, if it is applied during ventricular repolarisation (on the T wave), it may provoke VF. A 100–150 Joule shock is normally used.

## i

### 16.33 Digoxin toxicity

#### Extracardiac manifestations

- Anorexia, nausea, vomiting
- Diarrhoea
- Altered colour vision (xanthopsia)

#### Cardiac manifestations

- Bradycardia
- Multiple ventricular ectopics
- Ventricular bigeminy (alternate ventricular ectopics)
- Atrial tachycardia (with variable block)
- Ventricular tachycardia
- Ventricular fibrillation

## Defibrillation

Defibrillators deliver a DC, high-energy, short-duration shock via two large electrodes or paddles coated with conducting jelly or a gel pad, positioned over the upper right sternal border and the apex. Defibrillators are primarily used in the management of cardiac arrest due to VF and deliver an unsynchronised shock, since the precise timing of the discharge is not important in this situation. A biphasic shock is used during which the shock polarity is reversed mid-shock. This reduces the total shock energy required to depolarise the heart. In VF and other emergencies, the energy of the first and second shocks should be 150 Joules and thereafter up to 200 Joules; there is no need for an anaesthetic, as the patient is unconscious.

## Temporary pacemakers

Temporary pacing involves delivery of an electrical impulse into the heart to initiate tissue depolarisation and to trigger cardiac contraction. This is achieved by inserting a bipolar pacing electrode through the internal jugular, subclavian or femoral vein and positioning it at the apex of the RV, using fluoroscopic imaging. The electrode is connected to an external pacemaker with an adjustable energy output and pacing rate. The ECG of right ventricular pacing is characterised by regular broad QRS complexes with a left bundle branch block pattern. Each complex is immediately preceded by a 'pacing spike' (Fig. 16.50). The pacemaker will operate only if the heart rate falls below a preset level. Occasionally, temporary atrial or dual-chamber pacing (see below) is used.

Temporary pacing is indicated for transient AV block and other arrhythmias complicating acute MI or cardiac surgery, to maintain the rhythm in other situations of reversible bradycardia (such as metabolic disturbance or drug overdose), or as a bridge to permanent pacing. Complications include pneumothorax, brachial plexus or subclavian artery injury, local infection or sepsis (usually with *Staphylococcus aureus*), and pericarditis. Failure of the system may be due to lead displacement or a progressive increase in the threshold (exit block) caused by tissue oedema. Complication rates increase with time and so a temporary pacing system should ideally not be used for more than 7 days.

Transcutaneous pacing is administered by delivering an electrical stimulus through two large adhesive gel pad electrodes placed over the apex and upper right sternal border, or over the anterior and posterior chest. It is easy and quick to set up, but causes discomfort because it induces forceful pectoral and intercostal muscle contraction. Modern external defibrillators often incorporate a transcutaneous pacing system that can be used until transvenous pacing is established.

## Permanent pacemakers

Permanent pacemakers are small, flat, metal devices that are implanted under the skin, usually in the pectoral area (Fig. 16.51). They contain a battery, a pulse generator, and programmable electronics that allow adjustment of pacing and memory functions. Pacing electrodes (leads) can be placed via the subclavian or cephalic veins into the RV (usually at the apex), the right atrial appendage or, to maintain AV synchrony, both.

**Fig. 16.50 Dual-chamber pacing.** The first three beats show atrial and ventricular pacing with narrow pacing spikes in front of each P wave and QRS complex. The last four beats show spontaneous P waves with a different morphology and no pacing spike; the pacemaker senses or tracks these P waves and maintains atrioventricular synchrony by pacing the ventricle after an appropriate interval.

**Fig. 16.51 Cardiac implantable electronic devices.** **A** Single-chamber pacemaker. **B** Dual-chamber pacemaker. **C** Cardiac resynchronisation therapy pacemaker (CRT-P). **D** Cardiac resynchronisation therapy defibrillator (CRT-D).

Permanent pacemakers are controlled using an external programmer through a wireless telemetry system, allowing rate, output, timing and other parameters to be adjusted. This allows the device settings to be tailored to the patient's needs. Aside from their therapeutic role, pacemakers store useful diagnostic data about the patient's heart rate trends and the occurrence of tachyarrhythmias, such as VT.

Single-chamber atrial pacing is indicated in patients with SA disease without AV block and ventricular pacing in patients with continuous AF and bradycardia. Here the pacemaker acts as an external sinus node. Dual-chamber pacing is most often used in patients with second- or third-degree AV block. Here, the atrial electrode is used to detect spontaneous atrial activity and trigger ventricular pacing (see Fig. 16.50), thereby preserving AV synchrony and allowing the ventricular rate to increase, together with the sinus node rate, during exercise and other forms of stress. Dual-chamber pacing has many advantages over single-chamber ventricular pacing, including superior haemodynamics and better effort tolerance; a lower prevalence of atrial arrhythmias in patients with SA disease; and avoidance of 'pacemaker syndrome', in which a fall in BP and dizziness occur due to loss of AV synchrony.

A code is used to signify the pacing mode (Box 16.34). For example, a system that paces the atrium, senses the atrium and is inhibited if it senses spontaneous activity is designated AAI. Most dual-chamber pacemakers are programmed to a mode termed DDD; in this case, ventricular pacing is triggered by a sensed sinus P wave and inhibited by a sensed spontaneous QRS complex. A fourth letter, 'R', is added if the pacemaker has a rate response function. For example, the letters

**16.34 International generic pacemaker code**

Chamber paced	Chamber sensed	Response to sensing
O = none	O = none	O = none
A = atrium	A = atrium	T = triggered
V = ventricle	V = ventricle	I = inhibited
D = both	D = both	D = both

**16.35 Key indications for implantable cardiac defibrillator therapy****Primary prevention**

- After myocardial infarction, if the left ventricular ejection fraction is < 30%
- Mild to moderate symptomatic heart failure on optimal drug therapy, with left ventricular ejection fraction < 35%
- Some patients with inherited cardiac conditions (long QT syndrome, cardiomyopathy)

**Secondary prevention**

- Survivors of ventricular fibrillation or ventricular tachycardia cardiac arrest not having a transient or reversible cause
- Ventricular tachycardia with haemodynamic compromise or significant left ventricular impairment (left ventricular ejection fraction < 35%)

AAIR indicate an atrial demand pacemaker with a rate response function. Rate-responsive pacemakers are used in patients with chronotropic incompetence, who are unable to increase their heart rate during exercise. These devices have a sensor that triggers an increase in heart rate in response to movement or increased respiratory rate. The sensitivity of the sensor is programmable, as is the maximum paced heart rate.

Early complications of permanent pacing include pneumothorax, cardiac tamponade, infection and lead displacement. Late complications include infection (which usually necessitates removing the pacing system), erosion of the generator or lead, chronic pain related to the implant site, and lead fracture due to mechanical fatigue.

**Implantable cardiac defibrillators**

In addition to the functions of a permanent pacemaker, implantable cardiac defibrillators (ICDs) can also detect and terminate life-threatening ventricular tachyarrhythmias. ICDs are larger than pacemakers mainly because of the need for a large battery and capacitor to enable

cardioversion or defibrillation. ICD leads are similar to pacing leads but have one or two shock coils along the length of the lead, used for delivering defibrillation. ICDs treat ventricular tachyarrhythmias using overdrive pacing, cardioversion or defibrillation. They are implanted in a similar manner to pacemakers and carry a similar risk of complications. In addition, patients can be prone to psychological problems and anxiety, particularly if they have experienced repeated shocks from their device.

The evidence-based indications for ICD implantation are shown in **Box 16.35**. These can be divided into secondary prevention indications, when patients have already had a potentially life-threatening ventricular arrhythmia, and primary prevention indications, when patients are considered to be at significant future risk of arrhythmic death. A common primary prevention indication is in patients with inherited conditions associated with a high risk of sudden cardiac death, such as long QT syndrome, hypertrophic cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy. Treatment with ICDs is expensive and so the indications for which the devices are routinely implanted depend on the health-care resources available.

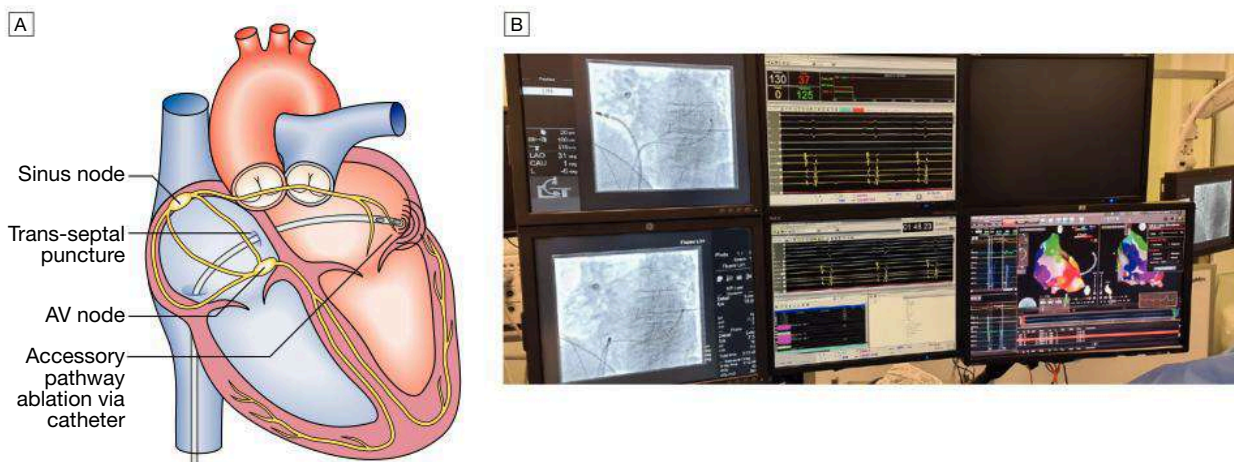

**Cardiac resynchronisation therapy**

Cardiac resynchronisation therapy (CRT) is a useful treatment for selected patients with heart failure, in whom cardiac function is impaired by the presence of left bundle branch block. This conduction defect is associated with poorly coordinated left ventricular contraction that can aggravate heart failure in susceptible patients. The systems used to deliver CRT comprise a right atrial lead, a right ventricular lead and a third lead that is placed via the coronary sinus into one of the veins on the epicardial surface of the LV (see **Fig. 16.28**). Simultaneous septal and left ventricular epicardial pacing resynchronises left ventricular contraction.

CRT improves symptoms and quality of life, and reduces mortality in patients with moderate to severe (NYHA class III–IV) heart failure who are in sinus rhythm, with left bundle branch block and left ventricular ejection fraction of 35% or less. CRT also prevents heart failure progression in similar patients with mild (NYHA class I–II) heart failure symptoms. These devices are more effective in patients in sinus rhythm than in those with AF. Most devices are also defibrillators (CRT-D) because many patients with heart failure are predisposed to ventricular arrhythmias. CRT pacemakers (CRT-P) are used when the focus is palliation of symptoms rather than prolonging life.

**Catheter ablation therapy**

Catheter ablation therapy is the treatment of choice for patients with SVT or atrial flutter, and is a useful treatment for some patients with AF or ventricular arrhythmias (**Fig. 16.52**). It involves inserting a series of catheter

**Fig. 16.52 Radiofrequency ablation.** **A** Schematic of an ablation of the accessory conducting pathway in Wolff–Parkinson–White syndrome (see text for details). **B** Fluoroscopy and mapping for an ablation procedure. (AV = atrioventricular)

electrodes into the heart through the venous system. These are used to record the activation sequence of the heart in sinus rhythm, during tachycardia and after pacing manoeuvres. Once the arrhythmia focus or circuit, such as an accessory pathway in WPW syndrome, has been identified, a catheter is used to ablate the culprit tissue. This can be done either by using heat, which is termed radiofrequency ablation, or by freezing, which is termed cryoablation. The procedure takes approximately 1–4 hours and does not require a general anaesthetic, although the patient may experience some discomfort during the ablation procedure. Serious complications are rare (<1%) but include complete heart block requiring pacemaker implantation, and cardiac tamponade. For many arrhythmias, radiofrequency ablation is very attractive because it offers the prospect of a lifetime cure, thereby eliminating the need for long-term drug therapy.

The technique has revolutionised the management of many arrhythmias and is now the treatment of choice for AVNRT and AV re-entrant (accessory pathway) tachycardias, when it is curative in over 90% of cases. Focal atrial tachycardias and atrial flutter can also be treated by radiofrequency ablation, although some patients subsequently experience episodes of AF. Ablation is highly effective in patients with VT occurring in a structurally normal heart, and can be life-saving in patients with refractory VT due to ventricular scar or structural disease. Catheter ablation techniques are also employed to prevent AF. This involves ablation at two sites: the ostia of the pulmonary veins, from which ectopic beats may trigger paroxysms of arrhythmia, and in the LA itself, where re-entry circuits maintain AF, once established. This is effective at reducing episodes of AF in around 70%–80% of younger patients with structurally normal hearts.

In patients with permanent AF and poor rate control, in whom drugs are ineffective or are not tolerated, rate control can be achieved by implantation of a permanent pacemaker, followed by ablation of the AV node to induce complete AV block and bradycardia, thus allowing the pacemaker to assume control of the heart rate.

## Coronary artery disease

Coronary artery disease (CAD) is the commonest cause of angina and acute coronary syndrome and the leading cause of death worldwide. It also has a devastating effect on quality of life. Disability-adjusted life years, a measure of healthy years of life lost, can be used to indicate the burden of disease rather than the resulting deaths. It has been estimated that CAD is responsible for 10% of disability-adjusted life years in low-income countries and 18% in high-income ones. In the UK, 1 in 3 men and 1 in 4 women die from CAD, an estimated 188 000 people have a myocardial infarct each year, and approximately 2.3 million people are living with CAD. The death rates from CAD in the UK are among the highest in Western Europe (more than 70 000 people) but are falling, particularly in younger age groups; over the last 50 years, CAD mortality has more than halved. In Eastern Europe and much of Asia, the rates of CAD are rapidly rising. Occult CAD is common in those who present with other forms of atherosclerotic vascular disease, such as intermittent claudication or stroke, and is an important cause of morbidity and mortality in these patients.

### Pathogenesis

In the vast majority of patients, CAD is caused by atherosclerosis (Box 16.36) but rarely it can occur as the result of aortitis, vasculitis and autoimmune connective tissue diseases. Atherosclerosis is a progressive inflammatory disorder of the arterial wall that is characterised by focal lipid-rich deposits of atheroma that remain clinically silent until they become large enough to impair tissue perfusion, or until ulceration and disruption of the lesion occurs resulting in thrombotic occlusion or distal embolisation of the vessel. Atherosclerosis begins early in life with deposits of lipids in the vessel wall, which tend to occur at sites of altered arterial shear stress, such as bifurcations, and are associated with abnormalities of endothelial function at that site. Abnormalities of arterial function have been detected among high-risk children and adolescents, such as cigarette smokers and those with familial hyperlipidaemia or

### 16.36 Coronary artery disease: clinical manifestations and pathology

Clinical problem	Pathology
<b>Stable angina</b>	Ischaemia due to fixed atheromatous stenosis of one or more coronary arteries
<b>Unstable angina</b>	Ischaemia caused by dynamic complete or partial obstruction of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
<b>Myocardial infarction (type 1)</b>	Myocardial necrosis caused by acute occlusion of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
<b>Myocardial infarction (type 2)</b>	Supply demand imbalance where blood flow cannot meet the needs of the myocardium. This may be caused by fixed atheromatous obstruction with high myocardial demand for blood
<b>Heart failure</b>	Myocardial dysfunction due to infarction or ischaemia
<b>Arrhythmia</b>	Altered conduction due to ischaemia or infarction
<b>Sudden death</b>	Ventricular arrhythmia, asystole or massive myocardial infarction

hypertension. Early lesions have been found in the arteries of victims of accidental death in the second and third decades of life but clinical manifestations often do not appear until the sixth, seventh or eighth decade. During evolution of an atherosclerotic plaque, monocytes and other inflammatory cells bind to receptors expressed by endothelial cells. Subsequently, they migrate into the intima, and take up oxidised low-density lipoprotein (LDL) particles by phagocytosis to become lipid-laden macrophages or foam cells. Extracellular lipid pools appear in the intimal space when foam cells die and release their contents (Fig. 16.53). In response to cytokines and growth factors produced by activated macrophages, smooth muscle cells migrate from the media of the arterial wall into the intima, and change from a contractile to a fibroblastic phenotype, which can stabilise the atherosclerotic lesion. If this is successful, the lipid core will be covered by smooth muscle cells and matrix, producing a stable atherosclerotic plaque that will remain asymptomatic until it becomes large enough to obstruct arterial flow.

In an established atherosclerotic plaque, macrophages mediate inflammation and smooth muscle cells promote repair. If inflammation predominates, the plaque becomes active or unstable and may be complicated by ulceration and thrombosis. Cytokines, such as interleukin-1, tumour necrosis factor- $\alpha$ , interferon- $\gamma$ , platelet-derived growth factors and matrix metalloproteinases, are released by activated macrophages. They cause the intimal smooth muscle cells overlying the plaque to become senescent and the collagen cross-links within the plaque to degrade. This results in thinning of the protective fibrous cap, making the lesion vulnerable to mechanical stress that ultimately causes erosion, fissuring or rupture of the plaque surface (see Fig. 16.53). Any breach in the integrity of the plaque will expose its contents to blood and will trigger platelet aggregation and thrombosis that extend into the atheromatous plaque and the arterial lumen. This may cause partial or complete obstruction at the site of the lesion or distal embolisation, resulting in infarction or ischaemia of the affected organ. This common mechanism underlies acute coronary syndromes, as well as other manifestations of atherosclerotic disease such as lower limb ischaemia and stroke (Ch. 29).

The number and complexity of arterial plaques increase with age and risk factors (see below) but the rate of progression of individual plaques is variable. There is a complex and dynamic interaction between mechanical wall stress and atherosclerotic lesions. Vulnerable plaques are characterised by a lipid-rich core, a thin fibrocellular cap, speckled calcification and an increase in inflammatory cells that release specific enzymes to degrade matrix proteins. In contrast, stable plaques are typified by a small lipid pool, a thick fibrous cap, heavy calcification and

Nomenclature and main histology		Sequences in progression	Main growth mechanism	Earliest onset	Clinical correlation
<b>Type I (initial) lesion</b> Isolated macrophage foam cells			Growth mainly by lipid accumulation	From first decade	Clinically silent
<b>Type II (fatty streak) lesion</b> Mainly intracellular lipid accumulation					
<b>Type III (intermediate) lesion</b> Type II changes and small extracellular lipid pools					
<b>Type IV (atheroma) lesion</b> Type II changes and core of extracellular lipid			Accelerated smooth muscle and collagen increase	From fourth decade	Clinically silent or overt
<b>Type V (fibroatheroma) lesion</b> Lipid core and fibrotic layer, or multiple lipid cores and fibrotic layers, or mainly calcific, or mainly fibrotic					
<b>Type VI (complicated) lesion</b> Surface defect, haematoma-haemorrhage, thrombus			Thrombosis, haematoma		

**Fig. 16.53** The six stages of atherosclerosis: American Heart Association classification. From Stary HC, Chandler B, Dinsmore RE, et al. A definition of advanced types of atherosclerotic lesions and a histological classification of atherosclerosis. *Circulation* 1995; 92:1355–1374. © 1995 American Heart Association.

plentiful collagenous cross-links. Fissuring or rupture tends to occur at sites of maximal mechanical stress, particularly the margins of an eccentric plaque, and may be triggered by a surge in BP, such as during exercise or emotional stress. Surprisingly, most plaque events are subclinical and heal spontaneously, although this may allow thrombus to be incorporated into the lesion, producing plaque growth and further obstruction to flow.

Atherosclerosis may induce complex changes in the media that lead to arterial remodelling. Some arterial segments may slowly constrict (negative remodelling), while others may gradually enlarge (positive remodelling). These changes are important because they may amplify or minimise the degree to which atheroma encroaches into the arterial lumen.

Many risk factors have been identified for atherosclerosis but the causes are incompletely understood, since unknown factors account for up to 40% of the variation in risk from one person to the next.

#### Age and sex

Age is the most powerful independent risk factor for atherosclerosis and sex also plays a role. Pre-menopausal women have lower rates of disease than men, although the sex difference disappears after the menopause. Hormone replacement therapy (HRT) is not effective in the prevention of CAD, and HRT in post-menopausal women is associated with an increased risk of cardiovascular events.

#### Genetics

Atherosclerotic CAD often runs in families and a positive family history is common in patients with early-onset disease (age <50 in men and <55 in women). Twin studies have shown that a monozygotic twin of an affected individual has an eightfold increased risk and a dizygotic twin a fourfold increased risk of dying from CAD, compared to the general population due to a combination of shared genetic, environmental and lifestyle factors. The most common risk factors, such as hypertension, hyperlipidaemia and diabetes mellitus, are inherited in a polygenic manner.

#### Smoking

There is a strong relationship between cigarette smoking and CAD, especially in younger (<70 years) individuals, and this is the most important modifiable risk factor.

#### Hypertension

The incidence of atherosclerosis increases as BP rises, and this is related to systolic and diastolic BP, as well as pulse pressure. Antihypertensive therapy reduces cardiovascular mortality, stroke and heart failure.

#### Hypercholesterolaemia

The risk of atherosclerosis rises with serum cholesterol concentrations and lowering serum total and LDL cholesterol concentrations reduces the risk of cardiovascular events.

#### Diabetes mellitus

This is a potent risk factor for all forms of atherosclerosis, especially type 2 diabetes mellitus. It is often associated with diffuse disease that is difficult to treat. Insulin resistance (normal glucose homeostasis with high levels of insulin) is associated with obesity and physical inactivity, and is also a risk factor for CAD. Glucose intolerance makes a major contribution to the high incidence of CAD in people from South Asia and some other ethnic groups.

#### Haemostatic factors

Platelet activation and high plasma fibrinogen concentrations are associated with an increased risk of coronary thrombosis, whereas antiphospholipid antibodies are associated with recurrent arterial thromboses.

#### Physical activity

Regular exercise (brisk walking, cycling or swimming for 20 minutes two or three times a week) has a protective effect, whereas inactivity roughly doubles the risk of CAD and is a major risk factor for stroke.

## Obesity

Obesity, particularly if central or truncal, is an independent risk factor, although it is often associated with other adverse factors such as hypertension, diabetes mellitus and physical inactivity.

## Alcohol

Excess alcohol consumption is associated with hypertension and cerebrovascular disease.

## Diet

Diets deficient in fresh fruit, vegetables and polyunsaturated fatty acids are associated with an increased risk of cardiovascular disease. The introduction of a Mediterranean-style diet reduces cardiovascular events. However, dietary supplements, such as vitamins C and E, beta-carotene, folate and fish oils, do not reduce cardiovascular events and, in some cases, have been associated with harm.

## Personality

While certain personality traits are associated with an increased risk, there is no evidence to support the popular belief that stress is a major cause of CAD.

## Social deprivation

Social deprivation is strongly associated with cardiovascular disease. This may be partly due to associations with lifestyle risk factors, such as smoking and alcohol excess, which are more common in socially deprived individuals. Current guidelines recommend that treatment thresholds should be lowered for patients from socially deprived areas.

The effect of risk factors can be multiplicative rather than additive. People with a combination of risk factors are at greatest risk and so assessment should take account of all identifiable risk factors. It is important to distinguish between relative risk (the proportional increase in risk) and absolute risk (the actual chance of an event). For example, a man of 35 years with a plasma cholesterol of 7 mmol/L (approximately 170 mg/dL), who smokes 40 cigarettes a day, is much more likely to die from CAD within the next decade than a non-smoking man of the same age with a normal cholesterol, but the absolute likelihood of his dying during this time is small (high relative risk, low absolute risk).

## Management

Two approaches can be employed. Primary prevention aims to introduce lifestyle changes or therapeutic interventions to prevent CAD and other forms of atherosclerosis in the whole population or in healthy individuals with an elevated risk of disease. Secondary prevention involves initiating treatment in patients who already have had an event, with the aim of reducing the risk of subsequent events. The distinction between primary and secondary prevention is increasingly seen as arbitrary since many people will have CAD despite having no symptoms or experienced any clinical events.

## Primary prevention

The population-based strategy aims to modify the risk factors of the whole population through diet and lifestyle advice, on the basis that even a small reduction in smoking or average cholesterol, or modification of exercise and diet, will produce worthwhile benefits (Box 16.37). Some risk factors, such as obesity and smoking, are also associated with a higher risk of other diseases and should be actively discouraged through public health measures. The effectiveness of this approach has been demonstrated by introduction of legislation to restrict smoking in public places, which has been associated with reductions in rates of MI.

The targeted strategy aims to identify and to treat high-risk individuals who have a combination of risk factors that can be quantified by composite scoring systems. It is important to consider the absolute risk of atheromatous cardiovascular disease that an individual is facing before initiating treatment since this will help to determine whether the potential benefits of intervention are likely to outweigh the expense, inconvenience and possible side-effects of treatment. For example, a 65-year-old man

### 16.37 Population-based strategies to prevent coronary disease

- Do not smoke
- Take regular exercise (minimum of 20 mins, three times per week)
- Maintain an 'ideal' body weight
- Eat a mixed diet rich in fresh fruit and vegetables
- Aim to get no more than 10% of energy intake from saturated fat

### 16.38 Factors influencing myocardial oxygen supply and demand

#### Oxygen demand: cardiac work

- Heart rate
- Blood pressure
- Myocardial contractility
- Left ventricular hypertrophy
- Valve disease

#### Oxygen supply: coronary blood flow\*

- Duration of diastole
- Coronary perfusion pressure (aortic diastolic minus coronary sinus or right atrial diastolic pressure)
- Coronary vasomotor tone
- Oxygenation: Haemoglobin Oxygen saturation

\*Coronary blood flow occurs mainly in diastole.

with an average BP of 150/90 mmHg, who smokes and has diabetes mellitus with a total:high-density lipoprotein (HDL) cholesterol ratio of 8, has a 10-year risk of MI or stroke of 56%. Conversely, a 55-year-old woman who has an identical BP, is a non-smoker, does not have diabetes mellitus, and has a total:HDL cholesterol ratio of 6 has a much better outlook, with a 10-year coronary MI or stroke risk of 5.7%. Lowering cholesterol will reduce the risk in both of these individuals by 30% and lowering BP will produce a further 20% reduction. In combination, both strategies would reduce the risk of an event from 56% to 25% in the male patient (treat 4 patients to prevent one event) and from 5.7% to 2.5% in the female patient (treat 40 patients to prevent one event). Thresholds for treatment vary in different countries. In the UK and North America, current guidelines recommend initiation of cholesterol and BP-lowering therapies in individuals with a 10-year cardiovascular risk of 7.5%–10%.

## Secondary prevention

This involves targeting interventions at individuals who have had cardiovascular disease. Patients who recover from a clinical event such as an MI are usually keen to help themselves and are particularly receptive to lifestyle advice, such as dietary modification and smoking cessation. Additional interventions that should be introduced in patients with angina pectoris or an acute coronary syndrome are discussed in more detail below.

## Angina pectoris

Angina pectoris is a symptom complex caused by transient myocardial ischaemia, which occurs whenever there is an imbalance between myocardial oxygen supply and demand (Box 16.38).

## Pathogenesis

Coronary atherosclerosis is by far the most common cause of angina pectoris. Angina may also occur in aortic valve disease and hypertrophic cardiomyopathy, and when the coronary arteries are involved with vasculitis or aortitis. The underlying mechanisms and risk factors for atherosclerosis have already been discussed. Approximately 10% of patients who report stable angina on effort have normal coronary arteries on angiography. The main causes are discussed in more detail below.

## Coronary artery spasm

Angina may result from vasospasm of the coronary arteries. This may coexist with atherosclerosis, especially in unstable angina (see below),

### 16.39 Classification of angina pectoris and chest pain

#### Three characteristic features of angina

1. Constricting discomfort in the centre of the chest, or in the neck, shoulders, jaw or arms
2. Precipitated by physical exertion
3. Relieved by rest (or GTN) within 5 minutes

#### Classification

- **Typical angina:** All three features
- **Atypical angina:** Two features
- **Non-anginal chest pain:** One or no features

#### NICE classification

- **Possible angina:** Typical angina, atypical angina or non-anginal chest pain with an abnormal resting 12-lead ECG
- **Non-anginal chest pain:** Non-anginal chest pain with a normal resting 12-lead ECG

(ECG = electrocardiogram; GTN = glyceryl trinitrate; NICE = National Institute for Health and Care Excellence)

### 16.40 Canadian Cardiovascular Society (CCS) angina score

#### Class I

- Angina only during strenuous or prolonged physical activity

#### Class II

- Slight limitation, with angina only during vigorous physical activity

#### Class III

- Moderate limitation where symptoms occur with everyday activities

#### Class IV

- Inability to perform any activity without angina or angina at rest, i.e. severe limitation

but may rarely occur as an isolated phenomenon in patients with normal coronary arteries on angiography. This is sometimes known as variant angina; when it is accompanied by transient ST elevation on the ECG, it is termed Prinzmetal's angina.

#### Syndrome X and microvascular angina

The constellation of typical angina on effort and normal coronary arteries on angiography with objective evidence of myocardial ischaemia on stress testing is sometimes known as Syndrome X. Many of these patients are women and the mechanisms of their symptoms are unclear. In a subset of patients, there is evidence of impaired myocardial vasodilatory reserve giving rise to the term microvascular angina. These disorders are poorly understood but carry a good prognosis and respond variably to anti-anginal therapy.

#### Other causes

Angina can occur in association with aortic stenosis, hypertrophic obstructive cardiomyopathy and aortitis, all of which are discussed in more detail later in this chapter. It may also rarely be found in association with some types of systemic vasculitis (Ch. 26).

#### Clinical features

The history is the most important factor in making the diagnosis. Stable angina is categorised as typical angina, atypical angina or non-anginal chest pain (Box 16.39; see also Fig. 9.1). Some patients find the discomfort comes when they start walking and that later it does not return despite greater effort ('warm-up angina'). The Canadian Cardiovascular Society (CCS) scoring system is commonly used to grade the severity of angina (Box 16.40). This is of clinical value, not only in documenting the severity of angina but also in assessing prognosis.

Physical examination is frequently unremarkable but should include a careful search for an ejection systolic murmur (particularly aortic stenosis and hypertrophic obstructive cardiomyopathy), important risk factors (hypertension, diabetes mellitus), left ventricular dysfunction (cardiomegaly, gallop rhythm), other manifestations of arterial disease (carotid bruits, peripheral arterial disease), and unrelated conditions that may exacerbate angina (anaemia, thyrotoxicosis).

#### Investigations

Stress testing and non-invasive imaging are advisable to confirm the diagnosis and to risk stratify patients with possible angina (see Box 16.39). An algorithm for the investigation and treatment of patients with stable angina is shown in Fig. 16.54. An exercise ECG is commonly performed using a standard treadmill or bicycle ergometer protocol, while monitoring the patient's pulse, BP and general condition. Planar or down-sloping ST segment depression of 1 mm or more is indicative of ischaemia (Fig. 16.55). Up-sloping ST depression is less specific; it often occurs in normal individuals and false-positive results can occur with digoxin therapy, left ventricular hypertrophy, bundle branch block and WPW syndrome. Overall, the exercise ECG confirms the history of exertional angina, provides an objective measure of the patient's exercise tolerance and is indicative of the underlying disease severity (Fig. 16.56) that can identify high-risk individuals with severe coronary disease in combination with other clinical features (Box 16.41). However, exercise testing may be normal in a substantial proportion of patients with CAD or may be inconclusive because of inadequate exercise tolerance due to reduced mobility or other non-cardiac problems.

If the diagnosis is unclear following the investigations listed above, CT coronary angiography is the imaging investigation of first choice. It clarifies the diagnosis and guides the use of preventative and anti-anginal therapies. It also serves as an excellent guide to the appropriate use of invasive cardiac catheterisation, reducing its use in those with normal coronary arteries (see Fig. 16.13) and targeting it to those with significant disease (see Fig. 16.54). Its use is also associated with a marked reduction in the future risk of MI, likely due to better targeted preventative interventions in those with previously unrecognised CAD.

In patients with known CAD, further imaging with myocardial perfusion scanning or stress echocardiography is indicated. A perfusion defect present during stress but not at rest provides evidence of reversible myocardial ischaemia (Fig. 16.57), whereas a persistent perfusion defect seen during both phases of the study is usually indicative of previous MI.

Coronary angiography provides detailed anatomical information about the extent and nature of CAD (see Fig. 16.15). It is usually performed when coronary artery bypass graft surgery or percutaneous coronary intervention is being considered.

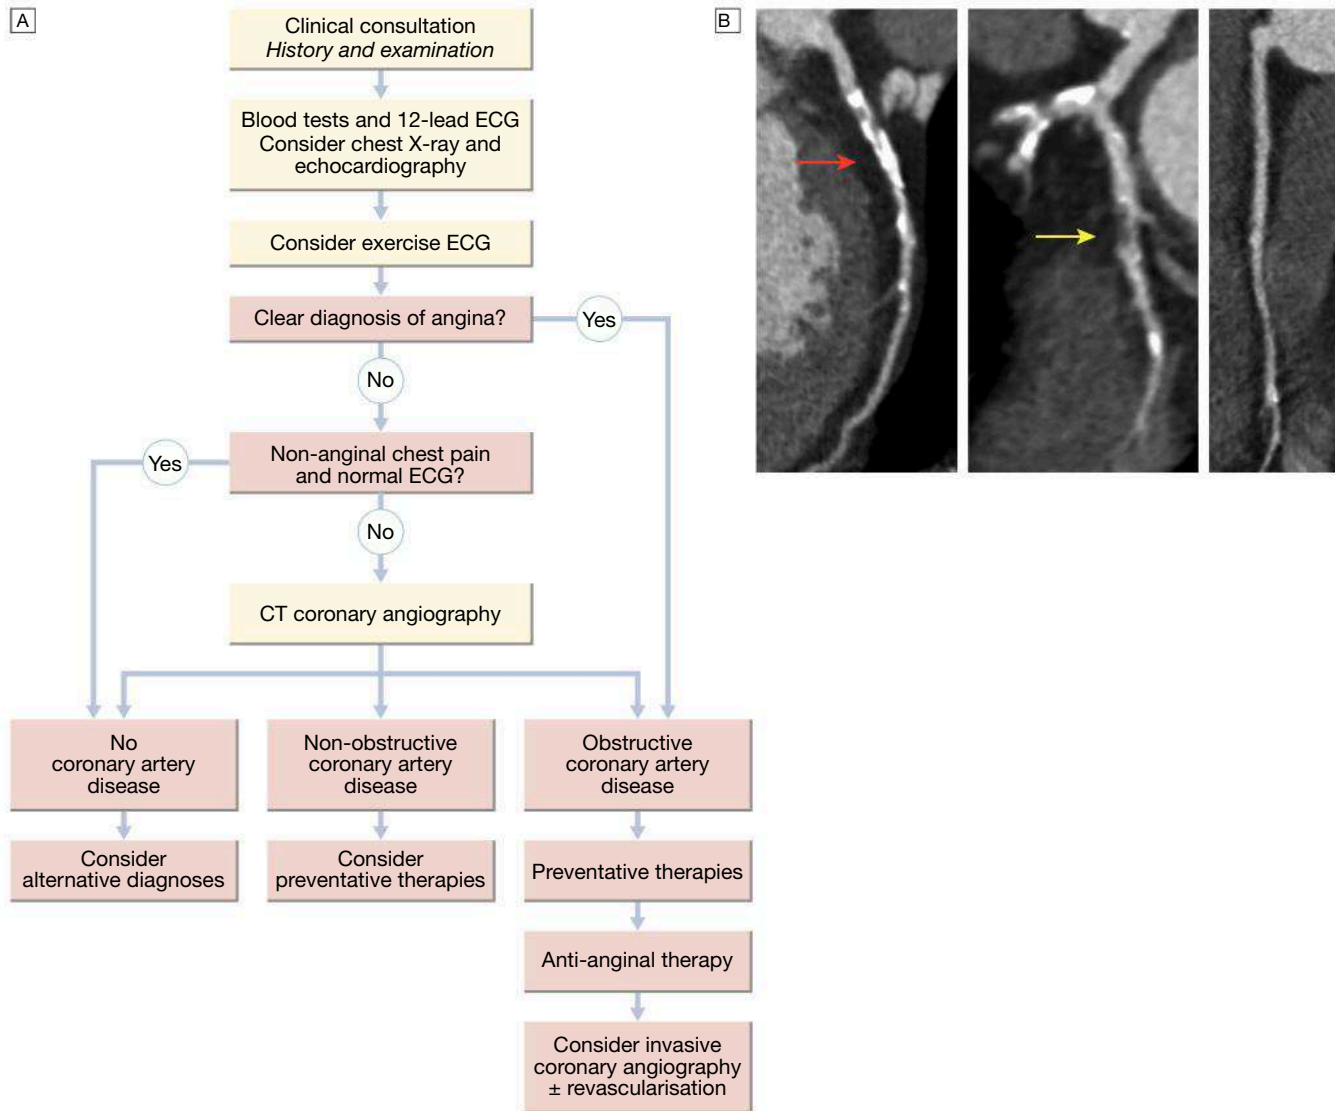

#### Management

This should begin with a careful explanation of the problem and a discussion of the lifestyle and medical interventions that can be deployed to relieve symptoms and improve prognosis (Box 16.42). Anxiety and misconceptions often contribute to disability. For example, some patients avoid all forms of exertion because they believe that each attack of angina is a 'mini-heart attack' that results in permanent damage. Education and reassurance can dispel these misconceptions and make a huge difference to the patient's quality of life.

The principles of management involve:

- identification and treatment of risk factors
- advice on smoking cessation
- introduction of drug treatment for symptom control
- a careful assessment of the extent and severity of CAD
- identification of high-risk patients for treatment to improve life expectancy.

All patients with angina secondary to CAD should receive antiplatelet therapy. Low-dose (75 mg) aspirin should be prescribed and continued

**Fig. 16.54** **A** A scheme for the investigation and treatment of stable angina on effort. This scheme is best adopted for patients without prior known coronary artery disease and possible angina. For patients with known coronary artery disease, further stress imaging (echocardiography, radionuclide perfusion or magnetic resonance perfusion) rather than computed tomography coronary angiography is recommended. **B** An example CT coronary angiogram showing coronary artery disease in all three vessels with evidence of 'soft' lipid-rich plaque (yellow arrow) and extensive calcified coronary atheroma (red arrow).

**Fig. 16.55** Forms of exercise-induced ST depression. **A** Planar ST depression is usually indicative of myocardial ischaemia. **B** Down-sloping depression also usually indicates myocardial ischaemia. **C** Up-sloping depression may be a normal finding.

indefinitely since it reduces the risk of MI. Clopidogrel (75 mg daily) is an equally effective alternative if aspirin causes dyspepsia or other side-effects. Similarly, all patients should be prescribed a statin, even if the serum cholesterol concentration is normal.

### Anti-anginal drug therapy

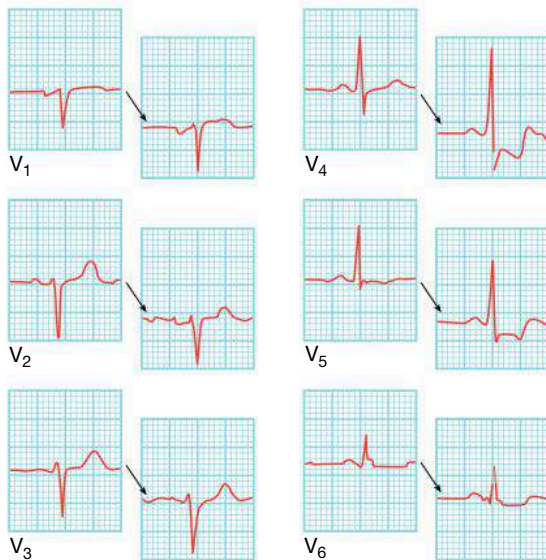

The goal of anti-anginal therapy is to control symptoms using a regimen that is as simple as possible and does not cause side-effects. Five main groups of drug are used in the treatment of angina but there is

little evidence that one group is more effective than another. It is conventional to start therapy with sublingual glyceryl trinitrate (GTN) and a  $\beta$ -blocker, and then add a calcium channel antagonist or a long-acting nitrate if needed. If the combination of two drugs fails to achieve an acceptable symptomatic response, the addition of further classes of drug has modest additional benefits and coronary revascularisation should be considered.

### Nitrates

Nitrates act directly on vascular smooth muscle to produce venous and arteriolar dilatation. Several preparations are available, as shown in [Box 16.43](#). They help angina by lowering preload and afterload, which reduces myocardial oxygen demand, and by increasing myocardial oxygen supply through coronary vasodilatation. Sublingual GTN, administered from a metered-dose aerosol (400  $\mu$ g per spray) or as a tablet (300 or 500  $\mu$ g), is indicated for acute attacks and relieves symptoms in 2–3 minutes. It can also be used before taking exercise to avoid provoking symptoms. Sublingual GTN has a short duration of action and side-effects include headache, symptomatic hypotension and, rarely, syncope. A more prolonged therapeutic effect can be achieved by giving GTN transcutaneously as a patch (5–10 mg daily) or as a slow-release

**Fig. 16.56** A positive exercise test (chest leads only). The resting 12-lead ECG shows some minor T-wave changes in the inferolateral leads but is otherwise normal. After 3 minutes' exercise on a treadmill, there is marked planar ST depression in leads  $V_4$  and  $V_5$  (right-hand offset). Subsequent coronary angiography revealed critical three-vessel coronary artery disease.

### 16.41 Risk stratification in patients with stable angina<sup>1</sup>

High risk	Low risk
Recent-onset symptoms (<6 months)	Long-standing symptoms
Class II to IV symptoms <sup>†</sup>	Class I symptoms <sup>2</sup>
Diabetes mellitus	
Comorbidity	
Post-infarct angina	Predictable exertional angina
Ischaemia at low workload	Ischaemia only at high workload
Left main or three-vessel disease	Single-vessel or two-vessel disease
Poor left ventricular function	Good left ventricular function

<sup>1</sup>Patients may fall between these two categories. <sup>2</sup>Canadian Cardiovascular Society Classification.

buccal tablet (1–5 mg 4 times daily). Isosorbide dinitrate (10–20 mg 3 times daily) and isosorbide mononitrate (20–60 mg once or twice daily) can be given by mouth, unlike GTN, which undergoes extensive metabolism in the liver. Headache is common with oral nitrates but tends to diminish if the patient perseveres with the treatment. Continuous nitrate therapy can cause pharmacological tolerance but this can be avoided by a 6–8-hour nitrate-free period, best achieved at night when the patient is inactive. If nocturnal angina is a predominant symptom, long-acting nitrates can be taken at the end of the day.

#### Beta-blockers

These lower myocardial oxygen demand by reducing heart rate, BP and myocardial contractility, but they may provoke bronchospasm in patients with asthma. Dosages of commonly used beta-blockers are shown in Box 16.18. In theory, non-selective  $\beta$ -blockers may aggravate coronary vasospasm by blocking coronary artery  $\beta_2$ -adrenoceptors, and so a once-daily cardioselective preparation such as slow-release metoprolol (50–200 mg daily) or bisoprolol (5–15 mg daily) is preferable. Beta-blockers should not be withdrawn abruptly, as rebound effects may precipitate dangerous arrhythmias, worsening angina or precipitate MI: the  $\beta$ -blocker withdrawal syndrome.

**Fig. 16.57** A myocardial perfusion scan showing reversible anterior myocardial ischaemia. The images are cross-sectional tomograms of the left ventricle. The resting scans (left) show even uptake of the <sup>99m</sup>technetium-labelled tetrofosmin and look like doughnuts. During stress there is reduced uptake of technetium, particularly along the anterior wall (arrows), and the scans look like crescents (right).

### 16.42 Advice to patients with stable angina

- Do not smoke
- Aim for an ideal body weight
- Take regular exercise (exercise up to, but not beyond, the point of chest discomfort is beneficial and may promote collateral vessels)
- Avoid severe unaccustomed exertion, and vigorous exercise after a heavy meal or in very cold weather
- Take sublingual nitrate before undertaking exertion that may induce angina

### 16.43 Duration of action of some nitrate preparations

Preparation	Peak action	Duration of action
Sublingual GTN	4–8 mins	10–30 mins
Buccal GTN	4–10 mins	30–300 mins
Transdermal GTN	1–3 hrs	Up to 24 hrs
Oral isosorbide dinitrate	45–120 mins	2–6 hrs
Oral isosorbide mononitrate	45–120 mins	6–10 hrs

(GTN = glyceryl trinitrate)

#### Calcium channel antagonists

These drugs lower myocardial oxygen demand by reducing BP and myocardial contractility. Since dihydropyridine calcium antagonists, such as nifedipine and amlodipine, may cause a reflex tachycardia, it is best to use them in combination with a  $\beta$ -blocker. In contrast, verapamil and diltiazem can be used as monotherapy because they slow SA node

## i

## 16.44 Calcium channel antagonists used for the treatment of angina

Drug	Dose	Feature
Nifedipine	5–20 mg 3 times daily*	May cause marked tachycardia
Nicardipine	20–40 mg 3 times daily	May cause less myocardial depression than the other calcium antagonists
Amlodipine	2.5–10 mg daily	Long-acting
Verapamil	40–80 mg 3 times daily*	Commonly causes constipation; useful anti-arrhythmic properties
Diltiazem	60–120 mg 3 times daily*	Similar anti-arrhythmic properties to verapamil

\*Once- or twice-daily sustained-release preparations are available.

**Fig. 16.58 Percutaneous coronary intervention.** A guidewire is advanced from the radial (or femoral) artery to the coronary artery under radiographic control (1). A fine balloon catheter is then advanced over the guidewire to the stenotic coronary artery and the balloon is inflated to dilate the stenosis (2). When this has been achieved, a stent is usually placed at the site of the stenosis to maintain patency of the artery (3) (see text for more details).

firing, inhibit conduction through the AV node and tend to cause bradycardia. They are particularly useful when  $\beta$ -blockers are contraindicated. Calcium channel antagonists reduce myocardial contractility and must be used with care in patients with poor LV function, since they can aggravate or precipitate heart failure. Other unwanted effects include peripheral oedema, flushing, headache and dizziness (Box 16.44).

#### Potassium channel activators

Nicorandil (10–30 mg twice daily orally) is the only drug in this class that is currently available for clinical use. It acts as a vasodilator with effects on the arterial and venous systems, and has the advantage that it does not exhibit the tolerance seen with nitrates.

#### I<sub>f</sub> channel antagonist

Ivabradine (initial dose 2.5–5 mg twice daily orally) is the first in this class of drug. It induces bradycardia by modulating ion channels in the sinus node. It does not inhibit myocardial contractility and appears to be safe in patients with heart failure.

#### Ranolazine

Ranolazine (initial dose 375 mg twice daily) inhibits the late inward sodium current in coronary artery smooth muscle cells, with a secondary effect on calcium flux and vascular tone, reducing angina symptoms.

### Non-pharmacological treatments

#### Percutaneous coronary intervention

Percutaneous coronary intervention (PCI) involves passing a fine guidewire across a coronary stenosis under radiographic control and using

**Fig. 16.59 Primary percutaneous coronary intervention.** **A** Acute right coronary artery occlusion. **B** Initial angioplasty demonstrates a large thrombus filling defect (arrows). **C** Complete restoration of normal flow following intracoronary stenting.

it to position a balloon, which is then inflated to dilate the stenosis (Fig. 16.58). This can be combined with deployment of a coronary stent, which is a piece of metallic ‘scaffolding’ that can be impregnated with drugs with antiproliferative properties and that helps to maximise and maintain dilatation of a stenosed vessel. The routine use of stents in appropriate vessels reduces both acute complications and the incidence of clinically important restenosis (Fig. 16.59).

Treatment with PCI often provides excellent symptom control but it does not reduce MI or improve survival in patients with chronic stable angina. It is mainly used in single- or two-vessel disease. Stenoses in bypass grafts can be dilated, as well as those in the native coronary arteries. The technique is often used to provide

**Fig. 16.60** Coronary artery bypass graft surgery. **A** Narrowed or stenosed arteries are bypassed using saphenous vein grafts connected to the aorta or by utilising the internal mammary artery. **B** Three-dimensional reconstruction of multidetector CT of the heart. The image shows the patent saphenous vein grafts (SVG) to the right coronary artery (RCA), obtuse marginal branch (OM) and diagonal branch (LADD), and left internal mammary artery graft (LIMA) to the left anterior descending (LAD) coronary artery.

palliative therapy for patients with recurrent angina after coronary artery bypass grafting.

The main acute complications of PCI are occlusion of the coronary artery by thrombus or a loose flap of intima (coronary artery dissection), and consequent MI. This occurs in about 2%–5% of procedures and can often be corrected by further intervention, although emergency coronary artery bypass grafting may occasionally be required. Mild myocardial damage, as indicated by elevation of cardiac troponin, occurs in up to 25%–30% of cases. The main long-term complication of PCI is restenosis, in up to one-third of cases. This is due to a combination of elastic recoil and smooth muscle proliferation and tends to occur within 3 months. Stenting substantially reduces the risk of restenosis, probably because it allows the operator to achieve more complete dilatation. Drug-eluting stents reduce this risk further by allowing an antiproliferative drug, such as sirolimus or paclitaxel, to elute slowly from the coating and prevent neo-intimal hyperplasia and in-stent restenosis. These are especially indicated in patients with diabetes, or in arteries with long calcific lesions or small diameters. Recurrent angina (affecting up to 5%–10% of patients at 6 months) may require further PCI or bypass grafting.

The risk of complications and the likely success of the procedure are closely related to the complexity of the disease, the experience of the operator and the presence of important comorbidity, such as diabetes and peripheral arterial disease. A good outcome is less likely if the target lesion is complex, long, eccentric or calcified, lies on a bend or within a tortuous vessel, involves a branch or contains thrombus.

Adjunctive therapy with a potent platelet inhibitor such as the P2Y<sub>12</sub> receptor antagonists (clopidogrel, prasugrel or ticagrelor) in combination with aspirin and heparin improves the outcome following PCI.

### Coronary artery bypass grafting

The internal mammary arteries, radial arteries or reversed segments of the patient's own saphenous vein can be used to bypass coronary artery stenoses (Fig. 16.60). This usually involves major surgery under cardiopulmonary bypass but, in some cases, grafts can be applied to the beating heart: 'off-pump' surgery. The operative mortality is approximately 1.5% but risks are higher in older patients, those with poor left ventricular function and those with significant comorbidity, such as renal failure.

Approximately 90% of patients are free of angina 1 year after coronary artery bypass grafting (CABG), but fewer than 60% of patients are asymptomatic after 5 or more years. Early post-operative angina is usually due to graft failure arising from technical problems during the operation, or poor 'run-off' due to disease in the distal native coronary vessels. Late recurrence of angina may be caused by progressive disease in the native coronary arteries or graft degeneration. Fewer than 50% of vein grafts are patent 10 years after surgery. Arterial grafts have a much better long-term patency rate with more than 80% of internal mammary artery grafts patent at 10 years. This has led many surgeons to consider total arterial revascularisation during CABG surgery. Aspirin (75–150mg daily) and clopidogrel (75mg daily) both improve graft patency, and one or the other should be prescribed indefinitely. Intensive lipid-lowering therapy slows the progression of disease in the native coronary arteries and bypass grafts and reduces clinical cardiovascular events. There is substantial excess cardiovascular morbidity and mortality in patients who continue to smoke after bypass grafting. Persistent smokers are twice as likely to die in the 10 years following surgery than those who give up at surgery.

Survival is improved by CABG in symptomatic patients with left main stem stenosis or three-vessel coronary disease when the LAD, CX and right coronary arteries are involved, or two-vessel disease involving the proximal LAD coronary artery. Improvement in survival is most marked in those with impaired left ventricular function or positive stress testing prior to surgery and in those who have undergone left internal mammary artery grafting.

Neurological complications are common, with a 1%–5% risk of peri-operative stroke. Between 30% and 80% of patients develop short-term cognitive impairment that typically resolves within 6 months. There are also reports of long-term cognitive decline that may be evident in more than 30% of patients at 5 years. PCI and CABG are compared in Box 16.45.

### Prognosis

The prognosis of CAD is related to the burden of CAD and the degree of left ventricular dysfunction. A patient with single-vessel disease and good left ventricular function has a 5-year survival of more than 90%. In contrast, a patient with severe left ventricular dysfunction and extensive three-vessel disease has a 5-year survival of less than 30% unless revascularisation is performed. Although symptoms are a poor guide to prognosis, the 5-year mortality of patients with severe angina (CCS angina scale III or IV, see Box 16.40) is nearly double that of patients with mild symptoms.

Some considerations specific to angina in old age are listed in Box 16.46.

## Acute coronary syndrome

Acute coronary syndrome is a term that encompasses both unstable angina and myocardial infarction. Unstable angina is characterised by

16.45 Comparison of percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG)		
	PCI	CABG
Death	<0.5%	<1.5%
Myocardial infarction*	2%	10%
Hospital stay	6–18 hrs	5–8 days
Return to work	2–5 days	6–12 weeks
Recurrent angina	15%–20% at 6 months	10% at 1 year
Repeat revascularisation	10%–20% at 2 years	2% at 2 years
Neurological complications	Rare	Common (see text)
Other complications	Emergency CABG Vascular damage related to access site	Diffuse myocardial damage Infection (chest, wound) Wound pain

\*Defined as CK-MB > 2× normal

16.46 Angina in old age	
<ul style="list-style-type: none"> <li><b>Incidence:</b> coronary artery disease increases in old age and affects women almost as often as men.</li> <li><b>Comorbid conditions:</b> anaemia and thyroid disease are common and may worsen angina.</li> <li><b>Calcific aortic stenosis:</b> common and should be sought in all older people with angina.</li> <li><b>Atypical presentations:</b> when myocardial ischaemia occurs, age-related changes in myocardial compliance and diastolic relaxation can cause the presentation to be with symptoms of heart failure, such as breathlessness, rather than with chest discomfort.</li> <li><b>Angioplasty and coronary artery bypass surgery:</b> provide symptomatic relief, although with increased procedure-related morbidity and mortality. Outcome is determined by the number of diseased vessels, severity of cardiac dysfunction and the number of concomitant diseases, as much as by age itself.</li> </ul>	

new-onset or rapidly worsening angina (crescendo angina), angina on minimal exertion or angina at rest in the absence of myocardial injury. Myocardial infarction (MI) is distinguished from unstable angina by the occurrence of myocardial necrosis and is diagnosed when myocardial injury occurs in the presence of clinical evidence of acute myocardial ischaemia (Box 16.47). The diagnosis of a prior MI can be made when any one of the features shown in Box 16.48 is present.

Acute coronary syndrome may present as a new phenomenon in patients with no previous history of heart disease or against a background of chronic stable angina. Approximately 12% of patients with acute coronary syndrome die within 1 month and 20% within 6 months of the index event. The risk markers that are indicative of an adverse prognosis include recurrent ischaemia, extensive ECG changes at rest or during pain, raised plasma troponin I or T concentrations, arrhythmias and haemodynamic complications (hypotension, mitral regurgitation) during episodes of ischaemia. Careful assessment and risk stratification are important because these guide the use of more complex pharmacological and interventional treatments (Fig. 16.61 and see Fig. 16.69), which can improve outcome.

### Pathogenesis

Acute coronary syndrome almost always occurs in patients who have coronary atherosclerosis. The culprit lesion that precipitates the acute event is usually a complex ulcerated or fissured atheromatous plaque with adherent platelet-rich thrombus and local coronary artery spasm

16.47 Classification and criteria for diagnosis of acute myocardial infarction	
<b>Criteria for acute myocardial infarction</b>	
The term acute myocardial infarction (MI) should be used when there is acute myocardial injury with clinical evidence of acute myocardial ischaemia and with detection of a rise and/or fall of cardiac troponin values with at least one value above the 99 <sup>th</sup> centile upper reference limit and at least one of the following:	
<ul style="list-style-type: none"> <li>• Symptoms of myocardial ischaemia</li> <li>• New ischaemic ECG changes</li> <li>• Development of pathological Q waves</li> <li>• Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology</li> <li>• Identification of a coronary thrombus by angiography or autopsy</li> </ul>	
<b>Classification of acute myocardial infarction</b>	
<ul style="list-style-type: none"> <li>• <b>Type 1 MI:</b> Acute atherothrombosis in the artery supplying the infarcted myocardium</li> <li>• <b>Type 2 MI:</b> An imbalance between myocardial oxygen supply and demand unrelated to acute atherothrombosis</li> <li>• <b>Type 3 MI:</b> Cardiac death in patients with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes before cardiac troponin values become available or abnormal</li> <li>• <b>Type 4 MI:</b> MI caused during percutaneous coronary intervention (PCI; type 4a). Other types include stent thrombosis (type 4b) and restenosis (type 4c) and consistent with type 1 MI</li> <li>• <b>Type 5 MI:</b> MI caused during coronary artery bypass grafting</li> </ul>	
<b>Coronary procedure-related MI</b> ≤ 48 hours after the index procedure is arbitrarily defined by an elevation of cardiac troponin values > 5× for type 4a MI and > 10× for type 5 MI of the 99 <sup>th</sup> centile upper reference limit in patients with normal baseline values together with at least one of the following:	
<ul style="list-style-type: none"> <li>• New ischaemic ECG changes (this criterion is related to type 4a MI only)</li> <li>• Development of new pathological Q waves</li> <li>• Imaging evidence of loss of viable myocardium that is presumed to be new and consistent with an ischaemic aetiology</li> <li>• Angiographic findings consistent with a procedural flow-limiting complication such as coronary dissection, occlusion of a major epicardial artery or graft, side-branch occlusion-thrombus, disruption of collateral flow or distal embolisation</li> </ul>	
<i>Adapted from Thygesen K, Alpert JS, Jaffe AS, et al. Fourth universal definition of myocardial infarction. Eur Heart J 2019; 40: 237–269.</i>	

16.48 Criteria for diagnosis of a previously unrecognised myocardial infarction	
<ul style="list-style-type: none"> <li>• Abnormal Q waves with or without symptoms in the absence of non-ischaemic causes</li> <li>• Imaging evidence of loss of viable myocardium in a pattern consistent with ischaemic aetiology</li> <li>• Patho-anatomical findings of a prior MI</li> </ul>	
<i>Adapted from Thygesen K, Alpert JS, Jaffe AS, et al. Fourth universal definition of myocardial infarction. Eur Heart J 2019; 40: 237–269.</i>	

(see Fig. 16.53). These vascular changes during an acute coronary syndrome are dynamic, such that the degree of obstruction may either increase, leading to complete vessel occlusion, or regress due to the effects of platelet disaggregation and endogenous fibrinolysis.

### Myocardial infarction

The criteria for diagnosis classification of acute MI and classification of subtypes of MI are shown in Box 16.47. In acute type 1 MI, occlusive thrombus is present at the site of rupture or erosion of an atheromatous plaque; so-called atherothrombosis. The thrombus may undergo spontaneous lysis over the course of the next few days, although irreversible myocardial damage will have occurred. Without treatment, the artery responsible for the type 1 MI remains permanently occluded in 20%–30% of patients. Since the process of infarction progresses over several hours (Fig. 16.62), most patients present when it is still possible to salvage myocardium and improve outcome.

## 1. Find points for each predictive factor

Killip class	Points	SBP (mmHg)	Points	Heart rate (beats/min)	Points	Age (years)	Points	Serum creatinine level (μmol/L)	Points	Other risk factors	Points
I	0	≤ 80	58	≤ 50	0	≤ 30	0	0–34	1		
II	20	80–99	53	50–69	3	30–39	8	35–70	4	Cardiac arrest at admission	39
III	39	100–119	43	70–89	9	40–49	25	71–105	7	ST-segment deviation	28
IV	59	120–139	34	90–109	15	50–59	41	106–140	10	Elevated cardiac biomarker concentrations	14
		140–159	24	110–149	24	60–69	58	141–176	21		
		160–199	10	150–199	38	70–79	75	177–353	21		
		≥ 200	0	≥ 200	46	80–89	95	≥ 353	28		
						≥ 90	100				

## 2. Sum points for all predictive factors

Killip class	+	SBP	+	Heart rate	+	Age	+	Creatinine level	+	Cardiac arrest at admission	+	ST-segment deviation	+	Elevated cardiac biomarker concentrations	=	Total points
--------------	---	-----	---	------------	---	-----	---	------------------	---	-----------------------------	---	----------------------	---	---	---	--------------

## 3. Look up risk corresponding to total points

Total points	≤ 60	70	80	90	100	110	120	130	140	150	160	170	180	190	200	210	220	230	240	≥ 250
Probability of in-hospital death (%)	≤ 0.2	0.3	0.4	0.6	0.8	1.1	1.6	2.1	2.9	3.9	5.4	7.3	9.8	13	18	23	29	36	44	≥ 52

## Examples

A patient has Killip class II, SBP of 99 mmHg, heart rate of 100 beats/min, is 65 years of age, has a serum creatinine level of 76 μmol/L, did not have a cardiac arrest at admission but did have ST-segment deviation and elevated cardiac troponin. His score would be: 20 + 53 + 15 + 58 + 7 + 0 + 28 + 14 = 195. This gives about a 16% risk of having an in-hospital death.

Similarly, a patient with Killip class I, SBP of 80 mmHg, heart rate of 60 beats/min, who is 55 years of age, has a serum creatinine level of 30 μmol/L, and no risk factors would have the following score: 0 + 58 + 3 + 41 + 1 = 103. This gives about a 0.9% risk of having an in-hospital death.

**Fig. 16.61 Risk stratification in the acute coronary syndrome: the GRACE score.** Killip class refers to a categorisation of the severity of heart failure based on easily obtained clinical signs. The main clinical features are as follows: class I = no heart failure; class II = crackles audible halfway up the chest; class III = crackles heard in all the lung fields; class IV = cardiogenic shock. To convert creatinine in μmol/L to mg/dL, divide by 88.4. (SBP = systolic blood pressure) From *Scottish Intercollegiate Guidelines Network (SIGN) Guideline no. 93 – Acute coronary syndromes; updated February 2013*.

**Fig. 16.62 The time course of myocardial infarction.** The relative proportion of ischaemic, infarcting and infarcted tissue slowly changes over a period of 12 hours. In the early stages of myocardial infarction, a significant proportion of the myocardium in jeopardy is potentially salvageable.

Myocardial infarction may also occur as the result of an imbalance between the blood supply and metabolic demands of the heart (type 2 MI). This may occur because of the presence of CAD and major non-cardiac stress, such as sepsis in a patient with three-vessel CAD, or because there is overwhelming demand in the presence of unobstructed coronary arteries, such as an excessively fast heart rate from a primary arrhythmia. For the diagnosis of type 2 MI, there needs to be clinical evidence of ischaemia, such as ECG changes or symptoms of chest pain. This should be distinguished from myocardial injury where there is evidence of elevated cardiac troponin concentration

(myocardial necrosis) without evidence of myocardial ischaemia, such as occurs in myocarditis. Myocardial injury can be acute or chronic depending upon its underlying cause.

The term type 3 MI is used to describe the situation where there is sudden death presumed to be due to MI. The terms type 4 and type 5 MI are used to describe the situations where MI occurs during or following the conduct of the coronary revascularisation procedures PCI and CABG, respectively. In these situations, clinical evidence of ischaemia is required to distinguish MI from procedure-related myocardial injury.

**Clinical features**

The differential diagnosis of acute coronary syndrome is wide and includes most causes of central chest pain or collapse. Chest pain at rest is the cardinal symptom but breathlessness, vomiting and collapse are also common features (Box 16.49). The pain occurs in the same sites as angina but is usually more severe and lasts longer; it is often described as a tightness, heaviness or constriction in the chest. In acute MI, the pain can be excruciating, and the patient's expression and pallor may vividly convey the seriousness of the situation. Most patients are breathless and, in some, this is the only symptom. Painless or 'silent' MI may also occur and is particularly common in older patients or those with diabetes mellitus. If syncope occurs, it is usually caused by an arrhythmia or profound hypotension. Vomiting and sinus bradycardia are often due to vagal stimulation and are particularly common in patients with inferior MI. Nausea and vomiting may also be caused or aggravated by opiates given for pain relief. Sometimes

 <b>16.49 Clinical features of acute coronary syndromes</b>	
<b>Symptoms</b>

<b>Signs of impaired myocardial function</b>	
<ul style="list-style-type: none"> <li>• Hypotension, oliguria, cold peripheries</li> <li>• Narrow pulse pressure</li> <li>• Raised jugular venous pressure</li> </ul>	<ul style="list-style-type: none"> <li>• Third heart sound</li> <li>• Quiet first heart sound</li> <li>• Diffuse apical impulse</li> <li>• Lung crepitations</li> </ul>
<b>Low-grade fever</b>	

 <b>16.50 Common arrhythmias in acute coronary syndrome</b>	
<ul style="list-style-type: none"> <li>• Ventricular fibrillation</li> <li>• Ventricular tachycardia</li> <li>• Accelerated idioventricular rhythm</li> <li>• Ventricular ectopics</li> <li>• Atrial fibrillation</li> </ul>	<ul style="list-style-type: none"> <li>• Sinus bradycardia (particularly after inferior myocardial infarction)</li> <li>• Atrioventricular block</li> </ul>

infarction occurs in the absence of physical signs. Sudden death, from ventricular fibrillation or asystole, may occur immediately and often within the first hour. If the patient survives this most critical stage, the liability to dangerous arrhythmias remains, but diminishes as each hour goes by. It is vital that patients know not to delay calling for help if symptoms occur. Complications may occur in all forms of acute coronary syndrome but have become less frequent in the modern era of immediate or early coronary revascularisation. Specific complications of acute coronary syndromes and their management are discussed below.

### Arrhythmias

Arrhythmias are common in patients with acute coronary syndrome (Box 16.50) but are often transient and of no haemodynamic or prognostic importance. The risk of arrhythmia can be minimised by adequate pain relief, rest and the correction of hypokalaemia. VF occurs in 5%–10% of patients who reach hospital and is thought to be the major cause of death in those who die before receiving medical attention. Prompt defibrillation restores sinus rhythm and is life-saving. The prognosis of patients with early VF (within the first 48 hours) who are successfully and promptly resuscitated is identical to that of patients who do not suffer VF. The presence of ventricular arrhythmias during the convalescent phase of acute coronary syndrome may be a marker of poor ventricular function and may herald sudden death. Selected patients may benefit from electrophysiological testing and specific anti-arrhythmic therapy, including ICDs, as discussed in the previous section on cardiac arrhythmias. AF is a common but frequently transient arrhythmia, and usually does not require emergency treatment. However, if it causes a rapid ventricular rate with hypotension or circulatory collapse, prompt cardioversion is essential. In other situations, digoxin or a  $\beta$ -blocker is usually the treatment of choice. AF may be a feature of impending or overt left ventricular failure, and therapy may be ineffective if heart failure is not recognised and treated appropriately. Anticoagulation is required if AF persists. Bradycardia may occur but does not require treatment unless there is hypotension or haemodynamic deterioration, in which case atropine (0.6–1.2 mg IV) may be given. Inferior MI may be complicated by AV block, which is usually

temporary and often resolves following reperfusion therapy. If there is clinical deterioration due to second-degree or complete AV block, a temporary pacemaker should be considered. AV block complicating anterior infarction is more serious because asystole may suddenly supervene. A prophylactic temporary pacemaker should be inserted in these patients.

### Recurrent angina

Patients who develop recurrent angina at rest or on minimal exertion following an acute coronary syndrome are at high risk and should be considered for prompt coronary angiography with a view to revascularisation. Patients with dynamic ECG changes and ongoing pain should be treated with intravenous glycoprotein IIb/IIIa receptor antagonists (tirofiban 400 ng/kg/min for 30 min, then 100 ng/kg/min for 48 hrs, or abciximab, initially 180  $\mu$ g/kg, then 2  $\mu$ g/kg/min for up to 72 hrs). Patients with resistant pain or marked haemodynamic changes should be considered for intra-aortic balloon counterpulsation and emergency coronary revascularisation. Post-infarct angina occurs in up to 50% of patients treated with thrombolysis. Most patients have a residual stenosis in the infarct-related vessel, despite successful thrombolysis, and this may cause angina if there is still viable myocardium downstream. For this reason, all patients who have received successful thrombolysis should be considered for early (within the first 24 hours) coronary angiography with a view to coronary revascularisation.

### Acute heart failure

Acute heart failure usually reflects extensive myocardial damage and is associated with a poor prognosis. All the other complications of MI are more likely to occur when acute heart failure is present. The assessment and management of heart failure is discussed in more detail earlier in this chapter.

### Pericarditis

This only occurs following infarction and is particularly common on the second and third days. The patient may recognise that a different pain has developed, even though it is at the same site, and that it is positional and tends to be worse or sometimes present only on inspiration. A pericardial rub may be audible. Opiate-based analgesia should be used. Non-steroidal (NSAIDs) and steroidal anti-inflammatory drugs may increase the risk of aneurysm formation and myocardial rupture in the early recovery period, and should be avoided.

### Dressler syndrome

This syndrome is characterised by persistent fever, pericarditis and pleurisy, and is probably due to autoimmunity. The symptoms tend to occur a few weeks or even months after MI and often subside after a few days. If the symptoms are prolonged or severe, treatment with high-dose aspirin, NSAIDs or even glucocorticoid steroids may be required.

### Papillary muscle rupture

This typically presents with acute pulmonary oedema and shock due to the sudden onset of severe mitral regurgitation. Examination usually reveals a pansystolic murmur and third heart sound but the murmur may be quiet or absent in patients with severe regurgitation. The diagnosis is confirmed by echocardiography, and emergency valve replacement may be necessary. Lesser degrees of mitral regurgitation due to papillary muscle dysfunction are common and may be transient.

### Ventricular septal rupture

This usually presents with sudden haemodynamic deterioration accompanied by a new loud pansystolic murmur radiating to the right sternal border, which may be difficult to distinguish from acute mitral regurgitation. Rupture of the intraventricular septum causes left-to-right shunting through a ventricular septal defect, which tends to cause acute right heart failure rather than pulmonary oedema. Doppler echocardiography and right heart catheterisation will confirm the diagnosis. Treatment is by emergency surgical repair; without this, the condition is usually fatal.

**Fig. 16.63** Infarct expansion and ventricular remodelling. Full-thickness myocardial infarction causes thinning and stretching of the infarcted segment (infarct expansion), which leads to increased wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling).

### Ventricular rupture

Rupture of the ventricle may lead to cardiac tamponade and is usually fatal, although it is occasionally possible to support a patient with an incomplete rupture until emergency surgery can be performed.

### Embolism

Thrombus often forms on the endocardial surface of freshly infarcted myocardium. This can lead to systemic embolism and occasionally causes a stroke or ischaemic limb. Venous thrombosis and pulmonary embolism may occur but have become less common with the use of prophylactic anticoagulants and early mobilisation.

### Ventricular remodelling

This is a potential complication of an acute transmural MI due to thinning and stretching of the infarcted segment. This leads to an increase in wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling, Fig. 16.63). As the ventricle dilates, it becomes less efficient and heart failure may supervene. Infarct expansion occurs over a few days and weeks but ventricular remodelling can take years. Beta-blocker, ACE inhibitor and mineralocorticoid receptor antagonist therapies can reduce late ventricular remodelling and prevent the onset of heart failure.

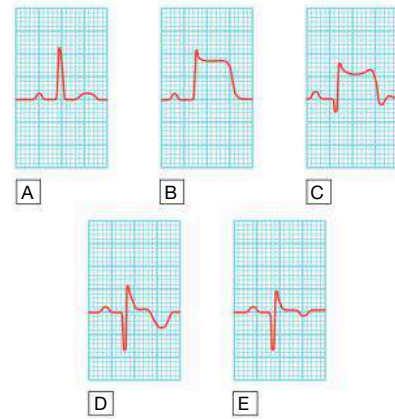

### Ventricular aneurysm

Ventricular aneurysm develops in approximately 10% of patients with MI and is particularly common when there is persistent occlusion of the infarct-related vessel. Heart failure, ventricular arrhythmias, mural thrombus and systemic embolism are all recognised complications of aneurysm formation. Other features include a paradoxical impulse on the chest wall, persistent ST elevation on the ECG, and sometimes an unusual bulge from the cardiac silhouette on the chest X-ray. Echocardiography is diagnostic. Surgical removal of a left ventricular aneurysm carries a high morbidity and mortality but is sometimes necessary.

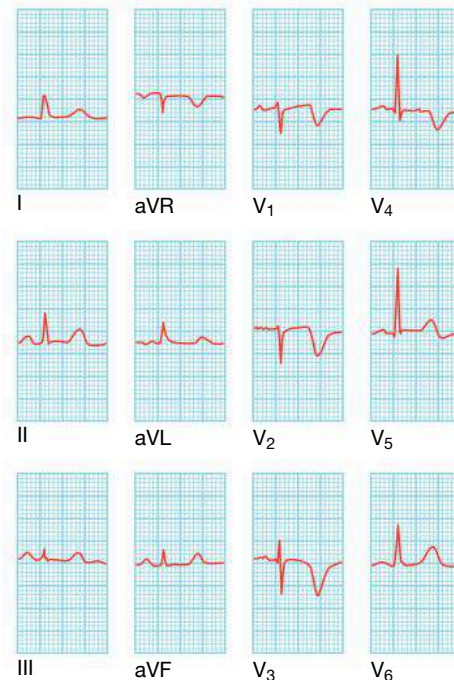

## Investigations

### Electrocardiogram

The standard 12-lead ECG is central to confirming the diagnosis and deciding immediate management but may be difficult to interpret if there is bundle branch block or previous MI. The initial ECG may be normal or non-diagnostic in one-third of cases. Repeated ECGs are important, especially where the diagnosis is uncertain or the patient has recurrent or persistent symptoms. The earliest ECG change is usually ST-segment deviation. With proximal occlusion of a major coronary artery, ST-segment elevation

**Fig. 16.64** The serial evolution of ECG changes in transmural myocardial infarction. **A** Normal ECG complex. **B** Acute ST elevation ('the current of injury'). **C** Progressive loss of the R wave, developing Q wave, resolution of the ST elevation and terminal T-wave inversion. **D** Deep Q wave and T-wave inversion. **E** Old or established infarct pattern; the Q wave tends to persist but the T-wave changes become less marked. The rate of evolution is very variable but, in general, stage B appears within minutes, stage C within hours, stage D within days and stage E after several weeks or months. This should be compared with the 12-lead ECGs in Figs. 16.65–16.67.

**Fig. 16.65** Recent anterior non-ST elevation (subendocardial) myocardial infarction. This ECG demonstrates deep symmetrical T-wave inversion, together with a reduction in the height of the R wave in leads  $V_1$ ,  $V_2$ ,  $V_3$  and  $V_4$ .

(or new bundle branch block) is seen initially, with later diminution in the size of the R wave and, in transmural (full-thickness) infarction, development of a Q wave. Subsequently, the T wave becomes inverted because of a change in ventricular repolarisation; this change persists after the ST segment has returned to normal. These sequential features (Fig. 16.64) are sufficiently reliable for the approximate age of the infarct to be deduced.

In non-ST segment elevation acute coronary syndrome, there is partial occlusion of a major vessel or complete occlusion of a minor vessel, causing unstable angina or partial-thickness (subendocardial) MI. This is usually associated with ST-segment depression and T-wave changes. In the presence of infarction, this may be accompanied by some loss of R waves in the absence of Q waves (Fig. 16.65).

**Fig. 16.66 Acute transmural anterior myocardial infarction.** This ECG was recorded from a patient who had developed severe chest pain 6 hours earlier. There is ST elevation in leads I, aVL, V<sub>2</sub>, V<sub>3</sub>, V<sub>4</sub>, V<sub>5</sub> and V<sub>6</sub>, and there are Q waves in leads V<sub>3</sub>, V<sub>4</sub> and V<sub>5</sub>. Anterior infarcts with prominent changes in leads V<sub>2</sub>, V<sub>3</sub> and V<sub>4</sub> are sometimes called 'anteroseptal' infarcts, as opposed to 'anterolateral' infarcts, in which the ECG changes are predominantly found in V<sub>4</sub>, V<sub>5</sub> and V<sub>6</sub>.

The ECG changes are best seen in the leads that 'face' the ischaemic or infarcted area. When there has been anteroseptal infarction, abnormalities are found in one or more leads from V<sub>1</sub> to V<sub>4</sub>, while anterolateral infarction produces changes from V<sub>4</sub> to V<sub>6</sub>, in aVL and in lead I. Inferior infarction is best shown in leads II, III and aVF, while, at the same time, leads I, aVL and the anterior chest leads may show 'reciprocal' changes of ST depression (Figs. 16.66 and 16.67). Infarction of the posterior wall of the LV does not cause ST elevation or Q waves in the standard leads, but can be diagnosed by the presence of reciprocal changes (ST depression and a tall R wave in leads V<sub>1</sub>–V<sub>2</sub>). Some infarctions (especially inferior) also involve the RV. This may be identified by recording from additional leads placed over the right precordium.

#### Cardiac biomarkers

Serial measurements of cardiac troponin concentration should be taken. In unstable angina, there is no detectable rise in troponin and the diagnosis is made on the basis of the clinical features and investigations such as ECG or coronary angiography. In contrast, MI causes a rise in plasma concentrations of troponin T and I and other cardiac muscle enzymes (Fig. 16.68 and see Box 16.47). Levels of troponins T and I increase within 3–6 hours, peak at about 36 hours and remain elevated for up to 2 weeks. A full blood count may reveal the presence of a leucocytosis, which reaches a peak on the first day. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are also elevated. Lipids should be measured within 24 hours of presentation because there is often a transient fall in cholesterol in the 3 months following infarction.

#### Radiography

A chest X-ray should be performed since this may demonstrate pulmonary oedema that is not evident on clinical examination (see Fig. 16.25). The heart size is often normal but there may be cardiomegaly due to pre-existing myocardial damage.

**Fig. 16.67 Acute transmural inferolateral myocardial infarction.** This ECG was recorded from a patient who had developed severe chest pain 4 hours earlier. There is ST elevation in inferior leads II, III and aVF and lateral leads V<sub>4</sub>, V<sub>5</sub> and V<sub>6</sub>. There is also 'reciprocal' ST depression in leads aVL and V<sub>2</sub>.

**Fig. 16.68 Changes in plasma cardiac biomarker concentrations after myocardial infarction.** Creatine kinase (CK) and troponins T (Tn-T) and I (Tn-I) are the first to rise, followed by aspartate aminotransferase (AST) and then lactate (hydroxybutyrate) dehydrogenase (LDH). In patients treated with reperfusion therapy, a rapid rise in plasma creatine kinase (curve CK(R)) occurs, due to a washout effect.

#### Echocardiography

Echocardiography is normally performed before discharge from hospital and is useful for assessing ventricular function and for detecting important complications, such as mural thrombus, cardiac rupture, ventricular septal defect, mitral regurgitation and pericardial effusion.

#### Coronary angiography

Coronary arteriography should be considered with a view to revascularisation in all patients at moderate or high risk of a further event, including those who fail to settle on medical therapy, those with extensive ECG changes, those with an elevated cardiac troponin and those with severe pre-existing stable angina (see Fig. 16.69). This often reveals disease that is amenable to PCI or urgent CABG (see below).

**Fig. 16.69 Summary of treatment for acute coronary syndrome (ACS).** \*Not required following PCI. For details of the GRACE score, see Fig. 16.61. (ACE = angiotensin-converting enzyme; ECG = electrocardiogram; GP = glycoprotein; IV = intravenous; LMW = low-molecular-weight; PCI = percutaneous coronary intervention; PO = by mouth; SC = subcutaneous) Adapted from Scottish Intercollegiate Guidelines Network (SIGN) Guideline no. 93 – Acute coronary syndromes, February 2007 and updated in SIGN 148, April 2016.

## Management

All patients with suspected acute coronary syndrome should be admitted urgently to hospital because there is a risk of death or recurrent myocardial ischaemia during the early unstable phase. Appropriate medical therapy can reduce the incidence of these complications by at least 60%. The key elements of immediate in-hospital management are shown in Fig. 16.69. Patients should ideally be managed in a dedicated cardiac unit, where the necessary expertise, monitoring and resuscitation facilities are available. Clinical risk factor analysis using tools such as the GRACE score (see Fig. 16.61) should be performed to identify patients that should be selected for intensive therapy, and

specifically early inpatient coronary angiography (thresholds vary, but a score of 140 points or more supports early intervention). If there are no complications and risk factor analysis shows that angiography is not required, the patient can be mobilised from the second day and discharged after 2–3 days. Low-risk patients without spontaneous angina may be considered for an exercise tolerance test 4–6 weeks after the acute coronary syndrome. This will help to identify those individuals who may require further investigation, and may help to boost the confidence of the remainder. Management of the acute event is discussed below and the principles of long-term management are summarised in Box 16.51.

## Analgesia

Adequate analgesia is essential, not only to relieve distress but also to lower adrenergic drive and thereby reduce vascular resistance, BP, infarct size and susceptibility to ventricular arrhythmias. Intravenous opiates (initially, morphine sulphate 5–10 mg or diamorphine 2.5–5 mg) and antiemetics (initially, metoclopramide 10 mg) should be administered, and titrated until the patient is comfortable. Intramuscular injections should be avoided because the clinical effect may be delayed by poor skeletal muscle perfusion, and a painful haematoma may form following thrombolytic or antithrombotic therapy.

## Reperfusion therapy

Immediate reperfusion therapy with PCI (see Fig. 16.59) is indicated when the ECG shows new bundle branch block or characteristic ST-segment elevation in two contiguous leads of 1 mm or more in the limb leads or 2 mm or more in the chest leads. This is the treatment of choice for those presenting within 12 hours of symptom onset (see Fig. 16.69). If PCI cannot be performed within 120 minutes for any reason, and thrombolysis is contraindicated, the procedure should be performed as soon as practically possible. Patients should be considered for PCI within the first 24 hours, even if they have reperfused spontaneously or with thrombolytic therapy. Coronary artery patency is restored in over 95% of patients undergoing PCI. The procedure preserves left ventricular function with a marked reduction in the progression to heart failure, more than halves rates of recurrent MI and dramatically improves mortality with more than 95% 1-year survival rates in clinical trials. Successful therapy is also associated with rapid pain relief, resolution of acute ST elevation and occasional transient arrhythmias.

Reperfusion therapy with PCI confers no immediate mortality benefit in patients with non-ST segment elevation acute coronary syndrome. Selected medium- to high-risk patients do benefit from in-hospital coronary angiography and coronary revascularisation but this does not need to take place in the first 12 hours unless there are high-risk features, such as ongoing chest pain or ECG changes.

## Thrombolytic therapy

If primary PCI cannot be achieved in a timely manner in patients with ST-segment elevation MI (see Fig. 16.69), thrombolytic therapy should be administered. Although the survival advantage is not as good as primary PCI, mortality is reduced and this is maintained for at least 10 years. The benefit of thrombolytic therapy is greatest in those patients who receive treatment within the first 12 hours and especially the first 2 hours. Modern thrombolytic agents, such as tenecteplase (TNK) and reteplase (rPA), are analogues of human tissue plasminogen activator and can be given as an intravenous bolus, allowing prompt treatment to be given in

16.52 Relative contraindications to thrombolytic therapy	
<ul style="list-style-type: none"> <li>Active internal bleeding</li> <li>Previous subarachnoid or intracerebral haemorrhage</li> <li>Uncontrolled hypertension</li> <li>Recent surgery (within 1 month)</li> <li>Recent trauma (including traumatic resuscitation)</li> <li>High probability of active peptic ulcer</li> <li>Pregnancy</li> </ul>	

the emergency department or in the pre-hospital setting. The major hazard of thrombolytic therapy is bleeding. Cerebral haemorrhage causes 4 extra strokes per 1000 patients treated, and the incidence of other major bleeds is between 0.5% and 1%. Accordingly, the treatment should be withheld if there is a significant risk of serious bleeding (Box 16.52). For some patients, thrombolytic therapy is contraindicated or fails to achieve coronary arterial reperfusion (see Fig. 16.69). Emergency PCI may then be considered, particularly where there is evidence of cardiogenic shock. Even where thrombolysis successfully achieves reperfusion, PCI should be considered within 24 hours to prevent recurrent infarction and improve outcome.

## Antithrombotic therapy

Oral administration of 75–325 mg aspirin daily improves survival, with a 25% relative risk reduction in mortality. The first tablet (300 mg) should be given orally within the first 12 hours and therapy should be continued indefinitely if there are no side-effects. A P2Y<sub>12</sub> receptor antagonist (ticagrelor (180 mg, followed by 90 mg twice daily), prasugrel (60 mg, followed by 10 mg daily) or clopidogrel (300 mg, followed by 75 mg daily)) should be given in combination with aspirin for up to 12 months. Glycoprotein IIb/IIIa receptor antagonists, such as tirofiban and abciximab, block the final common pathway of platelet aggregation and are potent inhibitors of platelet-rich thrombus formation. They are of particular benefit in high-risk patients with acute coronary syndromes who undergo PCI, especially those with a high thrombus burden at angiography or who have received inadequate prior antiplatelet therapy. These intravenous agents should be administered in addition to oral aspirin and a P2Y<sub>12</sub> receptor antagonist. Anticoagulation further reduces the risk of thromboembolic complications, and prevents re-infarction in the absence of reperfusion therapy or after successful thrombolysis. Anticoagulation can be achieved using unfractionated heparin, fractionated (low-molecular-weight) heparin or a pentasaccharide, such as subcutaneous fondaparinux (2.5 mg daily). Comparative clinical trials show that the pentasaccharides have the best safety and efficacy profile but low-molecular-weight heparin, such as subcutaneous enoxaparin (1 mg/kg twice daily), is a reasonable alternative. Anticoagulation should be continued for 8 days or until discharge from hospital or coronary revascularisation has been completed. A period of treatment with an oral anticoagulant should be considered if there is persistent AF or evidence of extensive anterior infarction with mural thrombus because these patients are at increased risk of systemic thromboembolism.

## Anti-anginal therapy

Sublingual glyceryl trinitrate (300–500  $\mu$ g) is a valuable first-aid measure in unstable angina or threatened infarction, and intravenous nitrates (glyceryl trinitrate 0.6–1.2 mg/hr or isosorbide dinitrate 1–2 mg/hr) are useful for the treatment of left ventricular failure and the relief of recurrent or persistent ischaemic pain. Intravenous  $\beta$ -blockade (atenolol 5–10 mg or metoprolol 5–15 mg given over 5 min) relieves pain, reduces arrhythmias and improves short-term mortality in patients who present within 12 hours of symptom onset (see Fig. 16.69). However, they should be avoided if there is heart failure (pulmonary oedema), hypotension (systolic BP < 105 mmHg) or bradycardia (heart rate < 65/min). Nifedipine or amlodipine can be added if there is persistent chest discomfort but these drugs may cause tachycardia if used alone. Verapamil and diltiazem should be used if  $\beta$ -blockade

is contraindicated. In the longer term, treatment with an oral  $\beta$ -blocker reduces long-term mortality by approximately 25% among the survivors of an acute MI, especially those with left ventricular systolic dysfunction. Patients with heart failure, COPD or peripheral arterial disease appear to derive similar secondary preventative benefits from  $\beta$ -blocker therapy and should receive maintenance therapy unless poorly tolerated. Unfortunately, a minority of patients do not tolerate  $\beta$ -blockade because of bradycardia, AV block, hypotension or asthma.

### Renin–angiotensin blockade

Long-term treatment with ACE inhibitors such as enalapril (10 mg twice daily) or ramipril (2.5–5 mg twice daily) can counteract ventricular remodelling, prevent the onset of heart failure, improve survival, reduce recurrent MI and avoid rehospitalisation. The benefits are greatest in those with overt heart failure (clinical or radiological) but extend to patients with asymptomatic left ventricular systolic dysfunction and those with preserved left ventricular function. They should be considered in all patients with acute coronary syndrome. Caution must be exercised in hypovolaemic or hypotensive patients because ACE inhibition may exacerbate hypotension and impair coronary perfusion. In patients intolerant of ACE inhibitors, ARBs such as valsartan (40–160 mg twice daily) or candesartan (4–16 mg daily) are alternatives that are better tolerated.

### Mineralocorticoid receptor antagonists

Patients with acute MI and left ventricular dysfunction (ejection fraction <35%) and either pulmonary oedema or diabetes mellitus further benefit from additional mineralocorticoid receptor antagonists (eplerenone 25–50 mg daily, or spironolactone 25–50 mg daily).

### Lipid-lowering therapy

The benefits of lowering serum cholesterol following acute coronary syndrome have been demonstrated in several large-scale randomised trials. All patients should receive therapy with HMG CoA reductase enzyme inhibitors (statins) after acute coronary syndrome, irrespective of serum cholesterol concentrations. Patients with serum LDL cholesterol concentrations above 3.2 mmol/L (approximately 120 mg/dL) benefit from more intensive therapy, such as atorvastatin (80 mg daily). Other agents, such as ezetimibe, fibrates, anion exchange resins and injectable PCSK9 inhibitors, may be used in cases where total cholesterol or LDL cholesterol cannot be lowered adequately using statins alone.

### Smoking cessation

The 5-year mortality of patients who continue to smoke cigarettes is double that of those who quit smoking at the time of their acute coronary syndrome. Giving up smoking is the single most effective contribution a patient can make to their future. The success of smoking cessation can be increased by supportive advice and pharmacological therapy.

### Diet and exercise

Maintaining an ideal body weight, eating a Mediterranean-style diet, taking regular exercise, and achieving good control of hypertension and diabetes mellitus may all improve the long-term outlook.

### Rehabilitation

When there are no complications, the patient can mobilise on the second day, return home in 2–3 days and gradually increase activity, with the aim of returning to work in 4 weeks. The majority of patients may resume driving after 1–4 weeks, although, in most countries, drivers of heavy goods and public service vehicles require special assessment before returning to work. Emotional problems, such as denial, anxiety and depression, are common and must be addressed. Some patients are severely and even permanently incapacitated as a result of the psychological effects of acute coronary syndrome rather than the physical ones, and all benefit from thoughtful explanation, counselling and reassurance. Many patients

## 16.53 Myocardial infarction in old age

- **Atypical presentation:** often with anorexia, fatigue, weakness, delirium or falls rather than chest pain.
- **Case fatality:** rises steeply. Hospital mortality exceeds 25% in those over 75 years old, which is five times greater than that seen in those aged less than 55 years.
- **Survival benefit of treatments:** not influenced by age. The absolute benefit of evidence-based treatments may therefore be greatest in older people.
- **Hazards of treatments:** rise with age (for example, increased risk of intracerebral bleeding after thrombolysis) and are due partly to increased comorbidity.
- **Quality of evidence:** older patients, particularly those with significant comorbidity, were under-represented in many of the randomised controlled clinical trials that helped to establish the treatment of myocardial infarction. The balance of risk and benefit for many treatments, such as thrombolysis and primary percutaneous transluminal coronary angiography, in frail older people is uncertain.

mistakenly believe that stress was the cause of their heart attack and may restrict their activity inappropriately. The patient's spouse or partner will also require emotional support, information and counselling. Formal rehabilitation programmes, based on graded exercise protocols with individual and group counselling, are often very successful and, in some cases, have been shown to improve quality of life and long-term outcome.

### Implantable defibrillators

These devices are of benefit in preventing sudden cardiac death in patients who have severe left ventricular impairment (ejection fraction  $\leq$ 30%) after MI. More details are provided in the section on treatment of cardiac arrhythmias.

### Type 2 myocardial infarction

The optimal management and treatment of patients with type 2 MI has yet to be established. There is currently no evidence that treatments for type 1 MI are effective in the setting of type 2 MI. The focus for patients with type 2 MI should be on treating the underlying cause of their presentation and, where applicable, their previously undiagnosed concomitant CAD.

### Prognosis

The prognosis of patients who have survived an acute coronary syndrome is related to the extent of residual myocardial ischaemia, the degree of myocardial damage and the presence of ventricular arrhythmias. In almost one-quarter of all cases of MI, death occurs within a few minutes without medical care. Half the deaths occur within 24 hours of the onset of symptoms and about 40% of all affected patients die within the first month. The prognosis of those who survive to reach hospital is much better, with a 28-day survival of more than 85%. Patients with unstable angina have a mortality of approximately half that of patients with MI. Early death is usually due to an arrhythmia and is independent of the extent of MI. However, late outcomes are determined by the extent of myocardial damage, and unfavourable features include poor left ventricular function, AV block and persistent ventricular arrhythmias. The prognosis is worse for anterior than for inferior infarcts. Bundle branch block and high cardiac marker concentrations both indicate extensive myocardial damage. Old age, depression and social isolation are also associated with a higher mortality. Of those who survive an acute attack, more than 80% live for a further year, about 75% for 5 years, 50% for 10 years and 25% for 20 years.

Some considerations specific to myocardial infarction in old age are listed in [Box 16.53](#).

## Non-cardiac surgery in patients with heart disease

Non-cardiac surgery, particularly major vascular, abdominal or thoracic surgery, can precipitate serious perioperative cardiac complications,

**16.54 Major risk factors for cardiac complications of non-cardiac surgery**

- Recent (< 6 months) myocardial infarction or unstable angina
- Severe coronary artery disease: left main stem or three-vessel disease
- Severe stable angina on effort
- Severe left ventricular dysfunction
- Severe valvular heart disease (especially aortic stenosis)

such as MI and death, in patients with CAD and other forms of heart disease. Careful pre-operative cardiac assessment may help to determine the balance of benefit versus risk on an individual basis, and identify measures that minimise the operative risk (Box 16.54).

A hypercoagulable state is part of the normal physiological response to surgery, and may promote coronary thrombosis leading to an acute coronary syndrome in the early post-operative period. Patients with a history of recent PCI or acute coronary syndrome are at greatest risk and, whenever possible, elective non-cardiac surgery should be avoided for 3 months after such an event. Where possible, antiplatelet, statin and  $\beta$ -blocker therapies should be continued throughout the perioperative period.

Careful attention to fluid balance during and after surgery is particularly important in patients with impaired left ventricular function and valvular heart disease because vasopressin is released as part of the normal physiological response to surgery and, in these circumstances, the over-zealous administration of intravenous fluids can easily precipitate heart failure. Patients with severe valvular heart disease, particularly aortic stenosis and mitral stenosis, are also at increased risk because they may not be able to increase their cardiac output in response to the stress of surgery.

Atrial fibrillation is a common post-operative complication in patients with pre-existing heart disease which may be triggered by hypoxia, myocardial ischaemia or heart failure. It usually terminates spontaneously when the precipitating factors have been eliminated, but digoxin or  $\beta$ -blockers can be prescribed to control the heart rate if necessary.

**Peripheral arterial disease**

Peripheral arterial disease (PAD) has been estimated to affect about 20% of individuals aged 55–75 years in the UK. Only 25% of patients present with symptoms, the commonest of which is intermittent claudication (IC). About 1%–2% of patients with IC per year progress to a point where amputation or revascularisation is required. However, the annual mortality rate of people with IC is about 5%, which is 2–3 times higher than the general population of the same age and sex. The cause of death is typically an MI or stroke, reflecting the fact that IC nearly always occurs in association with widespread atherosclerosis.

**Pathogenesis**

In developed countries, almost all PAD is due to atherosclerosis and the risk factors are the same as described in patients with CAD. As with CAD, plaque rupture is responsible for the most serious manifestations of PAD, and not infrequently occurs in a plaque that hitherto has been asymptomatic. The clinical manifestations depend on the anatomical site, the presence or absence of a collateral supply, the speed of onset and the mechanism of injury (Box 16.55). Approximately 5%–10% of patients with PAD have diabetes but this proportion increases to 30%–40% in those with severe limb ischaemia. The mechanism of PAD in diabetes is atheroma affecting the medium to large-sized arteries rather than obstructive microangiopathy and so diabetes is not a contraindication to lower limb revascularisation. Nevertheless, patients with diabetes and PAD pose a number of particular problems (Box 16.56).

**16.55 Factors influencing the clinical manifestations of peripheral arterial disease (PAD)****Anatomical site****Cerebral circulation**

- TIA, amaurosis fugax, vertebrobasilar insufficiency

**Renal arteries**

- Hypertension and renal failure

**Mesenteric arteries**

- Mesenteric angina, acute intestinal ischaemia

**Limbs (legs >> arms)**

- Intermittent claudication, critical limb ischaemia, acute limb ischaemia

**Collateral supply**

- In a patient with a complete circle of Willis, occlusion of one carotid artery may be asymptomatic
- In a patient without cross-circulation, stroke is likely

**Speed of onset**

- Where PAD develops slowly, a collateral supply will develop
- Sudden occlusion of a previously normal artery is likely to cause severe distal ischaemia

**Mechanism of injury****Haemodynamic**

- Plaque must reduce arterial diameter by 70% ('critical stenosis') to reduce flow and pressure at rest. On exertion a moderate stenosis may become 'critical'. This mechanism tends to have a relatively benign course due to collateralisation

**Thrombotic**

- Occlusion of a long-standing critical stenosis may be asymptomatic due to collateralisation. However, acute rupture and thrombosis of a non-haemodynamically significant plaque usually has severe consequences

**Atheroembolic**

- Symptoms depend on embolic load and size
- Carotid (TIA, amaurosis fugax or stroke) and peripheral arterial (blue toe/finger syndrome) plaque are common examples

**Thromboembolic**

- Usually secondary to atrial fibrillation
- The consequences are usually dramatic, as the thrombus load is often large and occludes a major, previously healthy, non-collateralised artery suddenly and completely

(TIA = transient ischaemic attack)

**Clinical features**

Symptomatic PAD affects the legs about eight times more commonly than the arms. Several locations may be affected, including the aortoiliac vessels, the femoropopliteal vessels and the infrapopliteal vessels. One or more of these segments may be affected in a variable and asymmetric manner. In the arm, the subclavian artery is the most common site of disease. Peripheral artery disease can present clinically in a variety of ways, as detailed below.

**Intermittent claudication**

This is the most common presentation of PAD affecting the lower limbs. It is characterised by ischaemic pain affecting the muscles of the leg. The pain is usually felt in the calf because the disease most commonly affects the superficial femoral artery, but it may be felt in the thigh or buttock if the iliac arteries are involved. Typically, the pain comes on after walking, often once a specific distance has been covered, and rapidly subsides on resting. Resumption of walking leads to a return of the pain. Most patients describe a cyclical pattern of exacerbation and resolution due to the progression of disease and the subsequent development of collaterals. When PAD affects the upper limbs, arm claudication may occur, although this is uncommon.

**Critical limb ischaemia**

Critical limb ischaemia (CLI) is defined as rest pain requiring opiate analgesia, or ulceration or gangrene that has been present for more than

16.56 Peripheral vascular disease in diabetes	
Feature	Difficulty
<b>Arterial calcification</b>	Spuriously high ABPI due to incompressible ankle vessels. Inability to clamp arteries for the purposes of bypass surgery. Resistant to angioplasty
<b>Immunocompromise</b>	Prone to rapidly spreading cellulitis, gangrene and osteomyelitis
<b>Multisystem arterial disease</b>	Coronary and cerebral arterial disease increase the risks of intervention
<b>Distal disease</b>	Diabetic vascular disease has a predilection for the calf vessels. Although vessels in the foot are often spared, performing a satisfactory bypass or angioplasty to these small vessels is a technical challenge
<b>Sensory neuropathy</b>	Even severe ischaemia and/or tissue loss may be completely painless. Diabetic patients often present late with extensive destruction of the foot. Loss of proprioception leads to abnormal pressure loads and worsens joint destruction (Charcot joints)
<b>Motor neuropathy</b>	Weakness of the long and short flexors and extensors leads to abnormal foot architecture, abnormal pressure loads, callus formation and ulceration
<b>Autonomic neuropathy</b>	Leads to a dry foot deficient in sweat that normally lubricates the skin and is antibacterial. Scaling and fissuring create a portal of entry for bacteria. Abnormal blood flow in the bones of the ankle and foot may also contribute to osteopenia and bony collapse

(ABPI = ankle-brachial pressure index)

2 weeks, in the presence of an ankle BP of less than 50 mmHg. The typical progression of symptoms in CLI is summarised in Fig. 16.70. Rest pain only, with ankle pressures above 50 mmHg, is known as subcritical limb ischaemia (SCLI). The term severe limb ischaemia (SLI) is used to describe the situation where either CLI and SCLI occurs. Whereas IC is usually due to single-segment plaque, SLI is always due to multilevel disease. Many patients with SLI have not previously sought medical advice, principally because they have other comorbidity that prevents them from walking to a point where IC develops. Patients with SLI are at high risk of losing their limb, and sometimes their life, in a matter of weeks or months without surgical bypass or endovascular revascularisation by angioplasty or stenting. Treatment of these patients is difficult because most are older adults with extensive and severe disease and major multisystem comorbidities.

### Acute limb ischaemia

This is most frequently caused by acute thrombotic occlusion of a pre-existing stenotic arterial segment, thromboembolism and trauma that may be iatrogenic. The typical presentation is with paralysis (inability to wiggle toes or fingers) and paraesthesia (loss of light touch over the dorsum of the foot or hand); the so-called 'Ps of acute ischaemia' (Box 16.57). These features are non-specific and inconsistently related to its severity. Pain on squeezing the calf indicates muscle infarction and impending irreversible ischaemia. All patients with suspected acutely ischaemic limbs must be discussed immediately with a vascular surgeon; a few hours can make the difference between death/amputation and complete recovery of limb function. If there are no contraindications (acute aortic dissection or trauma, particularly head injury), an intravenous bolus of heparin (3000–5000 U) should be administered to limit propagation of thrombus and protect the collateral circulation. Distinguishing thrombosis from embolism is frequently difficult but is important because

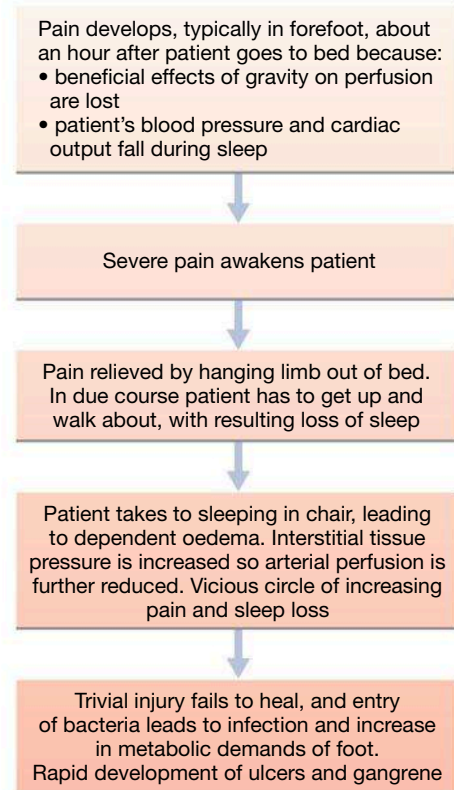

Fig. 16.70 Progressive night pain and the development of tissue loss.

16.57 Symptoms and signs of acute limb ischaemia	
Symptoms/signs	Comment
<b>Pain</b>	May be absent in complete acute ischaemia, and can be present in chronic ischaemia
<b>Pallor</b>	
<b>Pulselessness</b>	
<b>Perishing cold</b>	Unreliable, as the ischaemic limb takes on the ambient temperature
<b>Paraesthesia</b>	Important features of impending irreversible ischaemia
<b>Paralysis</b>	

treatment and prognosis are different (Box 16.58). Acute limb ischaemia due to thrombosis in situ can usually be treated medically in the first instance with intravenous heparin (target activated partial thromboplastin time (APTT) 2.0–3.0), antiplatelet agents, high-dose statins, intravenous fluids to avoid dehydration, correction of anaemia, oxygen and sometimes prostaglandins, such as iloprost. Embolism will normally result in extensive tissue necrosis within 6 hours unless the limb is revascularised. The indications for thrombolysis, if any, remain controversial. Irreversible ischaemia mandates early amputation or palliative care.

### Atheroembolism

This may be a presenting feature of PAD affecting the subclavian arteries. The presentation is with blue fingers, which are due to small emboli lodging in digital arteries. This may be confused with Raynaud's phenomenon but the symptoms of atheroembolism are typically unilateral rather than bilateral as in Raynaud's.

### Subclavian steal

This can be a feature of PAD affecting the upper limbs. The presentation is with dizziness, cortical blindness and/or collapse, which occurs when the arm is used and is thought to be caused by diversion (or steal) of blood from the brain to the limbs via the vertebral artery.

16.58 Distinguishing features of embolism and thrombosis in peripheral arteries		
Clinical features	Embolism	Thrombosis
<b>Severity</b>	Complete (no collaterals)	Incomplete (collaterals)
<b>Onset</b>	Seconds or minutes	Hours or days
<b>Limb</b>	Leg 3:1 arm	Leg 10:1 arm
<b>Multiple sites</b>	Up to 15%	Rare
<b>Embolic source</b>	Present (usually atrial fibrillation)	Absent
<b>Previous claudication</b>	Absent	Present
<b>Palpation of artery</b>	Soft, tender	Hard, calcified
<b>Bruits</b>	Absent	Present
<b>Contralateral leg pulses</b>	Present	Absent
<b>Diagnosis</b>	Clinical	Angiography
<b>Treatment</b>	Embolectomy, warfarin	Medical, bypass, thrombolysis
<b>Prognosis</b>	Loss of life > loss of limb	Loss of limb > loss of life

### Investigations

The presence and severity of ischaemia can usually be determined by clinical examination (Box 16.59) and measurement of the ankle-brachial pressure index (ABPI), which is the ratio between the highest systolic ankle and brachial blood pressures. In health, the ABPI is over 1.0, in IC typically 0.5–0.9 and in CLI usually less than 0.5. Further investigation with duplex ultrasonography, MRI or CT with intravenous injection of contrast agents may be used to characterise the sites of involvement further. Intra-arterial digital subtraction angiography (IA-DSA) is used for those undergoing endovascular revascularisation. Other investigations should look for evidence of treatable secondary causes including a full blood count (for thrombocythaemia), lipids (for hyperlipidaemia) and blood glucose (for diabetes mellitus).

### Management

Key elements of medical management are summarised in Box 16.60. This consists of smoking cessation (if applicable), taking regular exercise, antiplatelet therapy with low-dose aspirin or clopidogrel, therapy with a statin, and treatment of coexisting disease such as diabetes, hypertension or polycythaemia. Recent evidence suggests that low-dose factor Xa inhibition (rivaroxaban 2.5 mg twice daily) when used in combination with aspirin can further reduce cardiovascular events, ischaemic limb events and mortality in patients with PAD although there is a modest increase in bleeding risk. The peripheral vasodilator cilostazol has been shown to improve walking distance and should be considered in patients who do not respond adequately to best medical therapy. Intervention with angioplasty, stenting, endarterectomy or bypass is usually considered only after medical therapy has been given for at least 6 months to effect symptomatic improvement, and then just in patients who are severely disabled or whose livelihood is threatened by their disability. Subclavian artery disease is usually treated by means of angioplasty and stenting, as carotid-subclavian bypass surgery can be technically difficult.

Some considerations specific to atherosclerotic vascular disease in old age are listed in Box 16.61.

### Buerger's disease

Buerger's disease or thromboangiitis obliterans is an inflammatory disease of the arteries that is distinct from atherosclerosis and usually presents in young (20–30 years) male smokers. It is most common in those from the Mediterranean and North Africa. It characteristically affects distal

16.59 Clinical features of chronic lower limb ischaemia	
•	Pulses: diminished or absent
•	Bruits: denote turbulent flow but bear no relationship to the severity of the underlying disease
•	Reduced skin temperature
•	Pallor on elevation and rubor on dependency (Buerger's sign)
•	Superficial veins that fill sluggishly and empty ('gutter') on minimal elevation
•	Muscle-wasting
•	Skin and nails: dry, thin and brittle
•	Loss of hair

Box 16.60 Medical therapy for peripheral arterial disease	
•	Smoking cessation
•	Regular exercise (30 mins of walking, three times per week)
•	Antiplatelet agent (aspirin 75 mg or clopidogrel 75 mg daily)
•	Consider low-dose factor Xa inhibitor (rivaroxaban 2.5 mg twice daily)
•	Reduction of cholesterol: statins
•	Diet and weight loss
•	Diagnosis and treatment of diabetes mellitus
•	Diagnosis and treatment of associated conditions:
	Hypertension
	Anaemia
	Heart failure

16.61 Atherosclerotic vascular disease in old age	
•	<b>Prevalence:</b> related almost exponentially to age in developed countries, although atherosclerosis is not considered part of the normal ageing process.
•	<b>Statin therapy:</b> no role in the primary prevention of atherosclerotic disease in those over 75 years but reduces cardiovascular events in those with established vascular disease, albeit with no reduction in overall mortality.
•	<b>Presentation in the frail:</b> frequently with advanced multisystem arterial disease, along with a host of other comorbidities.
•	<b>Intervention in the frail:</b> in those with extensive disease and limited life expectancy, the risks of surgery may outweigh the benefits, and symptomatic care is all that should be offered.

arteries, giving rise to claudication in the feet or rest pain in the fingers or toes. Wrist and ankle pulses are absent but brachial and popliteal pulses are present. It may also affect the veins, giving rise to superficial thrombophlebitis. It often remits if the patient stops smoking. Symptomatic therapy with vasodilators such as prostacyclin and calcium antagonists or sympathectomy may also be helpful. Major limb amputation is the most frequent outcome if patients continue to smoke.

### Raynaud's syndrome

This common disorder affects 5%–10% of young women aged 15–30 years in temperate climates. It does not progress to ulceration or infarction, and significant pain is unusual. The underlying cause is unclear and no investigation is necessary. The patient should be reassured and advised to avoid exposure to cold. Usually, no other treatment is required, although vasodilators such as nifedipine can may be helpful if symptoms are troublesome. More severe Raynaud's syndrome can also occur in association with digital ulceration in patients with connective tissue disease.

## Diseases of the aorta

### Aortic aneurysm

Aortic aneurysm is defined as an abnormal dilatation of the aortic lumen. The most common site is the infrarenal abdominal aorta. The suprarenal abdominal aorta and a variable length of the descending thoracic aorta

**Fig. 16.71** Types of aortic disease and their complications. **A** Types of aortic aneurysm. **B** Types of aortic dissection.

may be affected in 10%–20% of patients but the ascending aorta is usually spared. Abdominal aortic aneurysms (AAAs) affect men three times more commonly than women and are estimated to occur in about 5% of men over the age of 60 years.

### Pathogenesis

The most common cause of aortic aneurysm is atherosclerosis, the risk factors for which have previously been described. However, smoking and hypertension predominate with 90%–95% of patients having one or both of these risk factors. There also appears to be an additional and specific genetic component since aortic aneurysm tends to run in families. This may explain in part why only some patients with risk factors for atheroma develop aneurysmal disease. Marfan syndrome is an inherited disorder of connective tissue that is associated with aortic aneurysm and aortic dissection.

### Clinical features

The clinical presentation is dependent on the site of the aneurysm. Thoracic aneurysms may typically present with acute severe chest pain but other features, including aortic regurgitation, compressive symptoms such as stridor (trachea, bronchus), hoarseness (recurrent laryngeal nerve) and superior vena cava syndrome, may occur (Fig. 16.71A). If the aneurysm erodes into an adjacent structure, such as the oesophagus or

bronchus, the presentation may be with massive bleeding. AAAs affect the infrarenal segment of the aorta. They can present in a number of ways, as summarised in Box 16.62. The usual age at presentation is 65–75 years for elective presentations and 75–85 years for emergency presentations.

### Investigations

Ultrasound is the best way of establishing the diagnosis of an abdominal aneurysm and of following up patients with asymptomatic aneurysms that are not yet large enough to warrant surgical repair. In the UK, a national screening programme for men over 65 years of age has been introduced using ultrasound scanning. For every 10000 men scanned, 65 ruptures are prevented and 52 lives saved. CT provides more accurate information about the size and extent of the aneurysm, the surrounding structures and the presence of any other intra-abdominal pathology. It is the standard pre-operative investigation but is not suitable for surveillance because of the high cost and radiation dose.

### Management

The risks of surgery generally outweigh the risks of rupture until an asymptomatic AAA has reached a maximum of 5.5cm in diameter. All symptomatic AAAs should be considered for repair, not only to rid the patient of symptoms but also because pain often predates rupture. Distal

### 16.62 Abdominal aortic aneurysm (AAA): common presentations

#### Incidental

- On physical examination, plain X-ray or, most commonly, abdominal ultrasound
- Even large AAAs can be difficult to feel, so many remain undetected until they rupture
- Studies are currently under way to determine whether screening will reduce the number of deaths from rupture

#### Pain

- In the central abdomen, back, loin, iliac fossa or groin

#### Thromboembolic complications

- Thrombus within the aneurysm sac may be a source of emboli to the lower limbs
- Less commonly, the aorta may undergo thrombotic occlusion

#### Compression

- Surrounding structures such as the duodenum (obstruction and vomiting) and the inferior vena cava (oedema and deep vein thrombosis)

#### Rupture

- Into the retroperitoneum, the peritoneal cavity or surrounding structures (most commonly the inferior vena cava, leading to an aortocaval fistula)

embolisation is a strong indication for repair, regardless of size, because otherwise limb loss is common. Most patients with a ruptured AAA do not survive to reach hospital, but if they do and surgery is thought to be appropriate, there must be no delay in getting them to the operating theatre to clamp the aorta.

Open AAA repair has been the treatment of choice in both the elective and the emergency settings, and entails replacing the aneurysmal segment with a prosthetic (usually Dacron) graft. The 30-day mortality for this procedure is approximately 5%–8% for elective asymptomatic AAA, 10%–20% for emergency symptomatic AAA and 50% for ruptured AAA. However, patients who survive the operation to leave hospital have a long-term survival approaching that of the normal population. Increasingly, endovascular aneurysm repair (EVAR), using a stent graft introduced via the femoral arteries in the groin, is replacing open surgery. It is cost-effective and likely to become the treatment of choice for infrarenal AAA. It is possible to treat many suprarenal and thoraco-abdominal aneurysms by EVAR too. If the aneurysm is secondary to Marfan syndrome, treatment with  $\beta$ -blockers reduces the rate of aortic dilatation and the risk of rupture. Elective replacement of the ascending aorta may also be considered in patients with evidence of progressive aortic dilatation but carries a mortality of 5%–10%.

## Aortic dissection

Aortic dissection occurs when a breach in the integrity of the aortic wall allows arterial blood to enter the media, which is then split into two layers, creating a false lumen alongside the existing or true lumen (Fig. 16.71B). The aortic valve may be damaged and the branches of the aorta may be compromised. Typically, the false lumen eventually re-enters the true lumen, creating a double-barrelled aorta, but it may also rupture into the left pleural space or pericardium with fatal consequences. The peak incidence is in the sixth and seventh decades but dissection can occur in younger patients, usually in association with Marfan syndrome, pregnancy or trauma; men are affected twice as frequently as women.

### Pathogenesis

The primary event is often a spontaneous or iatrogenic tear in the intima of the aorta; multiple tears or entry points are common. Other dissections are triggered by primary haemorrhage in the media of the aorta, which then ruptures through the intima into the true lumen. This form of spontaneous bleeding from the vasa vasorum is sometimes confined to the aortic wall, when it may present as a painful intramural haematoma.

### 16.63 Risk factors for aortic dissection

- Hypertension (in 80%)
- Atherosclerosis
- Coarctation
- Genetic:
  - Marfan syndrome
  - Ehlers–Danlos syndrome
- Fibromuscular dysplasia
- Previous cardiac surgery:
  - CABG
  - Aortic valve replacement
- Pregnancy (usually third trimester)
- Trauma
- Iatrogenic:
  - Cardiac catheterisation
  - Intra-aortic balloon pumping

(CABG = coronary artery bypass grafting)

**Fig. 16.72** Sagittal view of an MRI scan from a patient with long-standing aortic dissection, illustrating a biluminal aorta. There is sluggish flow in the false lumen (FL), accounting for its grey appearance. (TL = true lumen)

Aortic disease and hypertension are the most important aetiological factors but other conditions may also be implicated (Box 16.63). Chronic dissections may lead to aneurysmal dilatation of the aorta, and thoracic aneurysms may be complicated by dissection. It can therefore be difficult to identify the primary pathology.

Aortic dissection is classified anatomically and for management purposes into type A and type B (see Fig. 16.71B), involving or sparing the ascending aorta, respectively. Type A dissections account for two-thirds of cases and frequently also extend into the descending aorta.

### Clinical features

Involvement of the ascending aorta typically gives rise to anterior chest pain, and involvement of the descending aorta to intrascapular back pain. The pain is typically described as ‘tearing’ and very abrupt in onset; collapse is common. Unless there is major haemorrhage, the patient is invariably hypertensive. There may be asymmetry of the brachial, carotid or femoral pulses and signs of aortic regurgitation. Occlusion of aortic branches may cause MI (coronary), stroke (carotid), paraplegia (spinal), mesenteric infarction with an acute abdomen (coeliac and superior mesenteric), renal failure (renal) and acute limb (usually leg) ischaemia.

### Investigations

The investigations of choice are CT or MR angiography (Figs. 16.72 and 16.73), both of which are highly specific and sensitive. A chest X-ray should be performed. It characteristically shows broadening of the upper mediastinum and distortion of the aortic ‘knuckle’ but these findings are absent in 10% of cases. A left-sided pleural effusion is common. The

**Fig. 16.73** Images from a patient with an acute type B aortic dissection that had ruptured into the left pleural space and was repaired by deploying an endoluminal stent graft. **A** CT scan illustrating an intimal flap (arrow) in the descending aorta and a large pleural effusion. **B** Aortogram illustrating aneurysmal dilatation; a stent graft has been introduced from the right femoral artery and is about to be deployed. **C** CT scan after endoluminal repair. The pleural effusion has been drained but there is a haematoma around the descending aorta. **D** Aortogram illustrating the stent graft. **E** Three-dimensional reconstruction of an aortic stent graft. (E) Courtesy of Dr T. Lawton.

**Fig. 16.74** Echocardiograms from a patient with a chronic aortic dissection. Colour-flow Doppler shows flow from the larger false lumen (FL) into the true lumen (TL), characteristic of chronic disease.

ECG may show left ventricular hypertrophy in patients with hypertension or, rarely, changes of acute MI (usually inferior). Doppler echocardiography may show aortic regurgitation, a dilated aortic root and, occasionally, the flap of the dissection. TOE is particularly helpful because transthoracic echocardiography can provide images of the first 3–4 cm of the ascending aorta only (Fig. 16.74).

### Management

The early mortality of acute dissection is approximately 1%–5% per hour and so treatment is urgently required. Initial management comprises pain control and antihypertensive treatment. Type A dissections require emergency surgery to replace the ascending aorta. Type B dissections are treated medically unless there is actual or impending external rupture, or vital organ (gut, kidneys) or limb ischaemia, as the morbidity and mortality associated with surgery are very high. The aim of medical management is to maintain a mean arterial pressure (MAP) of 60–75 mmHg to reduce the force of the ejection of blood from the

LV. First-line therapy is with  $\beta$ -blockers; the additional  $\alpha$ -blocking properties of labetalol make it especially useful. Rate-limiting calcium channel blockers, such as verapamil or diltiazem, are used if  $\beta$ -blockers are contraindicated. Sodium nitroprusside may be considered if these fail to control BP adequately.

Percutaneous or minimal access endoluminal repair is sometimes possible and involves either ‘fenestrating’ (perforating) the intimal flap so that blood can return from the false to the true lumen (so decompressing the former), or implanting a stent graft placed from the femoral artery (see Fig. 16.73).

### Aortitis

Syphilis is a rare cause of aortitis that characteristically produces saccular aneurysms of the ascending aorta containing calcification. Other conditions that may be associated with aortitis include Takayasu’s disease, giant cell arteritis and axial spondyloarthritis, all of which are discussed in more detail in Chapter 26.

### Marfan syndrome

Marfan syndrome is a rare (0.02% of the population) inherited autosomal dominant disorder of connective tissue with a high risk of aortic aneurysm and dissection. It is caused by mutations of the *FBN1* gene which leads to deficiency of fibrillin-1 leading to reduced microfibril formation. This disrupts the mechanical integrity of connective tissue, giving rise to a wide range of clinical features.

### Clinical features

Aortic dissection and aneurysm are the most serious complications of Marfan syndrome but many other clinical manifestations may be observed. These include aortic and mitral valve regurgitation; skin laxity and joint hypermobility; abnormalities of body habitus, including long arms, legs and fingers (arachnodactyly), scoliosis, pectus excavatum and a high-arched palate; ocular abnormalities, such as lens dislocation and retinal detachment; and an increased risk of pneumothorax.

## Investigations

The diagnosis is usually suspected on the basis of the characteristic clinical features and can be confirmed by genetic testing. Imaging by chest X-ray may reveal evidence of aortic dilatation but echocardiography is more sensitive and can also demonstrate valvular disease, if present. Patients with Marfan syndrome should undergo serial monitoring of the aortic root by echocardiography; if evidence of dilatation is observed, then elective surgery should be considered.

## Management

Treatment with  $\beta$ -blockers or angiotensin receptor blockers may reduce the risk of aortic dilatation and should be given in all patients with Marfan syndrome. Activities that are associated with increases in cardiac output are best avoided. Surgery to replace the aortic root can be performed in patients with progressive aortic dilatation.

## Coarctation of the aorta

Coarctation of the aorta is the term used to describe a narrowing distal to the origin of the left subclavian artery. It is most commonly due to congenital heart disease, but narrowing of the aorta leading to similar symptoms can occur in other conditions such as Takayasu's arteritis and trauma. Diagnosis and management of coarctation are discussed later in this chapter in the section on congenital heart disease.

## Hypertension

The risk of cardiovascular diseases such as stroke and CAD is closely related to levels of BP, which follows a normal distribution in the general population. Although there is no specific cut-off above which the risk of cardiovascular risk suddenly increases, the diagnosis of hypertension is made when systolic and diastolic values rise above a specific threshold that corresponds to the level of BP at which the risk of cardiovascular complications and benefits of treatment outweigh the treatment costs and potential side-effects of therapy. The British Hypertension Society classification, provided in Box 16.64, defines mild hypertension as existing when the BP is above 140/90 mmHg. Similar thresholds have been published by the European Society of Hypertension and the WHO–International Society of Hypertension. The cardiovascular risks associated with high BP depend on the combination of risk factors in an individual, such as age, sex, weight, physical activity, smoking, family history, serum cholesterol, diabetes mellitus and pre-existing vascular disease.

16.64 Definition of hypertension		
Category	Systolic blood pressure (mmHg)	Diastolic blood pressure (mmHg)
<b>Blood pressure</b>		
Optimal	< 120	< 80
Normal	< 130	85
High normal	130–139	85–89
<b>Hypertension</b>		
Grade 1 (mild)	140–159	90–99
Grade 2 (moderate)	160–179	100–109
Grade 3 (severe)	$\geq$ 180	> 110
<b>Isolated systolic hypertension</b>		
Grade 1	140–159	< 90
Grade 2	$\geq$ 160	< 90

## Pathogenesis

Many factors may contribute to the regulation of BP and the development of hypertension, including renal dysfunction, peripheral resistance, vessel tone, endothelial dysfunction, autonomic tone, insulin resistance and neurohumoral factors. In more than 95% of cases, no specific underlying cause of hypertension can be found. Such patients are said to have essential hypertension. Hypertension is more common in some ethnic groups, particularly African Americans and Japanese, and approximately 40%–60% is explained by genetic factors. Age is a strong risk factor in all ethnic groups. Important environmental factors include a high salt intake, heavy consumption of alcohol, obesity and lack of exercise. Impaired intrauterine growth and low birth weight are associated with an increased risk of hypertension later in life. In about 5% of cases, hypertension is secondary to a specific disease, as summarised in Box 16.65.

Hypertension has a number of adverse effects on the cardiovascular system. In larger arteries (> 1 mm in diameter), the internal elastic lamina is thickened, smooth muscle is hypertrophied and fibrous tissue is deposited. The vessels dilate and become tortuous, and their walls become less compliant. In smaller arteries (< 1 mm), hyaline arteriosclerosis occurs in the wall, the lumen narrows and aneurysms may develop. Widespread atheroma develops and may lead to coronary and cerebrovascular disease, particularly if other risk factors are present. These structural changes in the vasculature often perpetuate and aggravate hypertension by increasing peripheral vascular resistance and reducing renal blood flow, thereby activating the renin–angiotensin–aldosterone axis.

## Clinical features

Hypertension is usually asymptomatic until the diagnosis is made at a routine physical examination or when a complication arises. Reflecting this fact, a BP check is advisable every 5 years in adults over 40 years of age to pick up occult hypertension. Sometimes clinical features may be observed that can give a clue to the underlying cause of hypertension. These include radio-femoral delay in patients with coarctation of the aorta (see Fig. 16.93), enlarged kidneys in patients with polycystic kidney disease, abdominal bruits that may suggest renal artery stenosis and the characteristic facies and habitus of Cushing's syndrome (see Box 16.65). Examination may also reveal evidence of risk factors for hypertension, such as central obesity and hyperlipidaemia. Other signs may be observed that are due to the complications of hypertension. These include signs of left ventricular hypertrophy, accentuation of the aortic component of the second heart sound, and a fourth heart sound.

## 16.65 Causes of secondary hypertension

### Alcohol

### Obesity

### Pregnancy

### Renal disease

- Parenchymal renal disease, particularly glomerulonephritis
- Renal vascular disease
- Polycystic kidney disease

### Endocrine disease

- Pheochromocytoma
- Cushing's syndrome
- Primary hyperaldosteronism (Conn syndrome)
- Glucocorticoid-suppressible hyperaldosteronism
- Hyperparathyroidism
- Acromegaly
- Primary hypothyroidism
- Thyrotoxicosis
- Congenital adrenal hyperplasia due to 11 $\beta$ -hydroxylase or 17 $\alpha$ -hydroxylase deficiency
- Liddle syndrome
- 11 $\beta$ -hydroxysteroid dehydrogenase deficiency

### Drugs

### Coarctation of the aorta

**Fig. 16.75 Retinal changes in hypertension.** **A** Grade 4 hypertensive retinopathy showing swollen optic disc, retinal haemorrhages and multiple cotton wool spots (infarcts). **B** Central retinal vein thrombosis showing swollen optic disc and widespread fundal haemorrhage, commonly associated with systemic hypertension. (A and B) Courtesy of Dr B. Cullen.

AF is common and may be due to diastolic dysfunction caused by left ventricular hypertrophy or the effects of CAD.

Severe hypertension can cause left ventricular failure in the absence of CAD, particularly when there is an impairment of renal function. The optic fundi are often abnormal (see Fig. 16.75 below) and there may be evidence of generalised atheroma or specific complications, such as aortic aneurysm, PAD or stroke. Examination of the optic fundi reveals a gradation of changes linked to the severity of hypertension; fundoscopy can provide an indication of the arteriolar damage occurring elsewhere (Box 16.66). ‘Cotton wool’ exudates are associated with retinal ischaemia or infarction, and fade in a few weeks (Fig. 16.75A). ‘Hard’ exudates (small, white, dense deposits of lipid) and microaneurysms (‘dot’ haemorrhages) are more characteristic of diabetic retinopathy (see Fig. 30.12A). Hypertension is also associated with central retinal vein thrombosis (Fig. 16.75B).

### Investigations

A decision to embark on antihypertensive therapy effectively commits the patient to life-long treatment, so readings must be as accurate as possible. The objectives are to:

- confirm the diagnosis by obtaining accurate, representative BP measurements
- identify contributory factors and any underlying causes
- assess other risk factors and quantify cardiovascular risk
- detect any complications that are already present
- identify comorbidity that may influence the choice of antihypertensive therapy.

### Blood pressure measurements

Measurements should be made to the nearest 2mmHg, in the sitting position with the arm supported, and repeated after 5 minutes’ rest if

## 16.66 Hypertensive retinopathy

### Grade 1

- Arteriolar thickening, tortuosity and increased reflectiveness (‘silver wiring’)

### Grade 2

- Grade 1 plus constriction of veins at arterial crossings (‘arteriovenous nipping’)

### Grade 3

- Grade 2 plus evidence of retinal ischaemia (flame-shaped or blot haemorrhages and ‘cotton wool’ exudates)

### Grade 4

- Grade 3 plus papilloedema

## 16.67 How to measure blood pressure

- Use a machine that has been validated, well maintained and properly calibrated
- Measure sitting BP routinely, with additional standing BP in older and diabetic patients and those with possible postural hypotension; rest the patient for 2 minutes
- Remove tight clothing from the arm
- Support the arm at the level of the heart
- Use a cuff of appropriate size (the bladder must encompass more than two-thirds of the arm)
- Lower the pressure slowly (2 mmHg per second)
- Read the BP to the nearest 2 mmHg
- Use phase V (disappearance of sounds) to measure diastolic BP
- Take two measurements at each visit

the first recording is high (Box 16.67). To avoid spuriously high readings in obese subjects, the cuff should contain a bladder that encompasses at least two-thirds of the arm circumference. Exercise, anxiety, discomfort and unfamiliar surroundings can all lead to a transient rise in BP. Sphygmomanometry, particularly when performed by a doctor, can cause a transient elevation in BP, which has been termed ‘white coat’ hypertension. It has been estimated that up to 20% of patients with a raised BP at outpatient clinics have a normal BP when it is recorded by automated devices used at home. The risk of cardiovascular disease in these patients is less than that in patients with sustained hypertension but greater than that in normotensive subjects. If clinic BP measurements show borderline levels or if white coat hypertension is suspected, then ambulatory measurement or home-based measurements are of value in confirming the diagnosis.

### Ambulatory blood pressure measurements

A series of automated ambulatory BP measurements obtained over 24 hours or longer provide a better profile than a limited number of clinic readings and correlate more closely with evidence of target organ damage than casual BP measurements. Treatment thresholds and targets (see Box 16.71) must be adjusted downwards, because ambulatory BP readings are systematically lower (approximately 12/7 mmHg) than clinic measurements. The average ambulatory daytime (not 24-hour or night-time) BP should be used to guide management decisions.

### Home blood pressure measurements

Patients can measure their own BP at home using a range of commercially available semi-automatic devices. The value of such measurements is dependent on the environment and timing of the readings measured. Home or ambulatory BP measurements are particularly helpful in patients with unusually labile BP, those with refractory hypertension, those who may have symptomatic hypotension, and those in whom white coat hypertension is suspected.

### 16.68 Investigation of hypertension

- Urinalysis for blood, protein and glucose
- Blood urea, electrolytes and creatinine  
Hypokalaemic alkalosis may indicate primary hyperaldosteronism but is usually due to diuretic therapy
- Blood glucose
- Serum total and HDL cholesterol
- Thyroid function tests
- 12-lead ECG (left ventricular hypertrophy, coronary artery disease)

(HDL = high-density lipoprotein)

### 16.69 Specialised investigation of hypertension

- Chest X-ray: to detect cardiomegaly, heart failure, coarctation of the aorta
- Ambulatory BP recording: to assess borderline or 'white coat' hypertension
- Echocardiogram: to detect or quantify left ventricular hypertrophy
- Renal ultrasound: to detect possible renal disease
- Renal angiography: to detect or confirm the presence of renal artery stenosis
- Urinary catecholamines: to detect possible pheochromocytoma
- Urinary cortisol and dexamethasone suppression test: to detect possible Cushing's syndrome
- Plasma renin activity and aldosterone: to detect possible primary aldosteronism

#### Other investigations

All hypertensive patients should undergo a limited number of investigations (Box 16.68) but additional investigations are appropriate in patients younger than 40 years of age or those with resistant hypertension (Box 16.69). Family history, lifestyle (exercise, salt intake, smoking habit) and other risk factors should also be recorded. A careful history will identify those patients with drug- or alcohol-induced hypertension and may elicit the symptoms of other causes of secondary hypertension, such as pheochromocytoma (paroxysmal headache, palpitation and sweating) or complications such as CAD.

#### Management

The objective of antihypertensive therapy is to reduce the incidence of adverse cardiovascular events, particularly CAD, stroke and heart failure. Randomised controlled trials have demonstrated that antihypertensive therapy can reduce the incidence of stroke and, to a lesser extent, CAD. The relative benefits (approximately 30% reduction in risk of stroke and 20% reduction in risk of CAD) are similar in all patient groups, so the absolute benefit of treatment (total number of events prevented) is greatest in those at highest risk. For example, to extrapolate from the Medical Research Council (MRC) Mild Hypertension Trial (1985), 566 young patients would have to be treated with bendroflumethiazide for 1 year to prevent 1 stroke, while in the MRC trial of antihypertensive treatment in older adults (1992), 1 stroke was prevented for every 286 patients treated for 1 year.

A formal estimate of absolute cardiovascular risk, which takes account of all the relevant risk factors, may help to determine whether the likely benefits of therapy will outweigh its costs and hazards. Several online risk calculators are available for this purpose, such as the Joint British Societies risk calculator (<http://www.jbs3risk.com>) and see 'Further information'). Most of the excess morbidity and mortality associated with hypertension are attributable to CAD and many treatment guidelines are therefore based on estimates of the 10-year CAD risk. Total cardiovascular risk can be estimated by multiplying CAD risk by 4/3 (i.e. if CAD risk is 30%, cardiovascular risk is 40%). The value of this approach can be illustrated by comparing the two hypothetical cases on page 426.

#### Intervention thresholds

Systolic BP and diastolic BP are both powerful predictors of cardiovascular risk. The British Hypertension Society management guidelines use

both readings, and treatment should be initiated if they exceed the given threshold (Fig. 16.76).

Patients with diabetes or cardiovascular disease are at particularly high risk and the threshold for initiating antihypertensive therapy is therefore lower ( $\leq 130/80$ ) in these patient groups. The thresholds for treatment in older adults are the same as for younger patients (Box 16.70).

#### Treatment targets

The optimum BP for reduction of major cardiovascular events has been found to be 139/83 mmHg, and even lower in patients with diabetes mellitus. The targets suggested by the British Hypertension Society (Box 16.71) are ambitious. Primary care strategies have been devised to improve screening and detection of hypertension that, in the past, remained undetected in up to half of affected individuals. Application of new guidelines should help establish patients on appropriate treatment, and allow step-up if lifestyle modification and first-line drug therapy fail to control hypertension.

Patients taking antihypertensive therapy require follow-up at regular intervals to monitor BP, minimise side-effects and reinforce lifestyle advice.

#### Non-drug therapy

Appropriate lifestyle measures may obviate the need for drug therapy in patients with borderline hypertension, reduce the dose or the number of drugs required in patients with established hypertension, and directly reduce cardiovascular risk.

Correcting obesity, reducing alcohol intake, restricting salt intake, taking regular physical exercise and increasing consumption of fruit and vegetables can all lower BP. Moreover, stopping smoking, eating oily fish and adopting a diet that is low in saturated fat may produce further reductions in cardiovascular risk that are independent of changes in BP.

#### Drug therapy

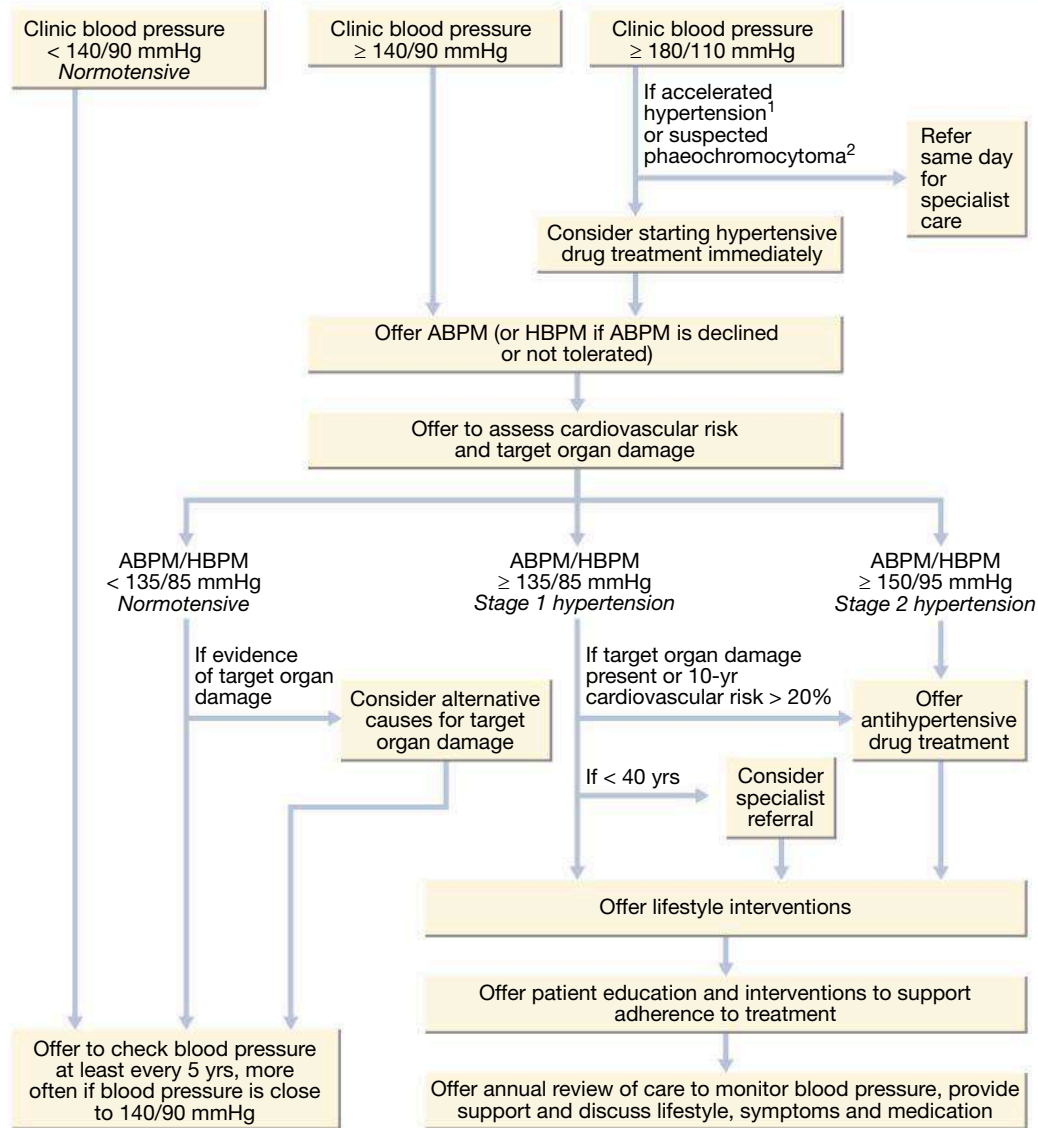

**Thiazides** The mechanism of action of these drugs is incompletely understood and it may take up to a month for the maximum effect to be observed. An appropriate daily dose is 2.5 mg bendroflumethiazide or 0.5 mg cyclopentiazide. More potent loop diuretics, such as furosemide (40 mg daily) or bumetanide (1 mg daily), have few advantages over thiazides in the treatment of hypertension, unless there is substantial renal impairment or they are used in conjunction with an ACE inhibitor.

**ACE inhibitors** ACE inhibitors (enalapril 5–40 mg daily, ramipril 5–10 mg daily or lisinopril 10–40 mg daily) are effective and usually well tolerated. They should be used with care in patients with impaired renal function or renal artery stenosis because they can reduce glomerular filtration rate and precipitate renal failure. Electrolytes and creatinine should be checked before and 1–2 weeks after commencing therapy. Side-effects include first-dose hypotension, cough, rash, hyperkalaemia and renal dysfunction.

**Angiotensin receptor blockers** ARBs (irbesartan 75–300 mg daily, valsartan 40–160 mg daily) have similar efficacy to ACE inhibitors but they do not cause cough and are better tolerated.

**Calcium channel antagonists** Amlodipine (5–10 mg daily) and nifedipine (30–90 mg daily) are effective and usually well tolerated antihypertensive drugs that are particularly useful in older people. Side-effects include flushing, palpitations and fluid retention. The rate-limiting calcium channel antagonists (diltiazem 200–500 mg daily, verapamil 240–480 mg daily in divided doses) can be useful when hypertension coexists with angina but may cause bradycardia. The main side-effect of verapamil is constipation.

**Beta-blockers** These are no longer used as first-line antihypertensive therapy, except in patients with another indication for the drug such as angina. Metoprolol (100–200 mg daily), atenolol (50–100 mg daily) and bisoprolol (5–10 mg daily), which preferentially block cardiac

**Fig. 16.76 Management of hypertension.** <sup>1</sup>Signs of papilloedema or retinal haemorrhage. <sup>2</sup>Labile or postural hypotension, headache, palpitations, pallor and diaphoresis. (ABPM = ambulatory blood pressure monitoring; HBPM = home blood pressure monitoring). Adapted from 2020 International Society of Hypertension Global Hypertension Practice Guidelines.

### 16.70 Hypertension in old age

- **Prevalence:** hypertension affects more than half of all people over the age of 60 years (including isolated systolic hypertension).
- **Risks:** hypertension is the most important risk factor for myocardial infarction, heart failure and stroke in older people.
- **Benefit of treatment:** absolute benefit from therapy is greatest in older people (at least up to age 80 years).
- **Target blood pressure:** targets may be relaxed in older people to 150/90 mmHg.
- **Tolerance of treatment:** antihypertensives are tolerated as well as in younger patients.
- **Drug of choice:** low-dose thiazides but, in the presence of coexistent disease such as gout or diabetes, other agents may be more appropriate.

$\beta_1$ -adrenoceptors, should be used rather than non-selective agents that also block  $\beta_2$ -adrenoceptors, which mediate vasodilatation and bronchodilatation.

**Combined  $\beta$ - and  $\alpha$ -blockers** Labetalol (200 mg–2.4g daily in divided doses) and carvedilol (6.25–25 mg twice daily) are combined  $\beta$ - and

### 16.71 Optimal target blood pressures<sup>1</sup>

Age	Clinic BP (mmHg)	Ambulatory or home BP (mmHg) <sup>2</sup>
< 80 years	< 140/90	< 135/85
$\geq$ 80 years	< 150/90	< 140/85

<sup>1</sup>Both systolic and diastolic values should be attained. <sup>2</sup>Average BP during waking hours.

$\alpha$ -adrenoceptor antagonists that are sometimes more effective than pure  $\beta$ -blockers. Labetalol can be used as an infusion in malignant phase hypertension (see below).

**Other vasodilators** A variety of other vasodilators may be used. These include the  $\alpha_1$ -adrenoceptor antagonists prazosin (0.5–20 mg daily in divided doses), indoramin (25–100 mg twice daily) and doxazosin (1–16 mg daily), and drugs that act directly on vascular smooth muscle, such as hydralazine (25–100 mg twice daily) and minoxidil (10–50 mg daily). Side-effects include first-dose and postural hypotension,

16.72 The influence of comorbidity on choice of antihypertensive drug therapy				
Class of drug	Compelling indications	Possible indications	Caution	Compelling contraindications
<b>α-blockers</b>	Benign prostatic hypertrophy	–	Postural hypotension, heart failure <sup>1</sup>	Urinary incontinence
<b>ACE inhibitors</b>	Heart failure Left ventricular dysfunction, post-MI or established CAD Type 1 diabetic nephropathy Secondary stroke prevention <sup>4</sup>	Chronic renal disease <sup>2</sup> Type 2 diabetic nephropathy	Renal impairment <sup>2</sup> PAD <sup>3</sup>	Pregnancy Renovascular disease <sup>2</sup>
<b>Angiotensin II receptor blockers</b>	ACE inhibitor intolerance  Type 2 diabetic nephropathy  Hypertension with left ventricular hypertrophy Heart failure in ACE-intolerant patients, after MI	Left ventricular dysfunction after MI  Intolerance of other antihypertensive drugs  Proteinuric or chronic renal disease <sup>2</sup> Heart failure	Renal impairment <sup>2</sup>  PAD <sup>3</sup>	Pregnancy
<b>β-blockers</b>	MI, angina  Heart failure <sup>5</sup>	–	Heart failure <sup>5</sup>  PAD Diabetes (except with CAD)	Asthma or chronic obstructive pulmonary disease Heart block
<b>Calcium channel blockers (dihydropyridine)</b>	Older patients, isolated systolic hypertension	Angina	–	–
<b>Calcium channel blockers (rate-limiting)</b>	Angina	Older patients	Combination with β-blockade	Atrioventricular block, heart failure
<b>Thiazides or thiazide-like diuretics</b>	Older patients, isolated systolic hypertension, heart failure, secondary stroke prevention	–	–	Gout <sup>6</sup>

<sup>1</sup>In heart failure when used as monotherapy. <sup>2</sup>ACE inhibitors or ARBs may be beneficial in chronic renal failure and renovascular disease but should be used with caution, close supervision and specialist advice when there is established and significant renal impairment. <sup>3</sup>Caution with ACE inhibitors and ARBs in PAD because of association with renovascular disease. <sup>4</sup>In combination with a thiazide or thiazide-like diuretic. <sup>5</sup>β-blockers are used increasingly to treat stable heart failure but may worsen acute heart failure. <sup>6</sup>Thiazides or thiazide-like diuretics may sometimes be necessary to control BP in people with a history of gout, ideally used in combination with allopurinol.  
(ACE = angiotensin-converting enzyme; ARBs = angiotensin II receptor blockers; CAD = coronary artery disease; MI = myocardial infarction; PAD = peripheral arterial disease)

headache, tachycardia and fluid retention. Minoxidil also causes increased facial hair and is therefore unsuitable for female patients.

**Aspirin** Antiplatelet therapy is a powerful means of reducing cardiovascular risk but may cause bleeding, particularly intracerebral haemorrhage, in a small number of patients. The benefits are thought to outweigh the risks in hypertensive patients aged 50 years or over who have well-controlled BP and either target organ damage or diabetes or a 10-year CAD risk of at least 15% (or 10-year cardiovascular disease risk of at least 20%).

**Statins** Treating hyperlipidaemia can produce a substantial reduction in cardiovascular risk. These drugs are strongly indicated in patients who have established vascular disease, or hypertension with a high (at least 10% in 10 years) risk of developing cardiovascular disease.

#### Choice of antihypertensive drug

Trials that have compared thiazides, calcium antagonists, ACE inhibitors and ARBs have not shown consistent differences in outcome, efficacy, side-effects or quality of life. Beta-blockers, which previously featured as first-line therapy in guidelines, have a weaker evidence base. The choice of antihypertensive therapy is initially dictated by the patient's age and ethnic background, although cost and convenience will influence the exact drug and preparation used. Response to initial therapy

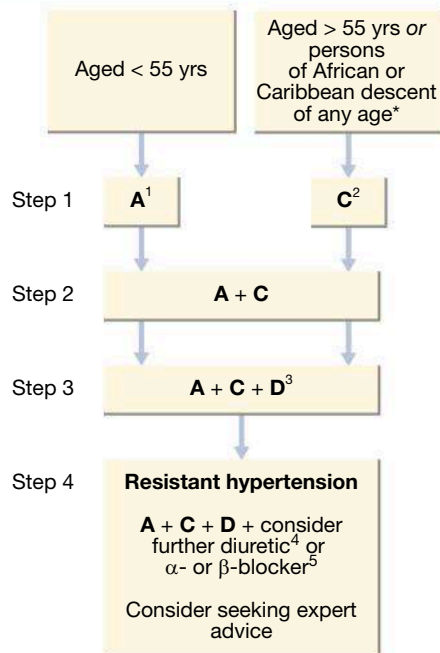

and side-effects guide subsequent treatment. Comorbid conditions also have an influence on initial drug selection (Box 16.72); for example, a β-blocker might be the most appropriate treatment for a patient with angina. Thiazide diuretics and dihydropyridine calcium channel antagonists are the most suitable drugs for treatment in older people.

#### Combination therapy

Although some patients can be treated with a single antihypertensive drug, a combination of drugs is often required to achieve optimal control (Fig. 16.77). Combination therapy may be desirable for other reasons; for example, low-dose therapy with two drugs may produce fewer unwanted effects than treatment with the maximum dose of a single drug. Some drug combinations have complementary or synergistic actions; for example, thiazides increase activity of the renin-angiotensin system, while ACE inhibitors block it.

#### Refractory hypertension

Refractory hypertension refers to the situation where multiple drug treatments do not give adequate control of BP. Although this may be due to genuine resistance to therapy in some cases, a more common cause of treatment failure is non-adherence to drug therapy. Resistant hypertension can also be caused by failure to recognise an underlying cause, such as renal artery stenosis or pheochromocytoma. There is no easy solution to problems with adherence, but simple treatment regimens,

**Fig. 16.77 Antihypertensive drug combinations.** \*Does not apply to those who are of mixed race. <sup>1</sup>A = Angiotensin-converting enzyme (ACE) inhibitor or consider angiotensin II receptor blocker (ARB); choose a low-cost ARB. <sup>2</sup>C = calcium channel blocker (CCB); a CCB is preferred but consider a thiazide-like diuretic if a CCB is not tolerated or the person has oedema, evidence of heart failure or a high risk of heart failure. <sup>3</sup>D = thiazide-type diuretic. <sup>4</sup>Consider a high dose of spironolactone or higher doses of a thiazide-like diuretic. <sup>5</sup>Consider an  $\alpha$ - or  $\beta$ -blocker if further diuretic therapy is not tolerated, or is contraindicated or ineffective. Adapted from 2020 International Society of Hypertension Global Hypertension Practice Guidelines.

attempts to improve rapport with the patient and careful supervision can all help. Spironolactone is a particularly useful addition in patients with treatment-resistant hypertension.

## Accelerated hypertension

Accelerated or malignant hypertension is a rare condition that can complicate hypertension of any aetiology. It is characterised by accelerated microvascular damage with necrosis in the walls of small arteries and arterioles (fibrinoid necrosis) and by intravascular thrombosis. The diagnosis is based on evidence of high BP and rapidly progressive end-organ damage, such as retinopathy (grade 3 or 4), renal dysfunction (especially proteinuria) and hypertensive encephalopathy (see above). Left ventricular failure may occur and death occurs within months if untreated.

## Management

In accelerated phase hypertension, lowering BP too quickly may compromise tissue perfusion due to altered autoregulation and can cause cerebral damage, including occipital blindness, and precipitate coronary or renal insufficiency. Even in the presence of cardiac failure or hypertensive encephalopathy, a controlled reduction to a level of about 150/90 mmHg over a period of 24–48 hours is ideal.

In most patients, it is possible to avoid parenteral therapy and bring BP under control with bed rest and oral drug therapy. Intravenous or intramuscular labetalol (2 mg/min to a maximum of 200 mg), intravenous GTN (0.6–1.2 mg/hr), intramuscular hydralazine (5 or 10 mg aliquots repeated at half-hourly intervals) and intravenous sodium nitroprusside (0.3–1.0  $\mu$ g/kg body weight/min) are all effective but require careful supervision, preferably in a high-dependency unit.

## Diseases of the heart valves

The heart valves allow forward movement of blood through the cardiac chambers when they are open and prevent backward flow when they are closed. A diseased valve may become narrowed, obstructing forward flow, or become leaky, causing backward flow or regurgitation. Breathlessness is a common symptom of valve disease, and acute severe breathlessness may be a presenting symptom of valve failure. The causes of this are shown in Box 16.73. Predisposition to valvular disease may be genetically determined, can arise as the result of rheumatic fever or infections, or can occur in association with dilatation of the cardiac chambers in heart failure. The principal causes of valvular disease are summarised in Box 16.74.

## Rheumatic heart disease

### Acute rheumatic fever

Acute rheumatic fever usually affects children and young adults between the ages of 5 and 15 years. It is now rare in high-income countries in Western Europe and North America, where the incidence is about 0.5 cases per 100 000, but remains endemic in South Asia, Africa and South America. Recent studies indicate that the current incidence of rheumatic heart disease in India ranges between 13 and 150 cases per 100 000 population per year, where it is the commonest cause of acquired heart disease in childhood and adolescence.

### Pathogenesis

The condition is triggered by an immune-mediated delayed response to infection with specific strains of group A streptococci, which have antigens that cross-react with cardiac myosin and sarcolemmal membrane proteins. Antibodies produced against the streptococcal antigens cause inflammation in the endocardium, myocardium and pericardium, as well as the joints and skin. Histologically, fibrinoid degeneration is seen in the collagen of connective tissues. Aschoff nodules are pathognomonic and

16

### 16.73 Causes of acute valve failure

#### Aortic regurgitation

- Aortic dissection
- Infective endocarditis

#### Mitral regurgitation

- Papillary muscle rupture due to acute myocardial infarction
- Infective endocarditis
- Rupture of chordae due to myxomatous degeneration

#### Prosthetic valve failure

- Mechanical valves: fracture, jamming, thrombosis, dehiscence
- Biological valves: degeneration with cusp tear

### 16.74 Principal causes of valve disease

#### Valve regurgitation

- Congenital
- Acute rheumatic carditis
- Chronic rheumatic carditis
- Infective endocarditis
- Cardiac failure\*
- Syphilitic aortitis
- Traumatic valve rupture
- Senile degeneration
- Damage to chordae and papillary muscles

#### Valve stenosis

- Congenital
- Rheumatic carditis
- Senile degeneration

\*Causes dilatation of the valve ring.

**Fig. 16.78 Clinical features of rheumatic fever.** Bold labels indicate Jones major criteria. (CCF = congestive cardiac failure) *Inset (Erythema marginatum)* From Savin JA, Hunter JAA, Hepburn NC. *Skin signs in clinical medicine*. London: Mosby-Wolfe, Elsevier; 1997.

occur only in the heart. They are composed of multinucleated giant cells surrounded by macrophages and T lymphocytes, and are not seen until the subacute or chronic phases of rheumatic carditis.

### Clinical features

Acute rheumatic fever is a multisystem disorder that usually presents with fever, anorexia, lethargy and joint pain, 2–3 weeks after an episode of streptococcal pharyngitis although there may be no history of sore throat. Arthritis occurs in approximately 75% of patients. Other features include rashes, subcutaneous nodules, carditis and neurological changes (Fig. 16.78). Using the revised Jones criteria (Box 16.75), the diagnosis is based on two or more major manifestations, or one major and two or more minor manifestations, along with evidence of preceding streptococcal infection. A presumptive diagnosis of acute rheumatic fever can be made without evidence of preceding streptococcal infection in cases of isolated chorea or pancarditis, if other causes have been excluded. In cases of established rheumatic heart disease or prior rheumatic fever, acute rheumatic fever can be diagnosed based only on the presence of multiple minor criteria and evidence of preceding group A streptococcal pharyngitis.

### Carditis

Rheumatic fever causes a pancarditis involving the endocardium, myocardium and pericardium to varying degrees. Its incidence declines with increasing age, ranging from 90% at 3 years to around 30% in adolescence. It may manifest as breathlessness (due to heart failure or pericardial effusion), palpitations or chest pain (usually due to pericarditis or pancarditis). Other features include tachycardia, cardiac enlargement and new or changed murmurs. A soft systolic murmur due to mitral regurgitation is very common. A soft mid-diastolic murmur (the Carey Coombs murmur) is typically due to valvulitis, with nodules forming on the mitral valve leaflets. Aortic regurgitation occurs in 50% of cases but the tricuspid and pulmonary valves are rarely involved. Pericarditis may cause chest pain, a pericardial friction rub and precordial tenderness. Cardiac failure may be due to myocardial dysfunction or valvular regurgitation. ECG evidence commonly includes ST and T wave changes. Conduction defects, including AV block, sometimes occur and may cause syncope.

## 16.75 Jones criteria for the diagnosis of rheumatic fever

### Major manifestations

- Carditis
- Polyarthritis
- Chorea
- Erythema marginatum
- Subcutaneous nodules

### Minor manifestations

- Fever
- Arthralgia
- Raised erythrocyte sedimentation rate or C-reactive protein
- Previous rheumatic fever
- Leucocytosis
- First-degree atrioventricular block

### Plus

- Supporting evidence of preceding streptococcal infection: recent scarlet fever, raised antistreptolysin O or other streptococcal antibody titre, positive throat culture\*

\*Evidence of recent streptococcal infection is particularly important if there is only one major manifestation.

### Arthritis

This is the commonest major manifestation and occurs early when streptococcal antibody titres are high. An acute painful, asymmetric and migratory inflammation of the large joints typically affects the knees, ankles, elbows and wrists. The joints are involved in quick succession and are usually red, swollen and tender for between a day and 4 weeks.

### Skin lesions

Erythema marginatum occurs in less than 5% of patients. The lesions start as red macules that fade in the centre but remain red at the edges, and occur mainly on the trunk and proximal extremities but not the face. The resulting red rings or 'margins' may coalesce or overlap (see Fig. 16.78). Subcutaneous nodules occur in 5%–7% of patients. They are small (0.5–2.0 cm), firm and painless, and are best felt over extensor surfaces of bone or tendons. They typically appear more than 3 weeks after the onset of other manifestations and therefore help to confirm rather than make the diagnosis.

### Sydenham's chorea

Sydenham's chorea, also known as St Vitus dance, is a late neurological manifestation that appears at least 3 months after the episode of acute rheumatic fever, when all the other signs may have disappeared. It occurs in up to one-third of cases and is more common in females. Emotional lability may be the first feature and is typically followed by purposeless, involuntary, choreiform movements of the hands, feet or face. Speech may be explosive and halting. Spontaneous recovery usually occurs within a few months. Approximately one-quarter of affected patients will go on to develop chronic rheumatic valve disease.

### Other features

Other systemic manifestations, such as pleurisy, pleural effusion and pneumonia, may occur but are rare.

### Investigations

Blood should be taken for measurement of ESR and CRP since these are useful for monitoring progress of the disease (Box 16.76). Throat cultures should be taken but positive results are obtained in only 10%–25% of cases since the infection has often resolved by the time of presentation. Serology for antistreptolysin O antibodies (ASO) should be performed and provide supportive evidence for the diagnosis but are normal in one-fifth of adult cases of rheumatic fever and most cases of chorea. Echocardiography should be carried out and typically shows mitral regurgitation with dilatation of the mitral annulus and prolapse of the anterior mitral leaflet; it may also demonstrate aortic regurgitation and pericardial effusion.

## 16.76 Investigations in acute rheumatic fever

### Evidence of a systemic illness

- Leucocytosis, raised erythrocyte sedimentation rate and C-reactive protein

### Evidence of preceding streptococcal infection

- Throat swab culture: group A  $\beta$ -haemolytic streptococci (also from family members and contacts)
- Antistreptolysin O antibodies (ASO titres): rising titres, or levels of > 200 U (adults) or > 300 U (children)

### Evidence of carditis

- Chest X-ray: cardiomegaly; pulmonary congestion
- ECG: first- and, rarely, second-degree atrioventricular block; features of pericarditis; T-wave inversion; reduction in QRS voltages
- Echocardiography: cardiac dilatation and valve abnormalities

## Management

The aims of management are to limit cardiac damage and relieve symptoms.

### Bed rest

Bed rest is important, as it lessens joint pain and reduces cardiac workload. The duration should be guided by symptoms, along with temperature, leucocyte count and ESR, and should be continued until these have settled. Patients can then return to normal physical activity but strenuous exercise should be avoided in those who have had carditis.

### Treatment of cardiac failure

Some patients, particularly those in early adolescence, can develop a fulminant form of the disease with severe mitral regurgitation and, sometimes, concomitant aortic regurgitation. If heart failure does not respond to medical treatment, valve replacement may be necessary and is often associated with a dramatic decline in rheumatic activity. Occasionally, AV block may occur but is seldom progressive and usually resolves spontaneously. Rarely, pacemaker insertion may be required.

### Antibiotic therapy

A single dose of benzathine benzylpenicillin (1.2 million U IM) or oral phenoxymethylpenicillin (250 mg 4 times daily for 10 days) should be given on diagnosis to eliminate any residual streptococcal infection. If the patient is penicillin-allergic, erythromycin or a cephalosporin can be used. Patients are susceptible to further attacks of rheumatic fever if another streptococcal infection occurs, and long-term prophylaxis with penicillin should be given with oral phenoxymethylpenicillin (250 mg twice daily) or as benzathine benzylpenicillin (1.2 million U IM monthly), if adherence is in doubt. Sulfadiazine or erythromycin may be used if the patient is allergic to penicillin; sulphonamides prevent infection but are not effective in the eradication of group A streptococci. Further attacks of rheumatic fever are unusual after the age of 21, when antibiotic treatment can usually be stopped. The duration of prophylaxis should be extended if an attack has occurred in the last 5 years, or if the patient lives in an area of high prevalence and has an occupation (such as teaching) with a high risk of exposure to streptococcal infection. In those with residual heart disease, prophylaxis should continue until 10 years after the last episode or 40 years of age, whichever is later. While long-term antibiotic prophylaxis prevents further attacks of acute rheumatic fever, it does not protect against infective endocarditis.

### Aspirin

This usually relieves the symptoms of arthritis rapidly and a response within 24 hours helps confirm the diagnosis. A reasonable starting dose is 60 mg/kg body weight/day, divided into six doses. In adults, 100 mg/kg per day may be needed up to the limits of tolerance or a maximum of 8 g per day. Mild toxicity includes nausea, tinnitus and deafness; vomiting, tachypnoea and acidosis are more serious. Aspirin should be continued until the ESR has fallen and then gradually tailed off.

## Glucocorticoid steroids

These produce more rapid symptomatic relief than aspirin and are indicated in cases with carditis or severe arthritis. There is no evidence that long-term steroids are beneficial. Prednisolone (1.0–2.0 mg/kg per day in divided doses) should be continued until the ESR is normal and then gradually reduced.

## Chronic rheumatic heart disease

Chronic valvular heart disease develops in at least half of those affected by rheumatic fever with carditis. Two-thirds of cases occur in women. Some episodes of rheumatic fever pass unrecognised and it is possible to elicit a history of rheumatic fever or chorea in only about half of all patients with chronic rheumatic heart disease.

The mitral valve is affected in more than 90% of cases; the aortic valve is the next most frequently involved, followed by the tricuspid and then the pulmonary valve. Isolated mitral stenosis accounts for about 25% of all cases, and an additional 40% have mixed mitral stenosis and regurgitation.

### Pathogenesis

The main pathological process in chronic rheumatic heart disease is progressive fibrosis. The heart valves are predominantly affected but involvement of the pericardium and myocardium also occurs and may contribute to heart failure and conduction disorders. Fusion of the mitral valve commissures and shortening of the chordae tendinae may lead to mitral stenosis with or without regurgitation. Similar changes in the aortic and tricuspid valves produce distortion and rigidity of the cusps, leading to stenosis and regurgitation. Once a valve has been damaged, the altered haemodynamic stresses perpetuate and extend the damage, even in the absence of a continuing rheumatic process.

## Mitral valve disease

### Mitral stenosis

Mitral stenosis is almost always rheumatic in origin, although in older people it can be caused by heavy calcification of the mitral valve. There is also a rare form of congenital mitral stenosis.

### Pathogenesis

In rheumatic mitral stenosis, the mitral valve orifice is slowly diminished by progressive fibrosis, calcification of the valve leaflets, and fusion of the cusps and subvalvular apparatus. The mitral valve orifice is normally about 5 cm<sup>2</sup> in diastole but can be reduced to < 1 cm<sup>2</sup> in severe mitral stenosis. The patient is usually asymptomatic until the orifice is < 2 cm<sup>2</sup>. As stenosis progresses, left ventricular filling becomes more dependent on left atrial contraction. There is dilatation and hypertrophy of the LA and left atrial pressure rises, leading to pulmonary venous congestion and breathlessness. Any increase in heart rate shortens diastole when the mitral valve is open and produces a further rise in left atrial pressure. Situations that demand an increase in cardiac output, such as pregnancy and exercise, also increase left atrial pressure and are poorly tolerated.

Atrial fibrillation is very common due to progressive dilatation of the LA. Its onset often precipitates pulmonary oedema because the accompanying tachycardia and loss of atrial contraction lead to haemodynamic deterioration and a rapid rise in left atrial pressure. In the absence of AF, a more gradual rise in left atrial pressure may occur. Irrespective of AF, pulmonary hypertension may occur, which can protect the patient from pulmonary oedema. Pulmonary hypertension leads to right ventricular hypertrophy and dilatation, tricuspid regurgitation and right heart failure. Fewer than 20% of patients remain in sinus rhythm but many of these have a small fibrotic LA and severe pulmonary hypertension.

16.77 Clinical features of mitral stenosis	
Clinical feature	Cause
<b>Symptoms</b>	
Breathlessness	Pulmonary congestion, low cardiac output
Fatigue	Low cardiac output
Oedema, ascites	Right heart failure
Palpitation	Atrial fibrillation
Haemoptysis	Pulmonary congestion
Cough	Pulmonary congestion
Chest pain	Pulmonary hypertension
Thromboembolism	Atrial stasis and atrial fibrillation
<b>Signs</b>	
Atrial fibrillation	Atrial dilatation
Mitral facies	Low cardiac output
Auscultation:	
Loud first heart sound, opening snap	Non-compliant, stenotic valve
Mid-diastolic murmur	
Crepitations	Left heart failure
Pulmonary oedema	
Pleural effusions	
Right ventricular heave, loud P <sub>2</sub>	Pulmonary hypertension

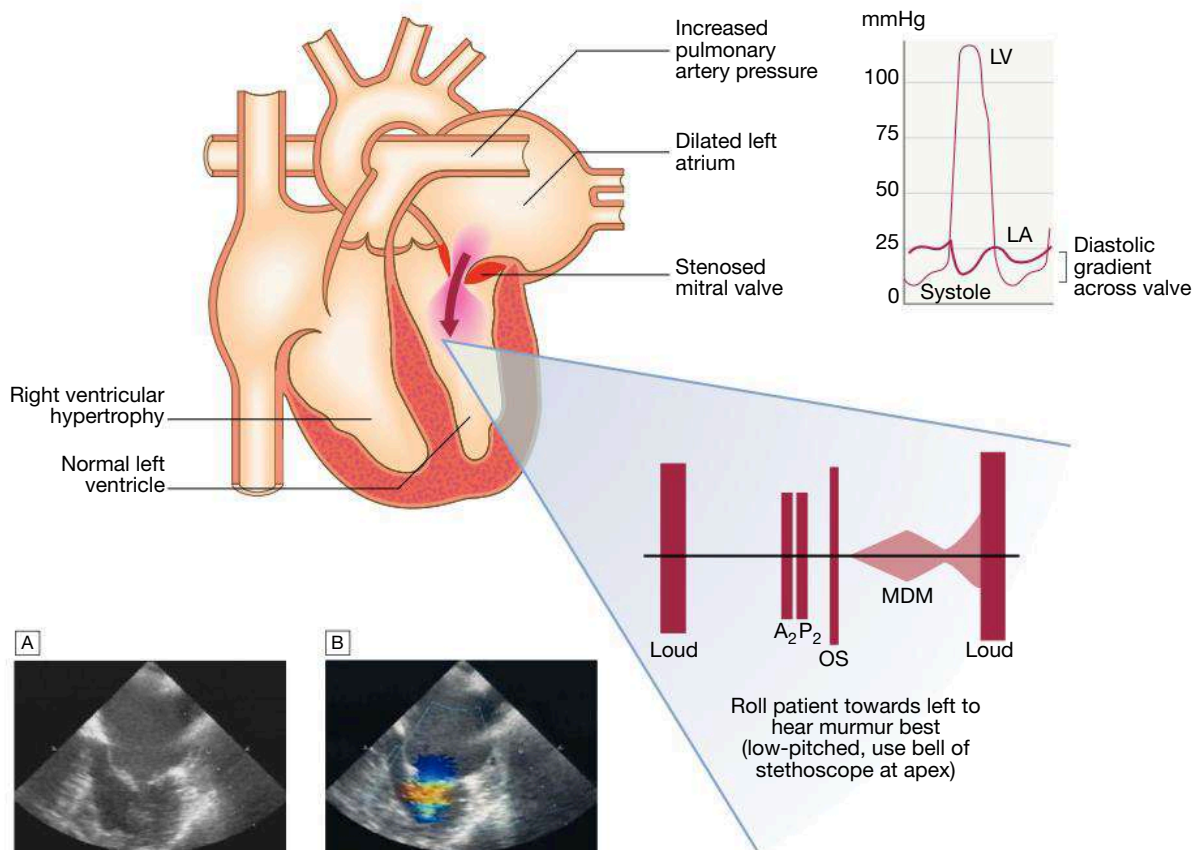

### Clinical features

Effort-related dyspnoea is usually the dominant symptom (Box 16.77). Typically, exercise tolerance diminishes very slowly over many years until symptoms eventually occur at rest. Patients frequently do not appreciate the extent of their disability until the diagnosis is made and their valve disease is treated. Acute pulmonary oedema or pulmonary hypertension can lead to haemoptysis. Fatigue is a common symptom due to a low cardiac output. Thromboembolism is a common complication, especially in patients with AF. Prior to the advent of anticoagulant therapy, emboli caused one-quarter of all deaths.

The physical signs of mitral stenosis are often found before symptoms develop and their recognition is of particular importance in pregnancy. The forces that open and close the mitral valve increase as left atrial pressure rises. The first heart sound (S1) is therefore loud and can be palpable (tapping apex beat). An opening snap may be audible and moves closer to the second sound (S2) as the stenosis becomes more severe and left atrial pressure rises. However, the first heart sound and opening snap may be inaudible if the valve is heavily calcified.

Turbulent flow produces the characteristic low-pitched mid-diastolic murmur and sometimes a thrill (Fig. 16.79). The murmur is accentuated by exercise and during atrial systole (pre-systolic accentuation). Early in the disease a pre-systolic murmur may be the only auscultatory abnormality, but in patients with symptoms, the murmur extends from the opening snap to the first heart sound. Coexisting mitral regurgitation causes a pansystolic murmur that radiates towards the axilla.

Pulmonary hypertension may ultimately lead to right ventricular hypertrophy and dilatation with secondary tricuspid regurgitation, which causes a parasternal lift, and a systolic murmur and giant 'v waves' in the venous pulse.

**Fig. 16.79** Mitral stenosis: murmur and the diastolic pressure gradient between left atrium (LA) and left ventricle (LV). (Mean gradient is reflected by the area between LA and LV in diastole.) The first heart sound is loud, and there is an opening snap (OS) and mid-diastolic murmur (MDM) with pre-systolic accentuation.

**A** Echocardiogram showing reduced opening of the mitral valve in diastole. **B** Colour Doppler showing turbulent flow.

## Investigations

Doppler echocardiography is the investigation of choice for evaluation of suspected mitral stenosis (see Fig. 16.79). Cardiac catheterisation may also be required if surgery or valvuloplasty is being considered, to screen for coexisting conditions such as CAD. The ECG may show either AF or bifid P waves (P mitrale) associated with left atrial hypertrophy (Box 16.78). A typical chest X-ray is shown in Fig. 16.9.

## Management

Patients with mild symptoms can be treated medically but intervention by balloon valvuloplasty, mitral valvotomy or mitral valve replacement should be considered if the patient remains symptomatic despite medical treatment or if pulmonary hypertension develops.

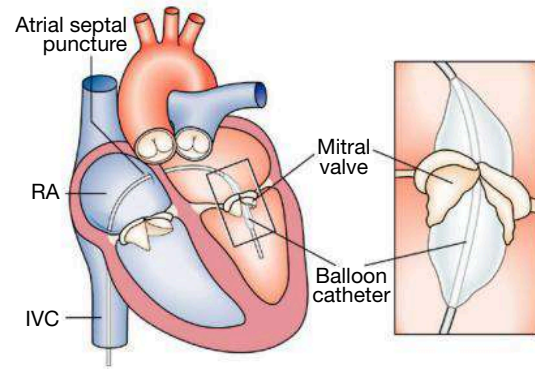

### Medical management

This consists of anticoagulation to reduce the risk of systemic embolism, ventricular rate control with digoxin,  $\beta$ -blockers or rate-limiting calcium antagonists for AF, and diuretic to control pulmonary congestion. Antibiotic prophylaxis against infective endocarditis is no longer routinely recommended.

### Mitral balloon valvuloplasty and valve replacement

Valvuloplasty is the treatment of choice if specific criteria are fulfilled (Box 16.79 and Fig. 16.80), although surgical closed or open mitral valvotomy is an acceptable alternative. Patients who have undergone mitral valvuloplasty or valvotomy should be followed up at 1–2-yearly intervals because restenosis may occur. Clinical symptoms and signs are a guide to the severity of mitral restenosis but Doppler echocardiography provides a more accurate assessment.

Valve replacement is indicated if there is substantial mitral reflux or if the valve is rigid and calcified.

**Fig. 16.80 Mitral valvuloplasty.** A guidewire is introduced into the right atrium (RA) from the femoral vein and the inferior vena cava (IVC). The interatrial septum is punctured, providing access to the left atrium and mitral valve. A balloon catheter is then advanced over the guidewire across the mitral valve and the balloon dilated to stretch the valve and reduce the degree of stenosis.

### 16.80 Causes of mitral regurgitation

- Mitral valve prolapse
- Dilatation of the left ventricle and mitral valve ring (coronary artery disease, cardiomyopathy)
- Damage to valve cusps and chordae (rheumatic heart disease, endocarditis)
- Ischaemia or infarction of the papillary muscle
- Myocardial infarction

16

### 16.78 Investigations in mitral stenosis

#### ECG

- Right ventricular hypertrophy: tall R waves in  $V_1$ – $V_3$
- P mitrale or atrial fibrillation

#### Chest X-ray

- Enlarged left atrium and appendage
- Signs of pulmonary venous congestion

#### Echo

- Thickened immobile cusps
- Reduced rate of diastolic filling of left ventricle
- Reduced valve area
- Enlarged left atrium

#### Doppler

- Pressure gradient across mitral valve
- Left ventricular function
- Pulmonary artery pressure

#### Cardiac catheterisation

- Coronary artery disease
- Mitral stenosis and regurgitation
- Pulmonary artery pressure

### 16.79 Criteria for mitral valvuloplasty\*

- Significant symptoms
- Isolated mitral stenosis
- No (or trivial) mitral regurgitation
- Mobile, non-calcified valve/subvalve apparatus on echo
- Left atrium free of thrombus

\*For comprehensive guidelines on valvular heart disease, see [www.acc.org](http://www.acc.org).

## Mitral regurgitation

Rheumatic disease is the principal cause in countries where rheumatic fever is common but elsewhere, including in the UK, other causes are more important (Box 16.80). Mitral regurgitation may also follow mitral valvotomy or valvuloplasty.

### Pathogenesis

Chronic mitral regurgitation causes gradual dilatation of the LA with little increase in pressure and relatively few symptoms. Nevertheless, the LV dilates slowly and the left ventricular diastolic and left atrial pressures gradually increase as a result of chronic volume overload of the LV. In contrast, acute mitral regurgitation causes a rapid rise in left atrial pressure (because left atrial compliance is normal) and marked symptomatic deterioration.

### Mitral valve prolapse

This is also known as ‘floppy’ mitral valve and is a common cause of mild mitral regurgitation (Fig. 16.81). Some cases are thought to be due to a developmental abnormality of the mitral valve and others due to degenerative myxomatous change in a normal mitral valve. Rarely, mitral valve prolapse may occur in association with Marfan syndrome.

In its mildest forms, the valve remains competent but bulges back into the atrium during systole, causing a mid-systolic click but no murmur. In the presence of a regurgitant valve, the click is followed by a late systolic murmur, which lengthens as the regurgitation becomes more severe. A click is not always audible and the physical signs may vary with both posture and respiration. Progressive elongation of the chordae tendineae leads to increasing mitral regurgitation, and if chordal rupture occurs, regurgitation suddenly becomes severe. This is rare before the fifth or sixth decade of life.

Mitral valve prolapse is associated with a variety of typically benign arrhythmias, atypical chest pain and a very small risk of embolic stroke or transient ischaemic attack (TIA). Nevertheless, the overall long-term prognosis is good.

**Fig. 16.81 Mitral regurgitation: murmur and systolic wave in left atrial pressure.** The first sound is normal or soft and merges with a pansystolic murmur (PSM) extending to the second heart sound. A third heart sound occurs with severe regurgitation. **[A]** A transoesophageal echocardiogram shows mitral valve prolapse, with one leaflet bulging towards the left atrium (LA, arrow). **[B]** This results in a jet of mitral regurgitation on colour Doppler (arrow). (LV = left ventricle)

**Other causes of mitral regurgitation**

Mitral valve function depends on the chordae tendineae and their papillary muscles; dilatation of the LV distorts the geometry of these and may cause mitral regurgitation (see Box 16.80). Dilated cardiomyopathy and heart failure from CAD are common causes of so-called ‘functional’ mitral regurgitation. Endocarditis is an important cause of acute mitral regurgitation.

**Clinical features**

Symptoms and signs depend on the underlying cause and how suddenly the regurgitation develops (Box 16.81). Chronic mitral regurgitation produces a symptom complex that is similar to that of mitral stenosis but sudden-onset mitral regurgitation usually presents with acute pulmonary oedema.

The regurgitant jet causes an apical systolic murmur (Fig. 16.82), which radiates into the axilla and may be accompanied by a thrill. Increased forward flow through the mitral valve causes a loud third heart sound and even a short mid-diastolic murmur. The apex beat feels active and rocking due to left ventricular volume overload and is usually displaced to the left as a result of left ventricular dilatation.

**Investigations**

Echocardiography is a pivotal investigation. The severity of regurgitation can be assessed by Doppler and information may also be gained on papillary muscle function and valve prolapse. An ECG should be performed and commonly shows AF, as a consequence of atrial dilatation.

16.81 Clinical features of mitral regurgitation	
Clinical feature	Cause
<b>Symptoms</b>	
Breathlessness	Pulmonary congestion
Fatigue	Low cardiac output
Oedema, ascites	Right heart failure
Palpitation	Atrial fibrillation
<b>Signs</b>	
Atrial fibrillation	Atrial dilatation
Displaced apex beat	Cardiomegaly
Auscultation:	
Apical pansystolic murmur	Regurgitation of blood from left ventricle to left atrium
Soft S1	Valve does not close properly
Apical S3	Rapid flow of blood into left ventricle
Crepitations	} Left heart failure
Pulmonary oedema	
Pleural effusions	
Right ventricular heave	Pulmonary hypertension
Raised jugular venous pressure	Right heart failure
Oedema	Right heart failure

**Fig. 16.82 Aortic stenosis.** Pressure traces show the systolic gradient between left ventricle (LV) and aorta. The 'diamond-shaped' murmur is heard best with the diaphragm in the aortic outflow and also at the apex. An ejection click (EC) may be present in young patients with a bicuspid aortic valve but not in older patients with calcified valves. Aortic stenosis may lead to left ventricular hypertrophy with a fourth sound at the apex and post-stenotic dilatation of the aortic arch. Fig. 16.11 shows the typical Doppler signal with aortic stenosis.

Cardiac catheterisation is indicated when surgery is being considered (Box 16.82). During catheterisation, the severity of mitral regurgitation can be assessed by left ventriculography and by the size of the  $v$  (systolic) waves in the left atrial or pulmonary artery wedge pressure trace.

### Management

Mitral regurgitation of moderate severity can be treated medically with diuretics and vasodilators. Digoxin and anticoagulants should be given if AF is present (Box 16.83). If systemic hypertension is present, it should be treated with vasodilators such as ACE inhibitors or ARBs, since high

### 16.83 Medical management of mitral regurgitation

- Diuretics
- Vasodilators if hypertension is present
- Digoxin if atrial fibrillation is present
- Anticoagulants if atrial fibrillation is present

afterload may worsen the degree of regurgitation. All patients should be reviewed at regular intervals, both clinically and by echocardiography. Worsening symptoms, progressive cardiomegaly or echocardiographic evidence of deteriorating left ventricular function are indications for mitral valve replacement or repair. Mitral valve repair is now the treatment of choice for severe mitral regurgitation, because early repair appears to prevent irreversible left ventricular damage. Mitral regurgitation often accompanies left ventricular failure associated with CAD. If such patients are to undergo CABG surgery, it is common practice to repair the valve and restore mitral valve function by inserting an annuloplasty ring to overcome annular dilatation and to bring the valve leaflets closer together. Unfortunately, it can be difficult to determine whether it is the ventricular dilatation or the mitral regurgitation that is the predominant problem. If ventricular dilatation is the underlying cause of mitral regurgitation, then mitral valve repair or replacement may actually worsen ventricular function, as the ventricle can no longer empty into the low-pressure LA.

## Aortic valve disease

### Aortic stenosis

There are several causes of aortic stenosis but the age at which patients present can give a clue to the most likely diagnosis (Box 16.84).

### 16.82 Investigations in mitral regurgitation

#### ECG

- P-mitrale
- Atrial fibrillation

#### Chest X-ray

- Enlarged left atrium
- Enlarged left ventricle
- Pulmonary venous congestion
- Pulmonary oedema (if acute)

#### Echo

- Dilated left atrium, left ventricle
- Dynamic left ventricle (unless myocardial dysfunction predominates)
- Structural abnormalities of mitral valve

#### Doppler

- Detects and quantifies regurgitation

#### Cardiac catheterisation

- Dilated left atrium, dilated left ventricle, mitral regurgitation
- Pulmonary hypertension
- Coexisting coronary artery disease

i 16.84 Causes of aortic stenosis
<b>Infants, children, adolescents</b>
<ul style="list-style-type: none"> <li>• Congenital aortic stenosis</li> <li>• Congenital subvalvular aortic stenosis</li> <li>• Congenital supra-avalvular aortic stenosis</li> </ul>
<b>Young to middle-aged adults</b>
<ul style="list-style-type: none"> <li>• Calcification and fibrosis of congenitally bicuspid aortic valve</li> <li>• Rheumatic aortic stenosis</li> </ul>
<b>Middle-aged to older adults</b>
<ul style="list-style-type: none"> <li>• Senile degenerative aortic stenosis</li> <li>• Calcification of bicuspid valve</li> <li>• Rheumatic aortic stenosis</li> </ul>

In congenital aortic stenosis, obstruction is present from birth or becomes apparent during infancy. With bicuspid aortic valves, obstruction may take years to develop as the valve becomes fibrotic and calcified, and these patients present as young to middle-aged adults. Rheumatic disease of the aortic valve presents at a similar age but is usually accompanied by mitral valve disease. In older people, tricuspid aortic valves may become stenotic as the result of fibrosis and calcification. Stenosis develops slowly, typically occurring at 30–60 years in those with rheumatic disease, 50–60 years in those with bicuspid aortic valves and 70–90 years in those with calcific aortic disease.

### Pathogenesis

Cardiac output is initially maintained in patients with aortic stenosis at the cost of a steadily increasing pressure gradient across the aortic valve. With progression of the stenosis, the LV becomes increasingly hypertrophied and coronary blood flow may be inadequate to supply the myocardium, such that angina can develop even in the absence of coexisting CAD. The fixed outflow obstruction limits the increase in cardiac output required on exercise. Eventually, the LV can no longer overcome the outflow tract obstruction and LV failure results, leading to pulmonary oedema.

### Clinical features

Aortic stenosis is commonly picked up in asymptomatic patients at routine clinical examination but the three cardinal symptoms are angina, breathlessness and syncope (Box 16.85). Angina arises either because of the increased demands of the hypertrophied LV working against the high-pressure outflow tract obstruction, or the presence of coexisting CAD, which affects over 50% of patients. Exertional breathlessness suggests cardiac decompensation as a consequence of the excessive pressure overload placed on the LV. Syncope usually occurs on exertion when cardiac output fails to rise to meet demand, leading to a fall in BP. Sometimes patients with severe aortic stenosis do not complain of symptoms. If, on clinical evaluation, this appears to be due to a sedentary lifestyle, a careful exercise test may reveal symptoms on modest exertion.

The characteristic clinical signs of severe aortic stenosis are shown in Box 16.85. A harsh ejection systolic murmur radiates to the neck, with a soft second heart sound, particularly in those with calcific valves. The murmur is often likened to a saw cutting wood and may (especially in older patients) have a musical quality like the 'mew' of a seagull (see Fig. 16.82). The severity of aortic stenosis may be difficult to gauge clinically, as older patients with a non-compliant 'stiff' arterial system may have an apparently normal carotid upstroke in the presence of severe aortic stenosis. Milder degrees of stenosis may be difficult to distinguish from aortic sclerosis, in which the valve is thickened or calcified but not obstructed. A careful examination should be made for other valve lesions, particularly in rheumatic heart disease, when there is frequently concomitant mitral valve disease. In contrast to patients with mitral stenosis, which tends to progress very slowly, patients with aortic stenosis

i 16.85 Clinical features of aortic stenosis
<b>Symptoms</b>
<ul style="list-style-type: none"> <li>• Mild or moderate stenosis: usually asymptomatic</li> <li>• Exertional dyspnoea</li> <li>• Angina</li> <li>• Exertional syncope</li> <li>• Sudden death</li> <li>• Episodes of acute pulmonary oedema</li> </ul>
<b>Signs</b>
<ul style="list-style-type: none"> <li>• Ejection systolic murmur</li> <li>• Slow-rising carotid pulse</li> <li>• Heaving apex beat (left ventricular pressure overload)</li> <li>• Narrow pulse pressure</li> <li>• Signs of pulmonary venous congestion</li> </ul>

typically remain asymptomatic for many years but deteriorate rapidly when symptoms develop; if otherwise untreated, they usually die within 3–5 years of presentation.

### Investigations

Echocardiography is a pivotal investigation in patients suspected of having aortic stenosis. It can demonstrate restricted valve opening (Fig. 16.83) and Doppler assessment permits calculation of the systolic gradient across the aortic valve, from which the severity of stenosis can be assessed (see Fig. 16.11). In patients with impaired left ventricular function, velocities across the aortic valve may be diminished because of a reduced stroke volume; this is called low-flow aortic stenosis. When marked aortic regurgitation or elevated cardiac output is present, velocities are increased because of an increased stroke volume and this may overestimate stenosis severity on Doppler echocardiography. In advanced cases, ECG features of LV hypertrophy (Box 16.86) are often pronounced (Fig. 16.84), and down-sloping ST segments and T inversion ('strain pattern') are seen in the lateral leads, reflecting left ventricular fibrosis. Nevertheless, the ECG can be normal, despite severe stenosis. Occasionally, there is evidence of AV block due to the encroachment of the fibrocalcific process on the adjacent AV node and His–Purkinje system; an occasional cause of syncope in these patients. Imaging with CT may be useful in assessing the degree of valve calcification where there is uncertainty of disease severity.

### Management

Irrespective of the severity of valve stenosis, patients with asymptomatic aortic stenosis have a good immediate prognosis and conservative management is appropriate. Such patients should be kept under review, as the development of angina, syncope, symptoms of low cardiac output or heart failure has a poor prognosis and is an indication for prompt surgery. In practice, patients with moderate or severe stenosis should be evaluated every 1–2 years with Doppler echocardiography to detect evidence of progression in severity. The intervals between reviews should be more frequent (typically 3–6-monthly) in older patients with heavily calcified valves.

Patients with symptomatic severe aortic stenosis should have prompt aortic valve replacement. Delay exposes the patient to the risk of sudden death or irreversible deterioration in ventricular function. Old age is not a contraindication to valve replacement and results are very good in experienced centres, even for those in their eighties (Box 16.87). This is especially the case with transcatheter aortic valve implantation (TAVI, see Fig. 16.86). Aortic balloon valvuloplasty is useful in congenital aortic stenosis but has limited value in older patients with calcific aortic stenosis.

Anticoagulants are required only in patients who have AF or those who have had a valve replacement with a mechanical prosthesis.

## Aortic regurgitation

This condition can result from either disease of the aortic valve cusps, infection, trauma or dilatation of the aortic root. The causes are summarised in Box 16.88.

**Fig. 16.83** Two-dimensional echocardiogram comparing a normal individual and a patient with calcific aortic stenosis. **A** Normal individual in diastole; the aortic leaflets are closed and thin, and a point of coaptation is seen (arrow). **B** Calcific aortic stenosis in diastole; the aortic leaflets are thick and calcified (arrow). **C** Normal in systole; the aortic leaflets are open (arrows). **D** Calcific aortic stenosis in systole; the thickened leaflets have barely moved (arrows). From Newby D, Grubb N. *Cardiology: an illustrated colour text*. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2005.

### Pathogenesis

Regurgitation of blood through the aortic valve causes the LV to dilate as cardiac output increases to maintain the demands of the circulation.

## 16.86 Investigations in aortic stenosis

### ECG

- Left ventricular hypertrophy
- Left bundle branch block

### Chest X-ray

- May be normal; sometimes enlarged left ventricle and dilated ascending aorta on postero-anterior view, calcified valve on lateral view

### Echo

- Calcified valve with restricted opening, hypertrophied left ventricle

### Doppler

- Measurement of severity of stenosis
- Detection of associated aortic regurgitation

### Cardiac catheterisation

- Mainly to identify associated coronary artery disease
- May be used to measure gradient between left ventricle and aorta

**Fig. 16.84** Left ventricular hypertrophy. QRS complexes in limb leads have increased amplitude with very large R waves in  $V_4$  and  $V_5$  and a deep S wave in  $V_3$ . There is ST depression and T-wave inversion in leads II, III, aVF,  $V_5$  and  $V_6$ : a 'left ventricular strain' pattern.

The stroke volume of the LV may eventually be doubled and the major arteries are then conspicuously pulsatile. As the disease progresses, left ventricular failure develops, leading to a rise in left ventricular end-diastolic pressure and pulmonary oedema.

### Clinical features

Until the onset of breathlessness, the only symptom may be an awareness of the heart beat (Box 16.89), particularly when lying on the left side, which results from the increased stroke volume. Paroxysmal nocturnal

**16.87 Aortic stenosis in old age**

- **Incidence:** the most common form of valve disease affecting the very old.
- **Symptoms:** a common cause of syncope, angina and heart failure in the very old.
- **Signs:** because of increasing stiffening in the central arteries, low pulse pressure and a slow-rising pulse may not be present.
- **Transcatheter aortic valve implantation (TAVI):** a good option in older individuals because less invasive than surgery.
- **Surgery:** can be successful in those aged 80 years or more in the absence of comorbidity, but with a higher operative mortality. The prognosis without surgery is poor once symptoms have developed.
- **Valve replacement type:** a biological valve is often preferable to a mechanical one because this obviates the need for anticoagulation, and the durability of biological valves usually exceeds the patient's anticipated life expectancy.

**16.88 Causes of aortic regurgitation****Congenital**

- Bicuspid valve or disproportionate cusps

**Acquired**

- Rheumatic disease
- Infective endocarditis
- Trauma
- Causes of aortic dilatation:
  - Marfan syndrome
  - Aneurysm
  - Aortic dissection
  - Syphilis
  - Ankylosing spondylitis

dyspnoea is sometimes the first symptom, and peripheral oedema or angina may occur. The characteristic murmur is best heard to the left of the sternum during held expiration (Fig. 16.85); a thrill is rare. A systolic murmur due to the increased stroke volume is common and does not necessarily indicate stenosis. The regurgitant jet causes fluttering of the mitral valve and, if severe, causes partial closure of the anterior mitral leaflet, leading to functional mitral stenosis and a soft mid-diastolic (Austin Flint) murmur.

Acute severe regurgitation may occur as the result of perforation or tear of an aortic cusp in endocarditis. In this circumstance there may be no time for compensatory left ventricular hypertrophy and dilatation to develop and the features of heart failure may predominate. The classical signs of aortic regurgitation in such patients may be masked by tachycardia and an abrupt rise in left ventricular end-diastolic pressure. The pulse pressure may also be normal or near-normal and the diastolic murmur may be short or even absent.

**Investigations**

Doppler echocardiography is the investigation of first choice for detecting regurgitation (Box 16.90). In severe acute aortic regurgitation the rapid rise in left ventricular diastolic pressure may cause premature mitral valve closure. Cardiac catheterisation and aortography are usually performed to assess the severity of regurgitation, to determine if there is dilatation of the aorta and to screen for the presence of coexisting CAD. MRI can also be useful in assessing the degree and extent of aortic dilatation if this is suspected on chest X-ray or echocardiography.

**Management**

Treatment may be required for underlying conditions, such as endocarditis or syphilis. Aortic valve replacement is indicated if aortic regurgitation causes symptoms, and this may need to be combined with aortic root replacement and coronary bypass surgery. Those with chronic aortic regurgitation can remain asymptomatic for many years because compensatory ventricular dilatation and hypertrophy occur, but should be advised to report the development of any symptoms of breathlessness

**16.89 Clinical features of aortic regurgitation****Symptoms****Mild to moderate aortic regurgitation**

- Often asymptomatic
- Palpitations

**Severe aortic regurgitation**

- Breathlessness
- Angina

**Signs****Pulses**

- Large-volume or 'collapsing' pulse
- Low diastolic and increased pulse pressure
- Bounding peripheral pulses
- Capillary pulsation in nail beds: Quincke's sign
- Femoral bruit ('pistol shot'): Duroziez's sign
- Head nodding with pulse: de Musset's sign

**Murmurs**

- Early diastolic murmur
- Systolic murmur (increased stroke volume)
- Austin Flint murmur (soft mid-diastolic)

**Other signs**

- Displaced, thrusting apex beat (volume overload)
- Pre-systolic impulse
- Third heart sound
- Fourth heart sound
- Crepitations (pulmonary venous congestion)

or angina. Asymptomatic patients should also be followed up annually with echocardiography for evidence of increasing ventricular size. If this occurs or if the end-systolic dimension increases to 55 mm or more, then aortic valve replacement should be undertaken. If systemic hypertension is present, non-rate-limiting vasodilators, such as nifedipine, should be used to control systolic BP. There is conflicting evidence regarding the need for aortic valve replacement in asymptomatic patients with severe aortic regurgitation. When aortic root dilatation is the cause of aortic regurgitation, as can occur in Marfan syndrome, aortic root replacement is usually necessary.

**Tricuspid valve disease****Tricuspid stenosis**

Tricuspid stenosis is usually rheumatic in origin and is rare in higher-income countries. Tricuspid disease occurs in fewer than 5% of patients with rheumatic heart disease and then nearly always occurs in association with mitral and aortic valve disease. Tricuspid stenosis and regurgitation may also occur in the carcinoid syndrome.

**Clinical features and investigations**

Although the symptoms of mitral and aortic valve disease predominate, tricuspid stenosis may cause symptoms of right heart failure, including hepatic discomfort and peripheral oedema.

The main clinical feature is a raised JVP with a prominent a wave, and a slow y descent due to the loss of normal rapid right ventricular filling. There is also a mid-diastolic murmur, best heard at the lower left or right sternal border. This is generally higher-pitched than the murmur of mitral stenosis and is increased by inspiration. Right heart failure causes hepatomegaly with pre-systolic pulsation (large a wave), ascites and peripheral oedema. The diagnosis can be confirmed by Doppler echocardiography, which shows similar appearances to those of rheumatic mitral stenosis.

**Management**

In patients who require surgery to other valves, the tricuspid valve can either be replaced or treated with valvotomy. Balloon valvuloplasty can be used to treat rare cases of isolated tricuspid stenosis.

**Fig. 16.85 Aortic regurgitation.** The early diastolic murmur is best heard at the left sternal border and may be accompanied by an ejection systolic ('to-and-fro') murmur. The aortic arch and left ventricle (LV) may become dilated. The inset shows a Doppler echocardiogram with the regurgitant jet (arrows). *Inset (Colour Doppler echo) From Newby D, Grubb N. ## Tricuspid regurgitation

Tricuspid regurgitation is common, and is most frequently functional, occurring as a result of right ventricular dilatation due to right heart failure or biventricular failure. It may also be the result of other conditions, as summarised in [Box 16.91](#).

### Clinical features

Symptoms are usually non-specific, with tiredness related to reduced cardiac output, and oedema and hepatic enlargement due to venous congestion. The most prominent sign is a 'giant' v wave in the jugular venous pulse (a cv wave replaces the normal x descent). Other features include a pansystolic murmur at the left sternal border and a pulsatile liver. Echocardiography may reveal dilatation of the RV. If the valve has been affected by rheumatic disease, the leaflets will appear thickened and, in endocarditis, vegetations may be seen.

### Management

Tricuspid regurgitation due to right ventricular dilatation often improves when the cardiac failure is treated. Patients with a normal pulmonary

16.91 Causes of tricuspid regurgitation	
<b>Primary</b>	
<ul style="list-style-type: none"> <li>Rheumatic heart disease</li> <li>Endocarditis, particularly in intravenous drug users</li> <li>Ebstein's congenital anomaly (see <a href="#">Box 16.102</a>)</li> </ul>	
<b>Secondary</b>	
<ul style="list-style-type: none"> <li>Right ventricular failure</li> <li>Right ventricular infarction</li> <li>Pulmonary hypertension, secondary to chronic pulmonary disease</li> </ul>	

artery pressure tolerate isolated tricuspid reflux well, and valves damaged by endocarditis do not usually need to be replaced. Patients undergoing mitral valve replacement, who have tricuspid regurgitation due to marked dilatation of the tricuspid annulus, benefit from valve repair with an annuloplasty ring to bring the leaflets closer together. Those with rheumatic damage may require tricuspid valve replacement.

## Pulmonary valve disease

### Pulmonary stenosis

This can occur in the carcinoid syndrome but is usually congenital, in which case it may be isolated or associated with other abnormalities, such as Fallot's tetralogy.

### Clinical features

The principal finding on examination is an ejection systolic murmur, loudest at the left upper sternum and radiating towards the left shoulder. There may be a thrill, best felt when the patient leans forwards and breathes out. The murmur is often preceded by an ejection sound (click). Delay in right ventricular ejection may cause wide splitting of the second heart sound. Severe pulmonary stenosis is characterised by a loud, harsh murmur, an inaudible pulmonary closure sound ( $P_2$ ), an increased right ventricular heave, and prominent a waves in the jugular pulse.

## Investigations

Doppler echocardiography is the definitive investigation. ECG may show evidence of right ventricular hypertrophy, and post-stenotic dilatation in the pulmonary artery may be observed on the chest X-ray.

## Management

Mild to moderate isolated pulmonary stenosis is relatively common and does not usually progress or require treatment. Severe pulmonary stenosis (resting gradient > 50 mmHg with a normal cardiac output) can be treated by percutaneous pulmonary balloon valvuloplasty or, if this is not available, by surgical valvotomy. Long-term results are very good. Post-operative pulmonary regurgitation is common but benign.

## Pulmonary regurgitation

This is rare in isolation and is usually associated with pulmonary artery dilatation due to pulmonary hypertension. It may complicate mitral stenosis, producing an early diastolic decrescendo murmur at the left sternal border that is difficult to distinguish from aortic regurgitation (Graham Steell murmur). The pulmonary hypertension may be secondary to other disease of the left side of the heart, primary pulmonary vascular disease or Eisenmenger syndrome. Trivial pulmonary regurgitation is a frequent finding in normal individuals and has no clinical significance.

## Prosthetic valves

Diseased heart valves can be replaced with mechanical or biological prostheses. The three main types of mechanical prosthesis are the ball and cage, tilting single disc and tilting bi-leaflet valves. All generate prosthetic sounds or clicks on auscultation. Pig or allograft valves mounted on a supporting stent are the most commonly used biological valves. They generate normal heart sounds. All prosthetic valves used in the aortic position produce a systolic flow murmur.

All mechanical valves require long-term anticoagulation because they can cause systemic thromboembolism or may develop valve thrombosis or obstruction (Box 16.92); the prosthetic clicks may become inaudible if the valve malfunctions. Biological valves have the advantage of not requiring anticoagulants to maintain proper function although many patients undergoing valve replacement surgery, especially mitral valve replacement, will have AF that requires anticoagulation anyway. Biological valves are less durable than mechanical valves and may degenerate 7 or more years after implantation, particularly when used in the mitral position. They are more durable in the aortic position and in older patients, so are particularly appropriate for patients over 65 undergoing aortic valve replacement.

## Transcatheter aortic valve implantation

For patients being considered for aortic valve surgery, especially due to aortic stenosis, transcatheter aortic valve implantation (TAVI) is an alternative to surgical aortic valve replacement. The native valve is not removed but is compressed by the new bioprosthetic valve, which is implanted within it. The bioprosthetic valve is mounted on a large stent-like structure and is implanted through a catheter inserted in the femoral

artery (Fig. 16.86). TAVI has several major advantages. It avoids the need for a sternotomy, is associated with a short recovery period, can be used in high-risk and otherwise inoperable patients, and is much better tolerated by older patients. Complications include stroke (2%) and heart block necessitating pacemaker implantation (5%–15%).

## Prosthetic valve dysfunction

Symptoms or signs of unexplained heart failure in a patient with a prosthetic heart valve may be due to valve dysfunction, and urgent assessment is required. Metallic valves can suffer strut fracture and fail, causing catastrophic regurgitation. Alternatively, they may thrombose and cause systemic thromboembolism or valve obstruction, especially in the presence of inadequate anticoagulation. Biological valve dysfunction is usually associated with the development of a regurgitant murmur and may begin to develop 8–10 years after implantation.

## Infective endocarditis

This is caused by microbial infection of a heart valve, the lining of a cardiac chamber or blood vessel, or a congenital anomaly. Both native and prosthetic valves can be affected. The most common causes of infective endocarditis are streptococci and staphylococci but other organisms may also be involved.

### Epidemiology

The incidence of infective endocarditis in community-based studies ranges from 5 to 15 cases per 100 000 per annum. More than 50% of patients are over 60 years of age (Box 16.93). In a large British study, the underlying condition was rheumatic heart disease in 24% of patients, congenital heart disease in 19%, and other cardiac abnormalities such as calcified aortic valve or floppy mitral valve in 25%. The remaining 32% were not thought to have a pre-existing cardiac abnormality. Bacterial endocarditis is a serious illness; the case fatality is approximately 20% even with treatment, and is even higher in those with prosthetic valve endocarditis and those infected with antibiotic-resistant organisms.

### Pathophysiology

Infective endocarditis typically occurs at sites of pre-existing endocardial damage, but infection with particularly virulent or aggressive organisms, such as *Staphylococcus aureus*, can cause endocarditis in a previously normal heart. Staphylococcal endocarditis of the tricuspid valve is a common complication of intravenous drug use. Many acquired and congenital cardiac lesions are vulnerable, particularly areas of endocardial damage caused by a high-pressure jet of blood, such as ventricular septal defect, mitral regurgitation and aortic regurgitation, many of which are haemodynamically insignificant. In contrast, the risk of endocarditis at the site of haemodynamically important low-pressure lesions, such as a large atrial septal defect, is minimal.

Infection tends to occur at sites of endothelial damage because they attract deposits of platelets and fibrin that are vulnerable to colonisation by blood-borne organisms. The avascular valve tissue and presence of fibrin and platelet aggregates help to protect proliferating organisms from host defence mechanisms. When the infection is established, vegetations composed of organisms, fibrin and platelets grow and may become large enough to cause obstruction or embolism. Adjacent tissues are destroyed and abscesses may form. Valve regurgitation may develop or increase if the affected valve is damaged by tissue distortion, cusp perforation or disruption of chordae. Extracardiac manifestations, such as vasculitis and skin lesions, may occur as the result of either emboli or immune complex deposition. Mycotic aneurysms may develop in arteries at the site of infected emboli. In fatal cases, infarction of the spleen and kidneys and, sometimes, an immune glomerulonephritis may be found at postmortem.

### Microbiology

Over three-quarters of cases are caused by streptococci or staphylococci. Viridans streptococci, such as *Streptococcus mitis* and *Strep.*

### 16.92 Anticoagulation targets and prosthetic heart valves

Mechanical valves	Target INR
Ball and cage (e.g. Starr–Edwards)	3.0–4.0
Tilting disc (e.g. Bjork–Shiley)

Appearance of an expanded bioprosthetic valve **A**, which is positioned through a large femoral catheter in an unexpanded form **B**, before the valve is deployed by a balloon **C** during rapid ventricular pacing, to leave behind the fully expanded valve **D**.

### 16.93 Endocarditis in old age

- **Symptoms and signs:** may be non-specific, with delirium, weight loss, malaise and weakness, and the diagnosis may not be suspected.
- **Common causative organisms:** often enterococci (from the urinary tract) and *Streptococcus gallolyticus* subsp. *gallolyticus* (from a colonic source).
- **Morbidity and mortality:** much higher.

*sanguis*, which are commensals in the oral cavity, can enter the blood stream on chewing or tooth-brushing, or at the time of dental treatment, and are common causes of subacute endocarditis (Box 16.94). Other organisms, including *Enterococcus faecalis*, *E. faecium* and *Strep. gallolyticus* subsp. *gallolyticus* (previously known as *Strep. bovis*), may enter the blood from the bowel or urinary tract. Patients who are found to have endocarditis caused by *Strep. gallolyticus* should undergo colonoscopy, since this organism is associated with large-bowel malignancy.

*Staph. aureus* has now overtaken streptococci as the most common cause of acute endocarditis. It originates from skin infections, abscesses or vascular access sites such as intravenous and central lines, or from intravenous drug use. It is highly virulent and invasive, usually producing florid vegetations, rapid valve destruction and abscess formation. Other causes of acute endocarditis include *Strep. pneumoniae* and *Strep. pyogenes*.

Post-operative endocarditis after cardiac surgery may affect native or prosthetic heart valves or other prosthetic materials. The most common organisms are coagulase-negative staphylococci such as *Staph. epidermidis*, which are part of the normal skin flora. There is frequently a

history of wound infection with the same organism. Coagulase-negative staphylococci cause native valve endocarditis in approximately 5% of cases and this possibility should always be considered before they are dismissed as blood culture contaminants. Another coagulase-negative staphylococcus, *Staph. lugdenensis*, causes a rapidly destructive acute endocarditis that is associated with previously normal valves and multiple emboli. Unless accurately identified, it may also be overlooked as a contaminant.

In Q fever endocarditis due to *Coxiella burnetii*, the patient often has a history of contact with farm animals. The aortic valve is usually affected and there may also be hepatitis, pneumonia and purpura. Life-long antibiotic therapy may be required.

In about 3%–4% of cases, endocarditis may be caused by Gram-negative bacteria of the so-called HACEK group (*Haemophilus aphrophilus* – now known as *Aggregatibacter aphrophilus*–*Aggregatibacter actinomycetemcomitans*; *Cardiobacterium hominis*; *Eikenella corrodens*; and *Kingella kingae*). These are slow-growing, fastidious Gram-negative organisms that are oropharyngeal commensals. The diagnosis may be revealed only after prolonged culture and the organisms may be resistant to penicillin.

*Brucella* endocarditis is associated with a history of contact with goats or cattle and often affects the aortic valve.

Yeasts and fungi, such as *Candida* and *Aspergillus*, may attack previously normal or prosthetic valves, particularly in immunocompromised patients or those with in-dwelling intravenous catheters. Abscesses and emboli are common, therapy is difficult, surgery is often required and mortality is high. Concomitant bacterial infection may be present.

Pathogen	Of native valve (n = 280)	In injection drug users (n = 87)	Of prosthetic valve	
			Early (n = 15)	Late (n = 72)
<b>Staphylococci</b>	124 (44%)	60 (69%)	10 (67%)	33 (46%)
<i>Staph. aureus</i>	106 (38%)	60 (69%)	3 (20%)	15 (21%)
Coagulase-negative	18 (6%)	0	7 (47%)	18 (25%)
<b>Streptococci</b>	86 (31%)	7 (8%)	0	25 (35%)
Oral	59 (21%)	3 (3%)	0	19 (26%)

Adapted from Moreillon P, Que YA. Infective endocarditis. Lancet 2004; 363:139–149.

### Clinical features

Endocarditis can take either an acute or a more insidious 'subacute' form; the latter often passes undetected initially. There is considerable overlap because the clinical pattern is influenced not only by the organism but also by the site of infection, prior antibiotic therapy and the presence of a valve or shunt prosthesis. The subacute form may abruptly develop acute life-threatening complications, such as valve disruption or emboli. The Duke criteria for diagnosis of infective endocarditis are shown in [Box 16.95](#).

### Subacute endocarditis

This should be suspected when a patient with congenital or valvular heart disease develops a persistent fever, complains of unusual tiredness, night sweats or weight loss, or develops new signs of valve dysfunction or heart failure. Less often, it presents as an embolic stroke or peripheral arterial embolism. Other features ([Fig. 16.87](#)) include purpura and petechial haemorrhages in the skin and mucous membranes, and splinter haemorrhages under the fingernails or toenails. Osler's nodes are painful, tender swellings at the fingertips that are probably the product of vasculitis; they are rare. Digital clubbing is a late sign. The spleen is frequently palpable; in *Coxiella* infections, the spleen and the liver may be considerably enlarged. Non-visible haematuria is common. The finding of any of these features in a patient with persistent fever or malaise is an indication for re-examination to detect hitherto unrecognised heart disease.

### Acute endocarditis

This presents as a severe febrile illness with prominent and changing heart murmurs and petechiae. Clinical stigmata of chronic endocarditis are usually absent. Embolic events are common, and cardiac or renal failure may develop rapidly. Abscesses may be detected on echocardiography. Partially treated acute endocarditis behaves like subacute endocarditis.

### Post-operative endocarditis

This may present as an unexplained fever in a patient who has had heart valve surgery. The infection usually involves the valve ring and may resemble subacute or acute endocarditis, depending on the virulence of the organism. Morbidity and mortality are high and revision surgery is often required. The range of organisms is similar to that seen in native valve disease, but when endocarditis occurs during the first few weeks after surgery it is usually due to infection with a coagulase-negative staphylococcus that was introduced during the perioperative period.

### 16.95 Diagnosis of infective endocarditis\*

#### Major criteria

##### Positive blood culture

- Typical organism from two cultures
- Persistent positive blood cultures taken > 12 hrs apart
- Three or more positive cultures taken over > 1 hr

##### Endocardial involvement

- Positive echocardiographic findings of vegetations
- New valvular regurgitation

#### Minor criteria

- Predisposing valvular or cardiac abnormality
- Intravenous drug misuse
- Pyrexia  $\geq 38^{\circ}\text{C}$
- Embolic phenomenon
- Vasculitic phenomenon
- Blood cultures suggestive: organism grown but not achieving major criteria
- Suggestive echocardiographic findings

\*Modified Duke criteria. Patients with two major, or one major and three minor, or five minor have definite endocarditis. Patients with one major and one minor, or three minor have possible endocarditis.

### Investigations

Blood culture (see [Fig. 6.6](#)) is the pivotal investigation to identify the organism that is the cause of the infection and to guide antibiotic therapy. Three to six sets of blood cultures should be taken prior to commencing therapy and should not wait for episodes of pyrexia. The first two specimens will detect bacteraemia in 90% of culture-positive cases. A meticulous aseptic technique is essential. Taking discrete sets of blood cultures from peripheral sites at intervals of  $\geq 6$  hours reduces the risk of misdiagnosis due to contamination with skin commensals. Isolation of a typical organism in more than one culture provides strong evidence in favour of the diagnosis (see [Box 16.95](#)). An in-dwelling line should not be used to take cultures. Both aerobic and anaerobic cultures are required.

Echocardiography is key for detecting and following the progress of vegetations, for assessing valve damage and for detecting abscess formation. Vegetations as small as 2–4 mm can be detected by transthoracic echocardiography, and even smaller ones (1–1.5 mm) can be visualised by TOE, which is particularly valuable for identifying abscess formation and investigating patients with prosthetic heart valves. Vegetations may be difficult to distinguish in the presence of an abnormal

**Fig. 16.87** Clinical features that may be present in endocarditis. Insets (Petechial rash, nail-fold infarct) From Newby D, Grubb N. *Cardiology: an illustrated colour text*. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2005.

valve; the sensitivity of transthoracic echo is approximately 65% but that of TOE is more than 90%. Failure to detect vegetations does not exclude the diagnosis.

Elevation of the ESR, a normocytic normochromic anaemia, and leucocytosis are common but not invariable. Measurement of serum CRP is more reliable than the ESR in monitoring progress. Proteinuria may occur and non-visible haematuria is usually present.

The ECG may show the development of AV block (due to aortic root abscess formation) and occasionally infarction due to emboli. The chest X-ray may show evidence of cardiac failure and cardiomegaly.

**Management**

A multidisciplinary approach, with cooperation between the physician, surgeon and microbiologist, increases the chance of a successful outcome. Any source of infection should be removed as soon as possible; for example, a tooth with an apical abscess should be extracted, or an in-dwelling catheter or device removed.

Empirical treatment depends on the mode of presentation, the suspected organism and the presence of a prosthetic valve or penicillin allergy. If the presentation is subacute, antibiotic treatment should ideally be withheld until the results of blood cultures are available. However, if empirical antibiotic treatment is considered necessary, amoxicillin (2 g IV 6 times daily) should be considered (with or without gentamicin). If the presentation is acute, empirical therapy should be started with vancomycin (1 g IV twice daily) and gentamicin (1 mg/kg IV twice daily), with dose adjustment based on antibiotic levels. The same regimen is used in true penicillin allergy. Patients with suspected prosthetic valve

endocarditis should be treated with vancomycin and gentamicin at the above-mentioned doses, plus rifampicin orally in a dose of 300–600 mg twice daily. Following identification of the causal organism, determination of the minimum inhibitory concentration (MIC) for the organism helps guide antibiotic therapy. Recommended regimens for some of the most common scenarios are shown in Box 16.96. More detailed information can be found in the 2012 British Society for Antimicrobial Chemotherapy guidelines (see ‘Further reading’).

A 2-week treatment regimen may be sufficient for fully sensitive strains of streptococci, provided specific conditions are met (Box 16.97).

Cardiac surgery with débridement of infected material and valve replacement may be required in a substantial proportion of patients, particularly those with *Staph. aureus* and fungal infections (Box 16.98). Antimicrobial therapy must be started before surgery.

**Prevention**

Antibiotic prophylaxis is no longer routinely given to people at risk of infective endocarditis undergoing interventional procedures. It can be considered in those at the highest risk of endocarditis.

**Congenital heart disease**

Congenital heart disease can be the result of defects in the formation of the heart or great vessels or can arise because the anatomical changes that occur during transition between the fetus and the newborn child fail to proceed normally. Congenital heart disease usually presents in

### 16.96 Antimicrobial treatment of common causative organisms in infective endocarditis

Antimicrobial susceptibility	Antimicrobial	Dose	Duration	
			Native valve	Prosthetic valve
<b>Streptococci</b>				
Penicillin MIC $\leq 0.125$ mg/L	Benzylpenicillin IV	1.2 g 6 times daily	4 weeks <sup>d</sup>	6 weeks
Penicillin MIC $> 0.125, \leq 0.5$ mg/L	Benzylpenicillin IV and gentamicin IV	2.4 g 6 times daily	4 weeks	6 weeks
		1 mg/kg twice daily <sup>2</sup>	2 weeks	2 weeks
Penicillin MIC $> 0.5$ mg/L	Vancomycin IV and gentamicin IV	1 g twice daily <sup>3</sup>	4 weeks	6 weeks
		1 mg/kg twice daily <sup>2</sup>	4 weeks	6 weeks
<b>Enterococci</b>				
Amoxicillin MIC $\leq 4$ mg/L and gentamicin MIC $\leq 128$ mg/L	Amoxicillin IV and gentamicin IV <sup>2</sup>	2 g 6 times daily	4 weeks	6 weeks
		1 mg/kg twice daily <sup>2</sup>	4 weeks	6 weeks
Amoxicillin MIC $> 4$ mg/L and gentamicin MIC $\leq 128$ mg/L	Vancomycin IV and gentamicin IV <sup>2</sup>	1 g twice daily <sup>3</sup>	4 weeks	6 weeks
		1 mg/kg twice daily <sup>2</sup>	4 weeks	6 weeks
<b>Staphylococci – native valve</b>				
Meticillin-sensitive	Flucloxacillin IV	2 g 4–6 times daily <sup>d</sup>	4 weeks	–
Meticillin-resistant, vancomycin MIC $\leq 2$ mg/L, rifampicin-sensitive	Vancomycin IV	1 g twice daily <sup>3</sup>	4 weeks	–
	Rifampicin orally	300–600 mg twice daily	4 weeks	–
<b>Staphylococci – prosthetic valve</b>				
Meticillin-sensitive	Flucloxacillin IV	2 g 4–6 times daily	–	6 weeks
	and gentamicin IV	1 mg/kg twice daily <sup>2</sup>	–	6 weeks
	and rifampicin orally	300–600 mg twice daily	–	6 weeks
Meticillin-resistant, vancomycin MIC $\leq 2$ mg/L, rifampicin-sensitive	Vancomycin IV	1 g twice daily <sup>3</sup>	–	6 weeks
	and rifampicin orally	300–600 mg twice daily	–	6 weeks

<sup>1</sup>When conditions in Box 16.97 are met, 2 weeks of benzylpenicillin and gentamicin (1 mg/kg twice daily) may be sufficient. Ceftriaxone 2 g once daily IV/IM can be used instead of benzylpenicillin for those with non-severe penicillin allergy. <sup>2</sup>Pre-dose gentamicin level should be  $\leq 1$  mg/L, post-dose 3–5 mg/L. Adjust dose according to levels and renal function. <sup>3</sup>Pre-dose vancomycin level should be 15–20 mg/L. Adjust dose according to levels and renal function. <sup>4</sup>Use 6 times daily if weight  $> 85$  kg. (IM = intramuscular; IV = intravenous; MIC = minimum inhibitory concentration)

### 16.97 Conditions for the short-course treatment of endocarditis caused by fully sensitive streptococci

- Native valve infection
  - Minimum inhibitory concentration (MIC)  $\leq 0.125$  mg/L
  - No adverse prognostic factors (heart failure, aortic regurgitation, conduction defect)
  - No evidence of thromboembolic disease
  - No vegetations  $> 5$  mm diameter
- Clinical response within 7 days

childhood but some patients do not present until adult life. It has been estimated that the incidence of haemodynamically significant congenital cardiac abnormalities is about 0.8% of live births (Box 16.99). Defects that are well tolerated, such as atrial septal defect, may cause no symptoms until adult life or may be detected incidentally on routine examination or chest X-ray. Congenital defects that were previously fatal in childhood can now be corrected, or at least partially, so that survival to adult life is the norm. Such patients remain well for many years but subsequently re-present in later life with related problems, such as arrhythmia or heart failure (Box 16.100).

#### Pathophysiology

Understanding the fetal circulation helps clarify how some forms of congenital heart disease occur. Fig. 16.88 shows the fetal circulation

### 16.98 Indications for cardiac surgery in infective endocarditis\*

- Heart failure due to valve damage
- Failure of antibiotic therapy (persistent/uncontrolled infection)
- Large vegetations on left-sided heart valves with echo appearance suggesting high risk of emboli
- Previous evidence of systemic emboli
- Abscess formation

\*Patients with prosthetic valve endocarditis or fungal endocarditis often require cardiac surgery.

and the changes that normally occur immediately after birth. In the fetus there is little blood flow through the lungs, which are collapsed because they are not required for gas exchange. Instead, oxygenated blood from the placenta passes directly from the right atrium to the left side of the heart through the foramen ovale without having to flow through the lungs, and also from the pulmonary artery into the aorta via the ductus arteriosus.

During early embryonic life, the heart develops as a single tube that folds back on itself and then divides into two separate circulations. Failure of septation can cause some forms of atrial and ventricular septal defect, whereas failure of alignment of the great vessels with the ventricles contributes to transposition of the great arteries, tetralogy of Fallot and truncus arteriosus. Atrial septal defects occur because the foramen ovale fails to close at birth, as is normal. Similarly, a persistent ductus arteriosus will

### 16.99 Incidence and relative frequency of congenital cardiac malformations

### 16.100 Presentation of congenital heart disease throughout life

Birth and neonatal period	
• Cyanosis	• Heart failure
Infancy and childhood	
• Cyanosis	• Murmur
• Heart failure	• Failure to thrive
• Arrhythmia	
Adolescence and adulthood	
• Heart failure	• Complications of previous cardiac surgery:
• Murmur	Arrhythmia related to scarring
• Arrhythmia	Heart failure secondary to scarring
• Eisenmenger syndrome	
• Hypertension (coarctation)	

remain if it fails to close after birth. Failure of the aorta to develop at the point of the aortic isthmus and where the ductus arteriosus attaches can lead to coarctation of the aorta. Maternal infection and exposure to drugs or toxins are important causes of congenital heart disease. Maternal rubella infection is associated with persistent ductus arteriosus, pulmonary valvular and/or artery stenosis, and atrial septal defect. Maternal alcohol misuse is associated with septal defects, and maternal lupus erythematosus with congenital complete heart block. Genetic or chromosomal abnormalities, such as Down syndrome, may cause septal defects, and gene defects have also been identified as leading to specific abnormalities, such as Marfan syndrome and Turner syndrome (karyotype XO).

#### Clinical features

Symptoms may be absent, or the child may be breathless or fail to attain normal growth and development. Some defects are not compatible with extrauterine life and lead to neonatal death. Clinical signs vary with the anatomical lesion. Murmurs, thrills or signs of cardiomegaly may be present. In coarctation of the aorta, radio-femoral delay may be noted (Fig. 16.89) and some female patients have the features of Turner syndrome (p. 674). Features of other congenital conditions, such as Marfan syndrome or Down syndrome, may also be apparent. Cerebrovascular events and cerebral abscesses may complicate severe cyanotic congenital disease.

Early diagnosis is important because many types of congenital heart disease are amenable to surgery, but this opportunity is lost if secondary changes, such as irreversible pulmonary hypertension, occur.

#### Central cyanosis and digital clubbing

Central cyanosis of cardiac origin occurs when desaturated blood enters the systemic circulation without passing through the lungs (right-to-left

shunting). In the neonate, the most common cause is transposition of the great arteries, in which the aorta arises from the RV and the pulmonary artery from the LV in association with a ventricular septal defect. In older children, cyanosis is usually the consequence of a ventricular septal defect combined with severe pulmonary stenosis (as in tetralogy of Fallot) or with pulmonary vascular disease (Eisenmenger syndrome). Chronic cyanosis is associated with finger and toe clubbing.

#### Growth retardation and learning difficulties

These may occur with large left-to-right shunts at ventricular or great arterial level, and also with other defects, especially if they form part of a genetic syndrome. Major intellectual impairment is uncommon in children with isolated congenital heart disease but minor learning difficulties can occur. Cerebral function can also be affected after cardiac surgery if cerebral perfusion is compromised.

#### Syncope

In the presence of increased pulmonary vascular resistance or severe left or right ventricular outflow obstruction, exercise may provoke syncope as systemic vascular resistance falls but pulmonary vascular resistance rises, worsening right-to-left shunting and cerebral oxygenation. Syncope can also occur because of associated arrhythmias.

#### Pulmonary hypertension

Persistently raised pulmonary flow with a left-to-right shunt causes increased pulmonary vascular resistance followed by pulmonary hypertension. Progressive changes, including obliteration of distal arterioles, take place and are irreversible. At this stage, central cyanosis occurs and digital clubbing develops. The chest X-ray shows enlarged central pulmonary arteries and peripheral 'pruning' of the pulmonary vessels. The ECG shows features of right ventricular hypertrophy.

#### Eisenmenger syndrome

In patients with severe and prolonged pulmonary hypertension the left-to-right shunt may reverse, resulting in right-to-left shunt and marked cyanosis. This is termed Eisenmenger syndrome. The cyanosis in Eisenmenger syndrome may be more apparent in the feet and toes than in the upper part of the body, resulting in so-called differential cyanosis. Eisenmenger syndrome is more common with large ventricular septal defects or persistent ductus arteriosus than with atrial septal defects. Patients with Eisenmenger syndrome are at particular risk from abrupt changes in afterload that exacerbate right-to-left shunting, such as vasodilatation, anaesthesia and pregnancy. The long-term prognosis is poor with around 50% of young adults surviving 10 years from diagnosis.

#### Congenital heart disease in pregnancy

During pregnancy, there is a 50% increase in plasma volume, a 40% increase in whole blood volume and a similar increase in cardiac output, so problems may arise in women with congenital heart disease (Box 16.101). Many with palliated or untreated disease will tolerate pregnancy well, however. Pregnancy is particularly hazardous in the presence of conditions associated with cyanosis or severe pulmonary hypertension; maternal mortality in patients with Eisenmenger syndrome is more than 50%.

### Persistent ductus arteriosus

Normally, the ductus arteriosus closes soon after birth but in this anomaly it fails to do so. Persistence of the ductus is often associated with other abnormalities and is more common in females.

#### Pathophysiology

During fetal life, before the lungs begin to function, most of the blood from the pulmonary artery passes through the ductus arteriosus into the aorta (see Fig. 16.88). Persistence of the ductus causes a continuous AV shunt from the aorta to the pulmonary artery since pressure in the aorta is higher than that in the pulmonary artery. The volume of

**Fig. 16.88** Changes in the circulation at birth. **A** In the fetus, oxygenated blood comes through the umbilical vein where it enters the inferior vena cava (IVC) via the ductus venosus (red). The oxygenated blood streams from the right atrium (RA) through the open foramen ovale to the left atrium (LA) and via the left ventricle (LV) into the aorta. Venous blood from the superior vena cava (SVC, blue) crosses under the main blood stream into the RA and then, partly mixed with oxygenated blood (purple), into the right ventricle (RV) and pulmonary artery (PA). The pulmonary vasculature has a high resistance and so little blood passes to the lungs; most blood passes through the ductus arteriosus to the descending aorta. The aortic isthmus is a constriction in the aorta that lies in the aortic arch before the junction with the ductus arteriosus and limits the flow of oxygen-rich blood to the descending aorta. This configuration means that less oxygen-rich blood is supplied to organ systems that take up their function mainly after birth, e.g. the kidneys and intestinal tract. **B** At birth, the lungs expand with air and pulmonary vascular resistance falls, so that blood now flows to the lungs and back to the LA. The left atrial pressure rises above right atrial pressure and the flap valve of the foramen ovale closes. The umbilical arteries and the ductus venosus close. In the next few days, the ductus arteriosus closes under the influence of hormonal changes (particularly prostaglandins) and the aortic isthmus expands. (PV = pulmonary vein) Adapted from *Drews U. Colour atlas of embryology. Stuttgart: Georg Thieme; 1995.*

**Fig. 16.89** Radio-femoral delay. The difference in pulse pressures is shown.

**16.101 Pregnancy in women with congenital heart disease**

- **Obstructive lesions:** poorly tolerated and associated with significant maternal morbidity and mortality.
- **Cyanotic conditions:** especially poorly tolerated. Specialised pre-conception counselling should explain the increased risks.
- **Surgically corrected disease:** patients often tolerate pregnancy well.
- **Children of patients with congenital heart disease:** 2%–5% will be born with cardiac abnormalities, especially if the mother is affected. The risk may be up to 20% in babies born of women with left-sided lesions.

the shunt depends on the size of the ductus but as much as 50% of the left ventricular output may be recirculated through the lungs, with a consequent increase in the work of the heart (Fig. 16.90). A large left-to-right shunt in infancy may cause a considerable rise in pulmonary

artery pressure and sometimes this leads to progressive pulmonary vascular damage.

### Clinical features

With small shunts there may be no symptoms for years, but when the ductus is large, growth and development may be retarded. Usually, there is no disability in infancy but cardiac failure may eventually ensue, dyspnoea being the first symptom. A continuous 'machinery' murmur is heard with late systolic accentuation, maximal in the second left intercostal space below the clavicle (see Fig. 16.90). It is often accompanied by a thrill. Pulses are increased in volume.

Enlargement of the pulmonary artery may be detected radiologically. The ECG is usually normal. If pulmonary vascular resistance increases, pulmonary artery pressure may rise until it equals or exceeds aortic pressure. The shunt through the defect may then reverse, causing Eisenmenger syndrome. The murmur becomes quieter, may be confined to systole or may disappear.

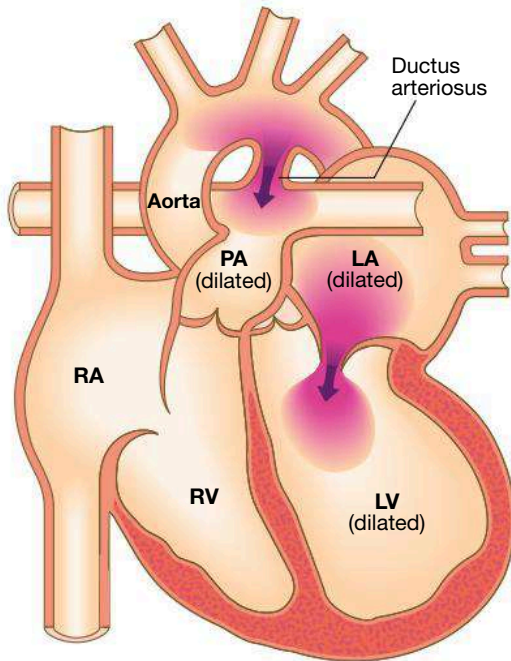

### Investigations

Echocardiography is the investigation of choice although the persistent ductus requires specific echocardiographic views, such as from the suprasternal notch, to reveal it. The ECG shows evidence of right ventricular hypertrophy.

### Management

A persistent ductus can be closed at cardiac catheterisation with an implantable occlusive device. Closure should be undertaken in infancy if the shunt is significant and pulmonary resistance not elevated, but this

**Fig. 16.90** Persistent ductus arteriosus. There is a connection between the aorta and the pulmonary artery with left-to-right shunting. (LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle)

may be delayed until later childhood in those with smaller shunts, for whom closure remains advisable to reduce the risk of endocarditis. When the ductus is structurally intact, a prostaglandin synthetase inhibitor (indomethacin or ibuprofen) may be used in the first week of life to induce closure. However, in the presence of a congenital defect with impaired lung perfusion, such as occurs in severe pulmonary stenosis and left-to-right shunt through the ductus, it may be advisable to improve oxygenation by keeping the ductus open with prostaglandin treatment. Unfortunately, these treatments do not work if the ductus is intrinsically abnormal.

## Coarctation of the aorta

This condition is twice as common in males and occurs in 1 in 4000 children. It is associated with other abnormalities, most frequently bicuspid aortic valve and 'berry' aneurysms of the cerebral circulation. Acquired coarctation of the aorta is rare but may follow trauma or occur as a complication of Takayasu's disease.

### Pathogenesis

Narrowing of the aorta occurs in the region where the ductus arteriosus joins the aorta, at the isthmus just below the origin of the left subclavian artery (see Fig. 16.88). This causes raised BP affecting vessels of the head and neck proximal to the coarctation, and reduced BP and impaired circulation distally.

### Clinical features

Aortic coarctation is an important cause of cardiac failure in the newborn but symptoms are often absent in older children or in adults. Headaches may occur from hypertension proximal to the coarctation, and occasionally weakness or cramps in the legs may result from decreased circulation in the lower part of the body. The BP is raised in the upper body but normal or low in the legs. The femoral pulses are weak and delayed in comparison with the radial pulse (see Fig. 16.89). A systolic murmur is usually heard posteriorly, over the coarctation. There may also be an ejection click and systolic murmur in the aortic area due to a bicuspid aortic valve. As a result of the aortic narrowing, collaterals form; they mainly involve the periscapular, internal mammary and intercostal arteries, and may result in localised bruits.

**Fig. 16.91** MRI scan of coarctation of the aorta. The aorta is severely narrowed just beyond the arch at the start of the descending aorta (arrow A). Extensive collaterals have developed; a large internal mammary artery (arrow B) and several intercostal arteries (arrows C) are shown. Unusually, in this case, there is also a coarctation of the abdominal aorta (arrow D).

### Investigations

Imaging by MRI is the investigation of choice (Fig. 16.91). The chest X-ray in early childhood is often normal but later may show changes in the contour of the aorta (indentation of the descending aorta, '3 sign') and notching of the under-surfaces of the ribs from collaterals. The ECG may show evidence of left ventricular hypertrophy, which can be confirmed by echocardiography.

### Management

In untreated cases death may occur from left ventricular failure, dissection of the aorta or cerebral haemorrhage. Surgical correction is advisable in all but the mildest cases. If this is carried out sufficiently early in childhood, persistent hypertension can be avoided. Patients repaired in late childhood or adult life often remain hypertensive or develop recurrent hypertension later on. Recurrence of stenosis may occur as the child grows and this may be managed by balloon dilatation and sometimes stenting. The latter may be used as the primary treatment. Coexistent bicuspid aortic valve, which occurs in over 50% of cases, may lead to progressive aortic stenosis or regurgitation, and also requires long-term follow-up.

## Atrial septal defect

Atrial septal defect is one of the most common congenital heart defects and occurs twice as frequently in females. Most are 'ostium secundum' defects, involving the fossa ovalis that, in utero, was the foramen ovale (see Fig. 16.88). 'Ostium primum' defects result from a defect in the atrioventricular septum and are associated with a 'cleft mitral valve' (split anterior leaflet).

### Pathogenesis

Since the normal RV is more compliant than the LV, a patent foramen ovale is associated with shunting of blood from the LA to the RA, and then to the RV and pulmonary arteries (Fig. 16.92). As a result, there is gradual enlargement of the right side of the heart and of the pulmonary arteries. Pulmonary hypertension and shunt reversal sometimes complicate atrial septal defect, but are less common and tend to occur later in life than with other types of left-to-right shunt.

### Clinical features

Most children are asymptomatic for many years and the condition is often detected at routine examination or following a chest X-ray. Symptoms include dyspnoea, cardiac failure and arrhythmias, especially AF. The characteristic physical signs are the result of the volume overload of the RV:

**Fig. 16.92 Atrial septal defect.** Blood flows across the atrial septum (arrow) from left to right. The murmur is produced by increased flow velocity across the pulmonary valve, as a result of left-to-right shunting and a large stroke volume. The density of shading is proportional to velocity of blood flow. (LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle)

- wide, fixed splitting of the second heart sound: wide because of delay in right ventricular ejection (increased stroke volume and RBBB), and fixed because the septal defect equalises left and right atrial pressures throughout the respiratory cycle
- a systolic flow murmur over the pulmonary valve.

In children with a large shunt, there may be a diastolic flow murmur over the tricuspid valve. Unlike a mitral flow murmur, this is usually high-pitched.

### Investigations

Echocardiography is diagnostic. It directly demonstrates the defect and typically shows right ventricular dilatation, right ventricular hypertrophy and pulmonary artery dilatation. The precise size and location of the defect are best defined by TOE (Fig. 16.93). The chest X-ray typically shows enlargement of the heart and the pulmonary artery, as well as pulmonary plethora. The ECG usually demonstrates incomplete RBBB because right ventricular depolarisation is delayed as a result of ventricular dilatation (with a 'primum' defect, there is also left axis deviation).

### Management

Atrial septal defects in which pulmonary flow is increased 50% above systemic flow (i.e. a flow ratio of 1.5:1) are often large enough to be clinically recognisable and should be closed surgically. Smaller defects may be managed conservatively and patients monitored periodically with echocardiography. Closure can also be accomplished at cardiac catheterisation using implantable closure devices (Fig. 16.94). The long-term prognosis thereafter is excellent, unless pulmonary hypertension has developed. Severe pulmonary hypertension and shunt reversal are both contraindications to surgery.

## Ventricular septal defect

Ventricular septal defect is the most common congenital cardiac defect, occurring once in 500 live births. The defect may be isolated or part of complex congenital heart disease.

**Fig. 16.93 Transoesophageal echocardiogram of an atrial septal defect.** The defect is clearly seen (arrow) between the left atrium above and right atrium below. Doppler colour-flow imaging shows flow (blue) across the defect.

**Fig. 16.94 Percutaneous closure of atrial septal defect.** The closure device is delivered across the interatrial septum and a disc deployed on either side to seal the defect. (IVC = inferior vena cava; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle)

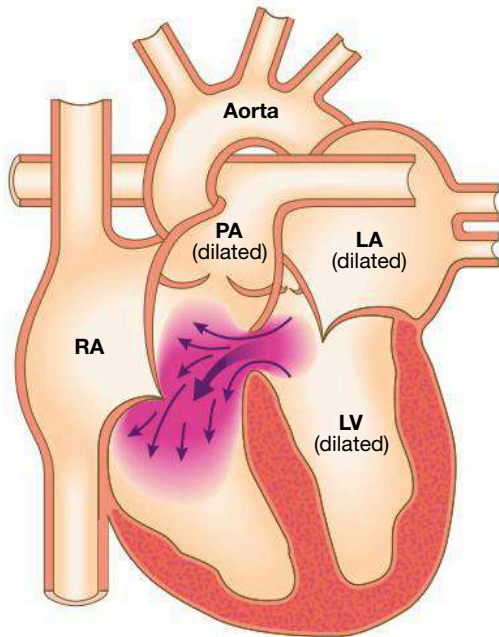

### Pathogenesis

Congenital ventricular septal defect occurs as a result of incomplete septation of the ventricles. Embryologically, the interventricular septum has a membranous and a muscular portion, and the latter is further divided into inflow, trabecular and outflow portions. Most congenital defects are 'perimembranous', occurring at the junction of the membranous and muscular portions of the septum.

### Clinical features

Flow from the high-pressure LV to the low-pressure RV during systole produces a pansystolic murmur, usually heard best at the left sternal border but radiating all over the precordium (Fig. 16.95). A small defect often produces a loud murmur (maladie de Roger) in the absence of other haemodynamic disturbance. Conversely, a large defect produces a quieter murmur, particularly if pressure in the RV is elevated. This may be found immediately after birth, while pulmonary vascular resistance remains high, or when the shunt is reversed in Eisenmenger syndrome. Congenital ventricular septal defect may present with cardiac failure in infants, as a murmur with only minor haemodynamic disturbance in older children or adults, or, rarely, as Eisenmenger syndrome. In some infants, the murmur becomes quieter or disappears due to spontaneous closure of the defect.

If cardiac failure complicates a large defect, it is usually absent in the immediate postnatal period and becomes apparent only in the first 4–6 weeks of life. In addition to the murmur, there is prominent parasternal pulsation, tachypnoea and indrawing of the lower ribs on inspiration.

**Fig. 16.95 Ventricular septal defect.** In this example, a large left-to-right shunt (arrows) has resulted in chamber enlargement. (LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium)

### Investigations

Echocardiography should be performed since it helps to identify the small septal defects that are not haemodynamically significant and are likely to close spontaneously. Patients with larger defects should be monitored by serial echocardiography to check for signs of pulmonary hypertension. With larger defects, the chest X-ray shows pulmonary congestion and the ECG shows bilateral ventricular hypertrophy.

### Management

Small ventricular septal defects require no specific treatment. If there is cardiac failure in infancy, this should initially be treated with digoxin, diuretics and sometimes ACE inhibitors. Persisting failure is an indication for surgical repair of the defect. Percutaneous closure devices are under development.

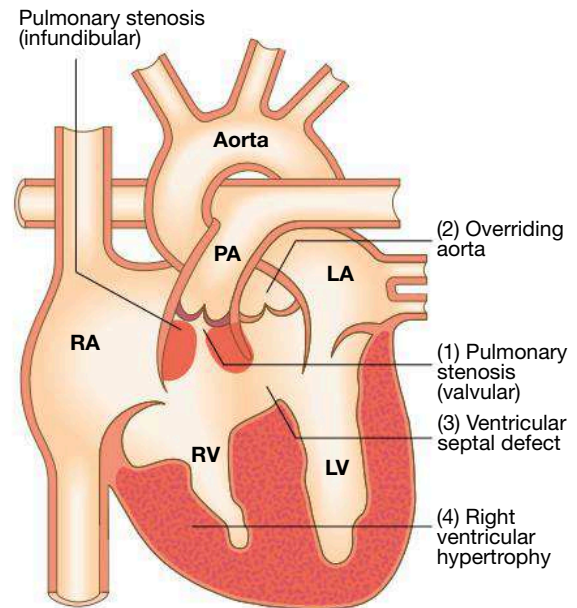

If serial ECG and echocardiography suggest that pulmonary hypertension is developing, surgical repair should be performed. Surgical closure is contraindicated in Eisenmenger syndrome, and heart–lung transplantation is the only effective treatment. The long-term prognosis is generally very good unless Eisenmenger syndrome develops, when death occurs in the second or third decade of life, but a few individuals survive to the fifth decade without transplantation.

## Tetralogy of Fallot

This is a complex defect consisting of right ventricular outflow tract obstruction and right ventricular hypertrophy, a large ventricular septal defect and an overriding aorta that, when combined with the septal defect, allows blood to be pumped directly from the RV into the aorta. It occurs in about 1 in 2000 births and is the most common cause of cyanosis in infancy after the first year of life.

### Pathogenesis

Tetralogy of Fallot occurs as the result of abnormal development of the bulbar septum that separates the ascending aorta from the pulmonary artery, and which normally aligns and fuses with the outflow part of the interventricular septum. The right ventricular outflow obstruction is most often subvalvular (muscular) but may be valvular, supra-valvular or a combination of these (Fig. 16.96). The subvalvular component of the right

**Fig. 16.96 Tetralogy of Fallot.** The tetralogy comprises (1) pulmonary stenosis, (2) overriding of the ventricular septal defect by the aorta, (3) a ventricular septal defect and (4) right ventricular hypertrophy. (LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle)

ventricular outflow obstruction is dynamic and may increase suddenly with sympathetic stimulation. The ventricular septal defect is usually large and similar in aperture to the aortic orifice. The combination results in elevated right ventricular pressure and right-to-left shunting of cyanotic blood across the ventricular septal defect into the aorta.

### Clinical features

Children are usually cyanosed but this may not be the case in the neonate because it is only when right ventricular pressure rises to equal or exceed left ventricular pressure that a large right-to-left shunt develops. The affected child may suddenly become increasingly cyanosed, often after feeding or a crying attack, and may become apnoeic and unconscious. In older children, cyanotic spells are uncommon but cyanosis becomes increasingly apparent, with stunting of growth, digital clubbing and polycythaemia. Some children characteristically obtain relief by squatting after exertion, which increases the afterload of the left heart and reduces the right-to-left shunting. This is called Fallot's sign. The natural history before the development of surgical correction was variable but most patients died in infancy or childhood.

On examination, the most characteristic feature is the combination of cyanosis with a loud ejection systolic murmur in the pulmonary area (as for pulmonary stenosis). Cyanosis may be absent in the newborn or in patients with only mild right ventricular outflow obstruction, however. This is called acyanotic tetralogy of Fallot.

### Investigations

Echocardiography is diagnostic and demonstrates that the aorta is not continuous with the anterior ventricular septum. The ECG shows right ventricular hypertrophy and the chest X-ray shows an abnormally small pulmonary artery and a 'boot-shaped' heart.

### Management

The definitive management is total correction of the defect by surgical relief of the pulmonary stenosis and closure of the ventricular septal defect. Primary surgical correction may be undertaken prior to the age of 5 years. If the pulmonary arteries are too hypoplastic for surgical repair, then palliation in the form of a Blalock–Taussig shunt may be performed, where an anastomosis is created between the pulmonary artery and

16.102 Other causes of cyanotic congenital heart disease	
Defect	Features
<b>Tricuspid atresia</b>	Absent tricuspid orifice, hypoplastic RV, RA-to-LA shunt, ventricular septal defect shunt, other anomalies  Surgical correction may be possible
<b>Transposition of the great arteries</b>	Aorta arises from the morphological RV, pulmonary artery from LV  Shunt via atria, ductus and possibly ventricular septal defect  Palliation by balloon atrial septostomy/enlargement  Surgical correction possible
<b>Pulmonary atresia</b>	Pulmonary valve atretic and pulmonary artery hypoplastic  RA-to-LA shunt, pulmonary flow via ductus  Palliation by balloon atrial septostomy  Surgical correction may be possible
<b>Ebstein's anomaly</b>	Tricuspid valve is dysplastic and displaced into RV, RV 'atrialised'  Tricuspid regurgitation and RA-to-LA shunt  Wide spectrum of severity  Arrhythmias  Surgical repair possible but significant risk

(LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle)

subclavian artery. This improves pulmonary blood flow and pulmonary artery development, and may facilitate later definitive correction.

The prognosis after total correction is good, especially if the operation is performed in childhood. Follow-up is needed to identify residual shunting, recurrent pulmonary stenosis and arrhythmias. An implantable defibrillator is sometimes recommended in adulthood.

### Other causes of cyanotic congenital heart disease

Other types of cyanotic congenital heart disease are summarised in Box 16.102.

### Grown-up congenital heart disease

There are increasing numbers of children who have had surgical correction of congenital defects and who may have further problems as adults. The transition period between paediatric and adult care needs to be managed in a carefully planned manner, addressing many diverse aspects of care (Box 16.103). Those who have undergone correction of coarctation of the aorta may develop hypertension in adult life. Those with transposition of the great arteries who have had a 'Mustard' repair, in which blood is redirected at atrial level leaving the RV connected to the aorta, may develop right ventricular failure in adult life. This is because the RV is unsuited for function at systemic pressures and may begin to dilate and fail when patients are in their twenties or thirties.

Those who have had surgery involving the atria may develop atrial arrhythmias, and those who have VSD repair (and consequent ventricular scar) may develop ventricular arrhythmias. Anti-arrhythmic drugs and an ICD may be required. Such patients require careful follow-up from adolescence throughout adult life, so that problems can be identified early and appropriate medical or surgical treatment instituted. The management of patients with grown-up congenital heart disease (GUCH) is complex and has developed as a cardiological subspecialty.

### 16.103 Congenital heart disease in adolescence

- **Patients:** a heterogeneous population with residual disease and sequelae that vary according to the underlying lesion and in severity; each patient must be assessed individually.
- **Management plan:** should be agreed with the patient and include short- and long-term goals and timing of transition to adult care.
- **Risks of surgery:** non-cardiac surgery for associated congenital abnormalities carries increased risks and needs to be planned, with careful pre-operative assessment. Risks include thrombosis, embolism from synthetic shunts or patches, and volume overload from fluid shifts. Operative approaches should address cosmetic concerns, such as site of implantation of abdominal generator.
- **Exercise:** patients with mild or repaired defects can undertake moderately vigorous exercise but those with complex defects, cyanosis, ventricular dysfunction or arrhythmias require specialist evaluation and individualised advice regarding exercise.
- **Genetics:** Between 10% and 15% have a genetic basis and this should be assessed to understand the impact it may have for the patient's own future children. A family history, genetic evaluation of syndromic versus non-syndromic disorders and, sometimes, cytogenetics are required.
- **Education and employment:** may be adversely affected and occupational activity levels need to be assessed.
- **End of life:** some adolescents with complex disorders may misperceive and think they have been cured; transition to adult services may be the first time they receive information about mortality. Expectations on life expectancy need to be managed and adolescents are often willing to engage with this and play a role in decision-making.

## Diseases of the myocardium

The myocardium can be injured secondary to ischaemia in CAD and to pressure or volume overload in hypertension or valvular heart disease. The heart muscle can be directly affected by primary heart muscle diseases.

### Myocarditis

This is an acute inflammatory condition that can have an infectious, toxic or autoimmune aetiology (Box 16.104). Myocarditis can complicate many infections in which inflammation may be due directly to infection of the myocardium or the effects of circulating toxins. Viral infections are the most common causes, such as Cocksackie (35 cases per 1000 infections), influenza A and B (25 cases per 1000 infections) and, more recently, SARS-CoV-2 infection. Myocarditis may occur several weeks after the initial viral symptoms, and susceptibility is increased by glucocorticoid treatment, immunosuppression, radiation, previous myocardial damage and exercise. Some bacterial and protozoal infections may be complicated by myocarditis; for example, approximately 5% of patients with Lyme disease (*Borrelia burgdorferi*) develop myopericarditis, which is often associated with AV block. Toxins such as alcohol and drugs such as cocaine, lithium and doxorubicin may directly injure the myocardium. Other drugs, including penicillins and sulphonamides, and poisons such as lead and carbon monoxide, may cause a hypersensitivity reaction and associated myocarditis. Occasionally, autoimmune conditions, such as systemic lupus erythematosus and rheumatoid arthritis, are associated with myocarditis.

#### Clinical features

Myocarditis may present in one of four ways:

- **Fulminant myocarditis** follows a viral prodrome or influenza-like illness and results in severe heart failure or cardiogenic shock.
- **Acute myocarditis** presents over a longer period with heart failure; it can lead to dilated cardiomyopathy.

- *Chronic active myocarditis* is rare and associated with chronic myocardial inflammation.
- *Chronic persistent myocarditis* is characterised by focal myocardial infiltrates and can cause chest pain and arrhythmia without necessarily causing ventricular dysfunction.

Myocarditis is self-limiting in most patients and the immediate prognosis is good. Death may, however, occur due to a ventricular arrhythmia

or rapidly progressive heart failure. Myocarditis has been reported as a cause of sudden and unexpected death in young athletes. Some forms of myocarditis may lead to chronic low-grade myocarditis or dilated cardiomyopathy (see below). For example, in Chagas' disease, the patient frequently recovers from the acute infection but goes on to develop a chronic dilated cardiomyopathy 10 or 20 years later.

### Investigations

The diagnosis of myocarditis is often made after other more common causes of cardiac dysfunction have been excluded. Echocardiography should be performed and may reveal left ventricular dysfunction that is sometimes regional (due to focal myocarditis). Cardiac MRI is also useful since it may show diagnostic patterns of myocardial inflammation or infiltration. The ECG is frequently abnormal but the changes are non-specific. Blood should be taken to assess for cardiac troponin I or T which can be used to monitor severity and progression of cardiac injury and myocarditis. Occasionally, endomyocardial biopsy may be required to confirm the diagnosis.

### Management

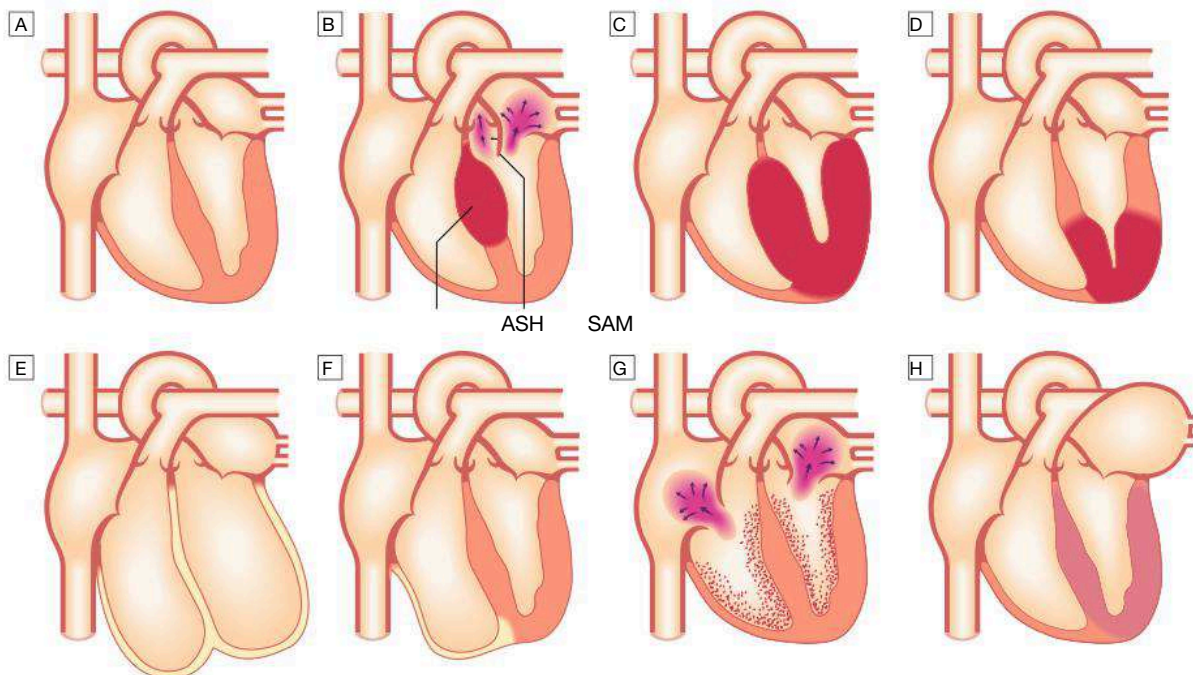

Treatment of myocarditis is primarily supportive. Treatment for cardiac failure or arrhythmias should be given and patients should be advised to avoid intense physical exertion because there is some evidence that this can induce potentially fatal ventricular arrhythmias. There is no evidence of benefit from treatment with glucocorticoids and immunosuppressive agents.

Specific antimicrobial therapy may be used if a causative organism has been identified but this is rare. Patients who do not respond adequately to medical treatment may temporarily require circulatory support with a mechanical ventricular assist device. Rarely, cardiac transplantation may be required.

### Cardiomyopathy

Cardiomyopathies are primary diseases of the myocardium, which are classified according to their effects on cardiac structure and function (Fig. 16.97). They can be inherited or be caused by infections or exposure to toxins. In some cases no cause is identified.

16.104 Some causes of myocarditis	
<b>Infections</b>	
<b>Viral</b>	
• Coxsackie	• Human immunodeficiency virus (HIV)
• Adenovirus	• Influenza B
• Influenza A	• SARS-CoV-2
<b>Bacterial</b>	
• <i>Borrelia burgdorferi</i> (Lyme disease)	• <i>Mycoplasma pneumoniae</i>
<b>Protozoal</b>	
• <i>Trypanosoma cruzi</i> (Chagas' disease)	• <i>Toxoplasma gondii</i>
<b>Fungal</b>	
• <i>Aspergillus</i>	
<b>Parasitic</b>	
• <i>Shistosoma</i>	
<b>Drugs/Toxins</b>	
• Alcohol	• Cocaine
• Anthracyclines	• Lithium
• Clozapine	
<b>Autoimmune</b>	
• Systemic lupus erythematosus	• Hypersensitivity reaction to penicillins, sulphonamides, lead, carbon monoxide
• Systemic sclerosis	
• Rheumatoid arthritis	
• Sarcoidosis	

**Fig. 16.97** Types of cardiomyopathy. **A** Normal heart. **B** Hypertrophic cardiomyopathy: asymmetric septal hypertrophy (ASH) with systolic anterior motion of the mitral valve (SAM), causing mitral reflux and dynamic left ventricular outflow tract obstruction. **C** Hypertrophic cardiomyopathy: concentric hypertrophy. **D** Hypertrophic cardiomyopathy: apical hypertrophy. **E** Dilated cardiomyopathy. **F** Arrhythmogenic right ventricular cardiomyopathy. **G** Obliterative cardiomyopathy. **H** Restrictive cardiomyopathy.

## Dilated cardiomyopathy

In North America and Europe, symptomatic dilated cardiomyopathy has an incidence of 20 per 100 000 and a prevalence of 38 per 100 000. Men are affected more than twice as often as women.

### Pathogenesis

Cardiomyopathy is characterised by dilatation and impaired contraction of the LV and often the RV. Left ventricular mass is increased but wall thickness is normal or reduced (see Fig. 16.97). Dilatation of the valve rings can lead to functional mitral and tricuspid incompetence. Histological changes are variable but include myofibrillary loss, interstitial fibrosis and T-cell infiltrates. The term 'dilated cardiomyopathy' encompasses a heterogeneous group of conditions. Alcohol may be an important cause in some patients. At least 25% of cases are inherited as an autosomal dominant trait and a variety of single-gene mutations have been identified. Most of these mutations affect proteins in the cytoskeleton of the myocytes, such as dystrophin, lamin A and C, titan, emerin and metavinculin. Many are also associated with abnormalities of skeletal muscle. The X-linked inherited skeletal muscular dystrophies, such as Becker and Duchenne, are also associated with cardiomyopathy. Finally, a late autoimmune reaction to viral myocarditis is thought to be the cause in a substantial subgroup of patients with dilated cardiomyopathy; a similar mechanism is believed to be responsible for the myocardial involvement that occurs in up to 10% of patients with advanced human immunodeficiency virus (HIV) infection.

### Clinical features

Most patients present with heart failure or are found to have the condition during routine investigation. Arrhythmia, thromboembolism and sudden death may occur at any stage but these are more common in advanced disease; non-exertional chest pain is surprisingly common. The differential diagnosis includes ventricular dysfunction due to CAD, and a diagnosis of dilated cardiomyopathy should be made only when this has been excluded.

### Investigations

Echocardiography and cardiac MRI are the most useful investigations. Although ECG changes are common, they are non-specific. Genetic testing is indicated if more than one family member is diagnosed with the condition.

### Management

The focus of management is to control heart failure using the strategies described earlier in this chapter. Although some patients remain well for many years, the prognosis is variable and cardiac transplantation may be indicated. Patients with dilated cardiomyopathy and moderate or severe heart failure are at risk of sudden arrhythmic death and this can be reduced by rigorous medical therapy with  $\beta$ -blockers and either ACE inhibitors or ARBs. Some patients may be considered for implantation of a cardiac defibrillator and/or cardiac resynchronisation therapy.

## Hypertrophic cardiomyopathy

This is the most common form of cardiomyopathy, with a prevalence of approximately 100 per 100 000. It is characterised by inappropriate left ventricular hypertrophy with malalignment of the myocardial fibres and myocardial fibrosis. The hypertrophy may be generalised or confined largely to the interventricular septum (asymmetric septal hypertrophy, see Fig. 16.97) or other regions of the heart. A specific variant termed apical hypertrophic cardiomyopathy is common in the Far East.

### Pathogenesis

Hypertrophic cardiomyopathy is a genetic disorder, usually with autosomal dominant transmission, a high degree of penetrance and variable expression. In most patients, it is due to a single-point mutation in one of the genes that encode sarcomeric contractile proteins. There are three common

groups of mutation with different phenotypes. Beta-myosin heavy-chain mutations are associated with marked ventricular hypertrophy. In contrast, troponin mutations are associated with little, if any, hypertrophy but are characterised by marked myocardial fibre disarray, exercise-induced hypotension and a high risk of sudden death. Myosin-binding protein C mutations tend to present late in life and are often associated with hypertension and arrhythmia. In all subtypes, heart failure may develop because the stiff, non-compliant LV impedes diastolic filling. Septal hypertrophy may also cause dynamic left ventricular outflow tract obstruction (hypertrophic obstructive cardiomyopathy, HOCM) and mitral regurgitation due to abnormal systolic anterior motion of the anterior mitral valve leaflet.

### Clinical features

Effort-related symptoms, such as angina, breathlessness, arrhythmia and sudden death, are the dominant clinical presentations. The symptoms and signs are similar to those of aortic stenosis, except that, in hypertrophic cardiomyopathy, the character of the arterial pulse is jerky (Box 16.105). The annual mortality from sudden death is 2%–3% among adults and 4%–6% in children and adolescents (Box 16.106). Sudden death typically occurs during or just after vigorous physical activity and is thought to be due to ventricular arrhythmias. Hypertrophic cardiomyopathy is the most common cause of sudden death in young athletes. In patients who do not suffer fatal arrhythmias, the natural history is variable but clinical deterioration is often slow.

### Investigations

Echocardiography is the investigation of choice and is usually diagnostic. Sometimes the diagnosis is more difficult when another cause of left ventricular hypertrophy is present but the degree of hypertrophy in hypertrophic cardiomyopathy is usually greater than in physiological hypertrophy and the pattern is asymmetrical. The ECG is abnormal and shows features of left ventricular hypertrophy with a wide variety of often bizarre abnormalities, including deep T-wave inversion. Genetic testing can be performed and is helpful in screening relatives of affected individuals.

### Management

Beta-blockers, rate-limiting calcium antagonists and disopyramide can help to relieve symptoms and prevent syncopal attacks. Arrhythmias often respond to treatment with amiodarone. No pharmacological

### 16.105 Clinical features of hypertrophic cardiomyopathy

#### Symptoms

- Angina on effort
- Syncope on effort
- Dyspnoea on effort
- Sudden death

#### Signs

- Jerky pulse\*
- Palpable left ventricular hypertrophy
- Double impulse at the apex (palpable fourth heart sound due to left atrial hypertrophy)
- Mid-systolic murmur at the base\*
- Pansystolic murmur (due to mitral regurgitation) at the apex

\*Signs of left ventricular outflow tract obstruction may be augmented by standing up (reduced venous return), inotropes and vasodilators

### 16.106 Risk factors for sudden death in hypertrophic cardiomyopathy

- A history of previous cardiac arrest or sustained ventricular tachycardia
- Recurrent syncope
- An adverse genotype and/or family history
- Exercise-induced hypotension
- Non-sustained ventricular tachycardia on ambulatory ECG monitoring
- Marked increase in left ventricular wall thickness

treatment has been identified that can improve prognosis, however. Outflow tract obstruction can be improved by partial surgical resection (myectomy) or by iatrogenic infarction of the basal septum (septal ablation) using a catheter-delivered alcohol solution. An ICD should be considered in patients with clinical risk factors for sudden death (see [Box 16.106](#)). Digoxin and vasodilators may increase outflow tract obstruction and should be avoided.

### Arrhythmogenic ventricular cardiomyopathy

Arrhythmogenic ventricular cardiomyopathy (AVC) predominantly affects the myocardium of the right ventricle. It is inherited in an autosomal dominant manner and has a prevalence of approximately 10 per 100 000. The genetic defect involves desmosomal protein genes, most commonly plakophilin 2 (*PKP-2*), although current genetic testing protocols will not identify the culprit gene in many cases. It is characterised by replacement of patches of the right ventricular myocardium with fibrous and fatty tissue (see [Fig. 16.97](#)). In some cases, the LV is also involved and this is associated with a poorer prognosis. The diagnosis is based on a complex set of criteria that take account of the ECG, structural assessment, genetics and arrhythmias. The dominant clinical problems are ventricular arrhythmias, sudden death and right-sided cardiac failure. The ECG typically shows a slightly broadened QRS complex and inverted T waves in the right precordial leads. MRI is a helpful diagnostic tool and is used, along with the 12-lead ECG and ambulatory ECG monitoring, to screen the first-degree relatives of affected individuals. Management is based on treating right-sided cardiac failure with diuretics and cardiac arrhythmias with  $\beta$ -blockers or, in patients at high risk of sudden death, an implantable defibrillator can be offered.

### Restrictive cardiomyopathy

In this rare condition, ventricular filling is impaired because the ventricles are 'stiff' (see [Fig. 16.97](#)). This leads to high atrial pressures with atrial hypertrophy, dilatation and, later, AF. Amyloidosis is the most common cause in the UK, although other forms of infiltration due to glycogen storage diseases, idiopathic perimyocyte fibrosis and a familial form of restrictive cardiomyopathy can also occur. The diagnosis can be difficult and requires assessment with Doppler echocardiography, CT or MRI, and endomyocardial biopsy. Treatment is symptomatic but the prognosis is usually poor and cardiac transplantation may be indicated.

### Obliterative cardiomyopathy

This is a rare form of restrictive cardiomyopathy, involving the endocardium of one or both ventricles; it is characterised by thrombosis and

fibrosis, with gradual obliteration of the ventricular cavities by fibrous tissue (see [Fig. 16.97](#)). The mitral and tricuspid valves become regurgitant. Heart failure and pulmonary and systemic embolism are prominent features. It can sometimes be associated with eosinophilia and can occur in eosinophilic leukaemia and eosinophilic granulomatosis with polyangiitis (formerly known as Churg–Strauss syndrome). In tropical countries, the disease may be responsible for up to 10% of cardiac deaths. Prognosis is poor, with a 50% mortality within 2 years of diagnosis. Anticoagulation and antiplatelet therapy are used to reduce the risk of embolism, and diuretics to treat heart failure. Surgery (tricuspid and/or mitral valve replacement with decortication of the endocardium) may be helpful in selected cases.

### Takotsubo cardiomyopathy

Takotsubo cardiomyopathy (Takotsubo syndrome) is a form of acute left ventricular dysfunction characterised by dilatation of the left ventricular apex and adjacent myocardium, with associated left ventricular impairment. The mechanism is poorly understood. It is often associated with acute environmental or emotional stress (such as a bereavement) and presents with chest pain, breathlessness and sometimes cardiac failure. It occurs more frequently in women than in men and there is a high prevalence of neurological and psychiatric disorders. The symptoms and ECG often mimic acute ST elevation acute coronary syndrome. The diagnosis is usually made at coronary angiography, when CAD is found to be absent or minimal. Echocardiography or left ventriculography then shows characteristic 'apical ballooning' of the LV. The dilated apex and narrow outflow of the LV resemble a Japanese octopus trap, or takotsubo ([Fig. 16.98](#)).

Left ventricular ejection fraction returns to normal within days to weeks. Although commonly thought to be a benign condition, it is associated with a recurrence rate of 10% and a mortality of 20% at 5 years. There are no known treatments that have been shown to influence clinical outcome.

### Secondary causes of cardiomyopathy

Many systemic conditions can produce a picture that is indistinguishable from dilated cardiomyopathy, including connective tissue disorders, sarcoidosis, haemochromatosis and alcoholic heart muscle disease ([Box 16.107](#)). In contrast, amyloidosis and eosinophilic heart disease produce symptoms and signs similar to those found in restrictive or obliterative cardiomyopathy, whereas the heart disease associated with Friedreich's ataxia can mimic hypertrophic cardiomyopathy.

**Fig. 16.98** Left ventriculograms in diastole **A** and systole **B** in a patient with Takotsubo cardiomyopathy. Note the ballooning of the left ventricular apex in systole which is characteristic of this condition (compare with [Fig. 16.16](#)).

16.107 Specific diseases of heart muscle	
<b>Infections</b>	
<b>Viral</b>	
• Coxsackie A and B	• HIV
• Influenza	• SARS-CoV-2
<b>Bacterial</b>	
• Diphtheria	• <i>Borrelia burgdorferi</i>
<b>Protozoal</b>	
• Trypanosomiasis	• <i>Toxoplasma gondii</i>
<b>Endocrine and metabolic disorders</b>	
• Diabetes	• Carcinoid syndrome
• Hypo- and hyperthyroidism	• Pheochromocytoma
• Acromegaly	• Inherited storage diseases
<b>Connective tissue diseases</b>	
• Systemic sclerosis	• Polyarteritis nodosa
• Systemic lupus erythematosus	
<b>Infiltrative disorders</b>	
• Haemochromatosis	• Sarcoidosis
• Haemosiderosis	• Amyloidosis
<b>Toxins</b>	
• Doxorubicin	• Cocaine
• Alcohol	• Irradiation
<b>Neuromuscular disorders</b>	
• Dystrophia myotonica	• Friedreich's ataxia

Treatment and prognosis are determined by the underlying disorder. Abstinence from alcohol may lead to a dramatic improvement in patients with alcoholic heart muscle disease.

## Cardiac tumours

Primary cardiac tumours are rare (<0.2% of autopsies) but the heart and mediastinum may be the sites of metastases. Most primary tumours are benign (75%) and, of these, the majority are myxomas. The remainder are fibromas, lipomas, fibroelastomas and haemangiomas.

### Atrial myxoma

Myxomas most commonly arise in the LA as single or multiple polypoid tumours, attached by a pedicle to the interatrial septum. They are usually gelatinous but may be solid and even calcified, with superimposed thrombus.

On examination, the first heart sound is usually loud, and there may be a murmur of mitral stenosis with a variable diastolic sound (tumour 'plop') due to prolapse of the mass through the mitral valve. The tumour can be detected incidentally on echocardiography, or following investigation of pyrexia, syncope, arrhythmias or emboli. Occasionally, the condition presents with malaise and features suggestive of a connective tissue disorder, including a raised ESR.

Treatment is by surgical excision. If the pedicle is removed, fewer than 5% of tumours recur.

## Diseases of the pericardium

The normal pericardial sac contains about 50 mL of fluid, similar to lymph, which lubricates the surface of the heart. The pericardium limits distension of the heart, contributes to the haemodynamic interdependence of the ventricles, and acts as a barrier to infection. Nevertheless, congenital absence of the pericardium does not result in significant clinical or functional limitations.

16.108 Causes of acute pericarditis and pericardial effusion	
<b>Infection</b>	
• Viral	Tuberculosis
• Bacterial	
<b>Inflammatory</b>	
• Rheumatoid arthritis	Rheumatic fever
• Systemic lupus erythematosus	
<b>Other</b>	
• Post-myocardial infarction	• Malignancy
• Uraemia	• Trauma

## Acute pericarditis

This is due to an acute inflammatory process affecting the pericardium, which may coexist with myocarditis.

### Pathogenesis

A number of causes are recognised (Box 16.108), but in some cases the cause is unclear. All forms of pericarditis may produce a pericardial effusion that, depending on the aetiology, may be fibrinous, serous, haemorrhagic or purulent. A fibrinous exudate may eventually lead to varying degrees of adhesion formation, whereas serous pericarditis often produces a large effusion of turbid, straw-coloured fluid with a high protein content. A haemorrhagic effusion is often due to malignant disease, particularly carcinoma of the breast or bronchus, and lymphoma. Purulent pericarditis is rare and may occur as a complication of sepsis, by direct spread from an intrathoracic infection, or from a penetrating injury.

### Clinical features

The typical presentation is with chest pain that is retrosternal, radiates to the shoulders and neck, and is typically aggravated by deep breathing, movement, a change of position, exercise and swallowing. A low-grade fever is common. A pericardial friction rub is a high-pitched, superficial scratching or crunching noise, produced by movement of the inflamed pericardium, and is diagnostic of pericarditis; it is usually heard in systole but may also be audible in diastole and frequently has a 'to-and-fro' quality.

### Investigations

The diagnosis can often be made on the basis of clinical features and the ECG; the latter shows ST elevation with upward concavity (Fig. 16.99) over the affected area, which may be widespread. PR interval depression is a very specific indicator of acute pericarditis. Later, there may be T-wave inversion, particularly if there is a degree of myocarditis. Echocardiography may be normal or may reveal pericardial effusion, in which case regular echocardiographic monitoring is recommended.

### Management

The pain usually responds to aspirin (600 mg 6 times daily) but a more potent anti-inflammatory agent, such as indometacin (500 mg 3 times daily), may be required. Colchicine is very effective at relieving symptoms and also prevents relapsing episodes if taken for 3 months from symptom onset. Glucocorticoids are no longer recommended for this condition. In viral pericarditis, recovery usually occurs within a few days or weeks but there may be recurrences (chronic relapsing pericarditis). Purulent pericarditis requires treatment with antimicrobial therapy, pericardiocentesis and, if necessary, surgical drainage.

## Pericardial effusion

Pericardial effusion often accompanies pericarditis and can have a number of causes, as shown in Box 16.108.

**Fig. 16.99** ECG in viral pericarditis. Widespread ST elevation (leads I, II, aVL and  $V_1$ – $V_6$ ) is shown. The upward concave shape of the ST segments (see leads II and  $V_6$ ) and the unusual distribution of changes (involving anterior and inferior leads) help to distinguish pericarditis from acute myocardial infarction.

### Clinical features

With the onset of an effusion the heart sounds may become quieter, and a friction rub, if present, may diminish in intensity but is not always abolished. Larger effusions may be accompanied by a sensation of retrosternal oppression. While most effusions do not have significant haemodynamic effects, large or rapidly developing effusions may cause cardiac tamponade. This term is used to describe acute heart failure due to compression of the heart and is described in detail below. Typical physical findings are a markedly raised JVP, hypotension, pulsus paradoxus and oliguria. Atypical presentations may occur when the effusion is loculated as a result of previous pericarditis or cardiac surgery.

### Investigations

Echocardiography is the definitive investigation and is helpful in monitoring the size of the effusion and its effect on cardiac function (Fig. 16.100). The QRS voltages on the ECG are often reduced in the presence of a large effusion. The QRS complexes may alternate in amplitude due to a to-and-fro motion of the heart within the fluid-filled pericardial sac (electrical alternans). The chest X-ray may show an increase in the size of the cardiac silhouette and, when there is a large effusion, this has a globular appearance. Aspiration of the effusion may be required for diagnostic purposes and, if necessary, for treatment of large effusions, as described below.

### Management

Patients with large effusions that are causing haemodynamic compromise or cardiac tamponade should undergo aspiration of the effusion. This involves inserting a needle under echocardiographic guidance medial to the cardiac apex or below the xiphoid process, directed upwards towards the left shoulder. The route of choice will depend on

**Fig. 16.100** Pericardial effusion: echocardiogram (apical view). Short-axis view of the heart showing a large circumferential pericardial effusion (arrows). (LV = left ventricle)

the experience of the operator, the shape of the patient and the position of the effusion. A pericardial drain may be placed to provide symptomatic relief. Complications of pericardiocentesis include arrhythmias, damage to a coronary artery and bleeding, with exacerbation of tamponade as a result of injury to the RV. When tamponade is due to cardiac rupture or aortic dissection, pericardial aspiration may precipitate further potentially fatal bleeding and, in these situations, emergency surgery is the treatment of choice. A viscous, loculated or recurrent effusion may also require formal surgical drainage.

### Tuberculous pericarditis

Tuberculous pericarditis may complicate pulmonary tuberculosis but may also be the first manifestation of the infection. In Africa, a tuberculous pericardial effusion is a common feature of AIDS. The condition typically presents with chronic malaise, weight loss and a low-grade fever. An effusion usually develops and the pericardium may become thick and unyielding, leading to pericardial constriction or tamponade. An associated pleural effusion is often present.

The diagnosis may be confirmed by aspiration of the fluid and direct examination or culture for tubercle bacilli. Treatment requires specific antituberculous chemotherapy (p. 522); in addition, a 3-month course of prednisolone (initial dose 60mg a day, tapering down rapidly) improves outcome.

### Chronic constrictive pericarditis

Constrictive pericarditis is due to progressive thickening, fibrosis and calcification of the pericardium. In effect, the heart is encased in a solid shell and cannot fill properly. The calcification may extend into the myocardium, so there may also be impaired myocardial contraction. The condition often follows an attack of tuberculous pericarditis but can also complicate haemopericardium, viral pericarditis, rheumatoid arthritis and purulent pericarditis. It is often impossible to identify the original insult.

### Clinical features

The symptoms and signs of systemic venous congestion are the hallmarks of constrictive pericarditis. AF is common and there is often dramatic ascites and hepatomegaly (Box 16.109). Breathlessness is not a prominent symptom because the lungs are seldom congested. The condition is sometimes overlooked but should be suspected in any patient

### 16.109 Clinical features of constrictive pericarditis

- Fatigue
- Rapid, low-volume pulse
- Elevated JVP with a rapid y descent
- Loud early third heart sound or 'pericardial knock'
- Kussmaul's sign
- Hepatomegaly
- Ascites
- Peripheral oedema
- Pulsus paradoxus

(JVP = jugular venous pressure)

**Fig. 16.101** Lateral chest X-ray from a patient with severe heart failure due to chronic constrictive pericarditis. There is heavy calcification of the pericardium.

with unexplained right heart failure and apparently normal heart size and function on echocardiography.

#### Investigations

A chest X-ray, which may show pericardial calcification (Fig. 16.101), and echocardiography often help to establish the diagnosis. CT scanning is useful for imaging the pericardial calcification. Constrictive pericarditis is often difficult to distinguish from restrictive cardiomyopathy and in such cases complex echo-Doppler studies and cardiac catheterisation may be required.

#### Management

The resulting diastolic heart failure is treated using loop diuretics and aldosterone antagonists, such as spironolactone. Surgical resection of the diseased pericardium can lead to a dramatic improvement but carries a high morbidity, especially if performed late in the disease course, as the pericardium becomes heavily bound to the myocardium.

### Cardiac tamponade

This term is used to describe acute heart failure due to compression of the heart as the result of a large pericardial effusion. Tamponade may complicate any form of pericarditis but can be caused by malignant disease, by blood in the pericardial space following trauma, or by rupture of the free wall of the myocardium following MI.

### 16.110 Clinical features of cardiac tamponade

- Dyspnoea
- Collapse
- Tachycardia
- Hypotension
- Gross elevation of the JVP
- Soft heart sounds with an early third heart sound
- Pulsus paradoxus (a large fall in BP during inspiration, when the pulse may be impalpable)
- Kussmaul's sign (a paradoxical rise in JVP during inspiration)

(JVP = jugular venous pressure)

#### Clinical features

Patients with tamponade are unwell, with hypotension, tachycardia and a markedly raised JVP. Other clinical features are summarised in Box 16.110.

#### Investigations

The pivotal investigation is echocardiography, which can confirm the diagnosis and also helps to identify the optimum site for aspiration of the fluid. The ECG may show features of the underlying disease, such as pericarditis or acute MI. When there is a large pericardial effusion, the ECG complexes are small and there may be electrical alternans: a changing axis with alternate beats caused by the heart swinging from side to side in the pericardial fluid. A chest X-ray shows an enlarged globular heart but can look normal.

#### Management

Cardiac tamponade is a medical emergency. When the diagnosis is confirmed, percutaneous pericardiocentesis should be performed as soon as possible, which usually results in a dramatic improvement. In some cases, surgical drainage may be required.

## Multiple Choice Questions

- 16.1. A 24-year-old woman presents at the emergency department with an episode of sudden-onset rapid regular palpitation of one hour's duration. She has no previous cardiovascular history. On examination, heart rate is 180 beats/min and regular, blood pressure 104/68 mmHg. Examination is otherwise unremarkable. The ECG shows a regular, narrow QRS tachycardia (see figure).

Which of the following is the most appropriate initial management for this rhythm?

- Intravenous adenosine
- Oral beta-blocker
- Valsalva manoeuvre with or without leg raising
- Bilateral carotid sinus pressure
- Intravenous atropine

Answer: C.

The diagnosis is supraventricular tachycardia (SVT), based on the sudden onset, the regular nature of the tachycardia, and the absence of obvious P waves on the ECG. SVT is usually caused by a re-entrant mechanism involving the atrioventricular node (see p. 415). Treatments that cause transient AV nodal block interrupt the tachycardia and restore sinus rhythm. Intravenous adenosine is usually effective but is not normally given until after vagal manoeuvres have been tried. The Valsalva manoeuvre is often effective and can be enhanced by leg raising after breath-holding is released (the 'REVERT' manoeuvre). Carotid sinus pressure may also be effective but should never be applied to both carotid arteries simultaneously. Atropine is an anticholinergic drug which is used to treat symptomatic bradycardia, not tachycardia.

- 16.2. A 77-year-old diabetic woman presents to her general practitioner because of fatigue and breathlessness. She is found to have an irregular pulse at 74 beats/min. An ECG confirms atrial fibrillation with good heart rate control. An echocardiogram is performed showing left atrial enlargement but no other abnormality. What is the most appropriate strategy to reduce this patient's risk of a future stroke?
- Oral aspirin, 75 mg once daily
  - Oral clopidogrel, 75 mg once daily
  - Immediate DC cardioversion
  - Oral digoxin
  - Oral anticoagulation with warfarin or a direct oral anticoagulant

Answer: E.

This woman has atrial fibrillation and a relatively high CHA<sub>2</sub>DS<sub>2</sub>-VASc score of 4 points (1 point each for gender and diabetes mellitus, and 2 points for age greater than 75 years). She has an annual stroke risk

of around 4% which would be reduced to 1% with oral anticoagulation using a direct oral anticoagulant such as apixaban or edoxaban, or with warfarin (target International Normalised Ratio 2–3). Oral antiplatelet drugs such as aspirin or clopidogrel are ineffective for stroke prevention in atrial fibrillation. Immediate cardioversion would increase stroke risk because a prior period of oral anticoagulation is required to make the procedure safe. Digoxin is used for heart rate control but has no impact on stroke risk. (For more on stroke prevention in atrial fibrillation see page 414.)

- 16.3. A fit 25-year-old man presents to the emergency department with an episode of syncope while running a half-marathon. He had a few seconds warning with lightheadedness, was syncopal for around 15 seconds, and made a rapid recovery. His father had died suddenly age 54 years with no cause determined. On examination the patient appeared well, pulse 50 and regular, BP 110/62 mmHg. Precordial examination revealed a forceful apical impulse and an ejection systolic murmur loudest in the aortic area. What is the most likely diagnosis?
- Hypertrophic obstructive cardiomyopathy
  - Aortic stenosis
  - Mitral regurgitation
  - Long QT syndrome
  - Dilated cardiomyopathy

Answer: A.

This patient presents with symptoms and signs of hypertrophic obstructive cardiomyopathy. Syncope is a common symptom and is caused either by left ventricular outflow tract obstruction during exercise, or by ventricular arrhythmia. The patient presents with typical cardiac syncope – a short prodrome, brief syncope and a rapid recovery. The family history of sudden death raises suspicion of an inherited cardiac condition. While aortic stenosis is a possibility, it is not likely in such a young patient and is rarely inherited. Hypertrophic cardiomyopathy is inherited with an autosomal dominant pattern and the murmur is caused by left ventricular outflow obstruction. Mitral regurgitation does cause a systolic murmur but it is usually pansystolic, and there is no association with syncope. Long QT syndrome can cause sudden death and is inherited, but is not associated with any structural abnormality or murmur. Dilated cardiomyopathy is sometimes inherited but does not commonly cause syncope or a murmur.

- 16.4. A 30-year-old woman presents with a 2-week history of fever and malaise, and develops sharp left-sided chest pain, worse on inspiration and on leaning forward. The pain radiates to her left shoulder. On examination pulse is 100 beats/min and regular, blood pressure 104/66 mmHg. The jugular venous pulse is not elevated. The apex beat is not displaced and feels normal. First and second are both present, with a harsh to-and-fro sound audible in systole and diastole. An echocardiogram shows a small pericardial effusion and no other abnormality. The 12-lead ECG is shown in the figure.

Which of the following treatments is most appropriate?

- A. Oral ibuprofen, 400mg three times daily
- B. Oral prednisolone, initially 40mg daily and reducing dose over 2 weeks
- C. Pericardiocentesis
- D. Oral colchicine 500 µg twice daily for 3 months
- E. Percutaneous coronary intervention

Answer: D.

The diagnosis is acute pericarditis, probably of viral aetiology because of the prodromal symptoms. Examination reveals a pericardial rub, and the ECG shows widespread saddle-shaped ST segment elevation

without reciprocal ST segment depression. The most effective treatment for symptoms and to prevent recurrence is colchicine. Non-steroidal anti-inflammatory drugs such as ibuprofen may also help acute symptoms, but oral corticosteroids are not effective. Pericardiocentesis would only be indicated if there was a large pericardial effusion and compromise (hypotension, pulsus paradoxus, elevated jugular venous pulse, oliguria). Percutaneous coronary intervention is not appropriate as the pattern of ST segment elevation suggests pericarditis and not ST elevation myocardial infarction.

Respiratory infections such as tuberculosis, pneumonia and virus infections (e.g. influenza, COVID-19) represent a major burden of morbidity and mortality globally. The increasing prevalence of allergy, asthma and chronic obstructive pulmonary disease (COPD) contributes to the burden of chronic disease in the community. By 2025, the number of cigarette smokers worldwide is anticipated to increase to 1.5 billion, ensuring a growing burden of tobacco-related respiratory conditions.

Respiratory disease covers many pathologies, including infectious, inflammatory, neoplastic and degenerative processes. The practice of respiratory medicine thus requires collaboration with a range of disciplines. Recent advances have improved the lives of many patients with obstructive lung disease, cystic fibrosis, obstructive sleep apnoea and pulmonary hypertension, but the outlook remains poor for lung and other respiratory cancers and for some of the interstitial lung diseases.

## Functional anatomy and physiology

The lungs occupy the upper two-thirds of the bony thorax, bounded medially by the spine, the heart and the mediastinum and inferiorly by the diaphragm. During breathing, free movement of the lung surface relative to the chest wall is facilitated by sliding contact between the parietal and visceral pleura, which cover the inner surface of the chest wall and the lung respectively, and are normally closely apposed. Inspiration involves downward contraction of the diaphragm (innervated by the phrenic nerves originating from C3, 4 and 5) and upward, outward movement of the ribs, caused by contraction of the external intercostal muscles (innervated by intercostal nerves originating from the thoracic spinal cord). Expiration is largely passive, driven by elastic recoil of the lungs.

The conducting airways from the nose to the alveoli connect the external environment with the alveolar surface. As air is inhaled through the upper airways it is filtered in the nose, heated to body temperature and fully saturated with water vapour; partial recovery of this heat and

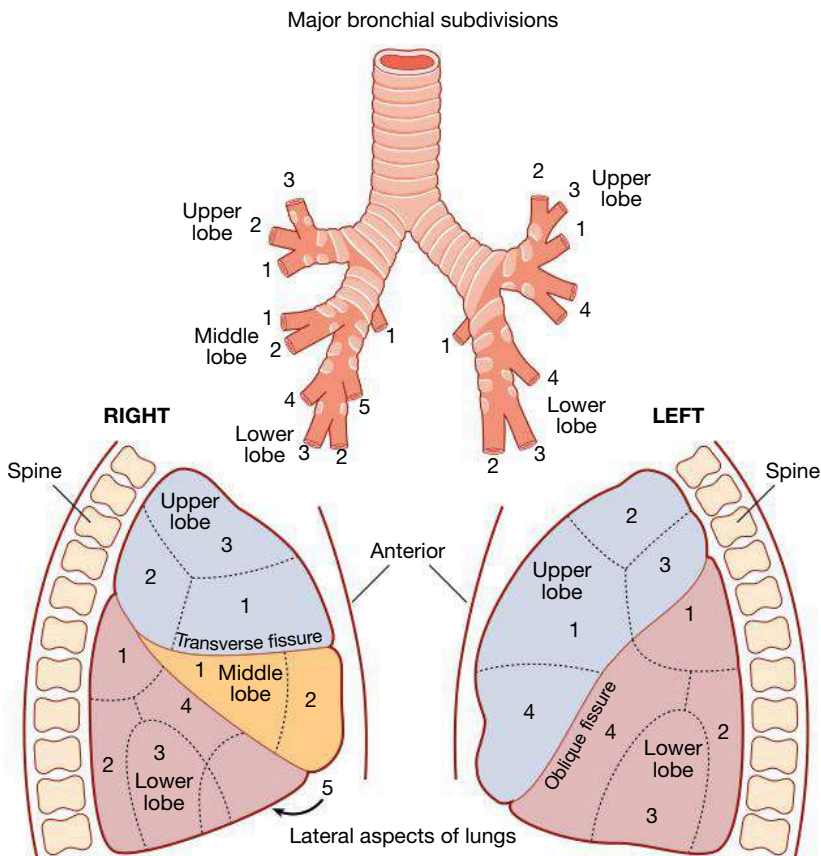

moisture occurs on expiration. Total airway cross-section is smallest in the glottis and trachea, making the central airway particularly vulnerable to obstruction. Normal breath sounds originate mainly from the rapid turbulent airflow in the larynx, trachea and main bronchi.

The multitude of small airways within the lung parenchyma has a very large combined cross-sectional area (over 300 cm<sup>2</sup> in the third-generation respiratory bronchioles), resulting in very slow flow rates. Airflow is virtually silent here and gas transport occurs largely by diffusion in the final generations. Major bronchial and pulmonary divisions are shown in Figure 17.1.

The acinus (Fig. 17.2) is the gas exchange unit of the lung and comprises branching respiratory bronchioles and clusters of alveoli. Here the air makes close contact with the blood in the pulmonary capillaries (gas-to-blood distance < 0.4 µm), and oxygen uptake and CO<sub>2</sub> excretion occur. The alveoli are lined with flattened epithelial cells (type I pneumocytes) and a few, more cuboidal, type II pneumocytes. The latter produce surfactant, which is a phospholipid mixture that reduces surface tension and thereby counteracts the tendency of alveoli to collapse. Type II pneumocytes can divide to reconstitute type I pneumocytes after lung injury.

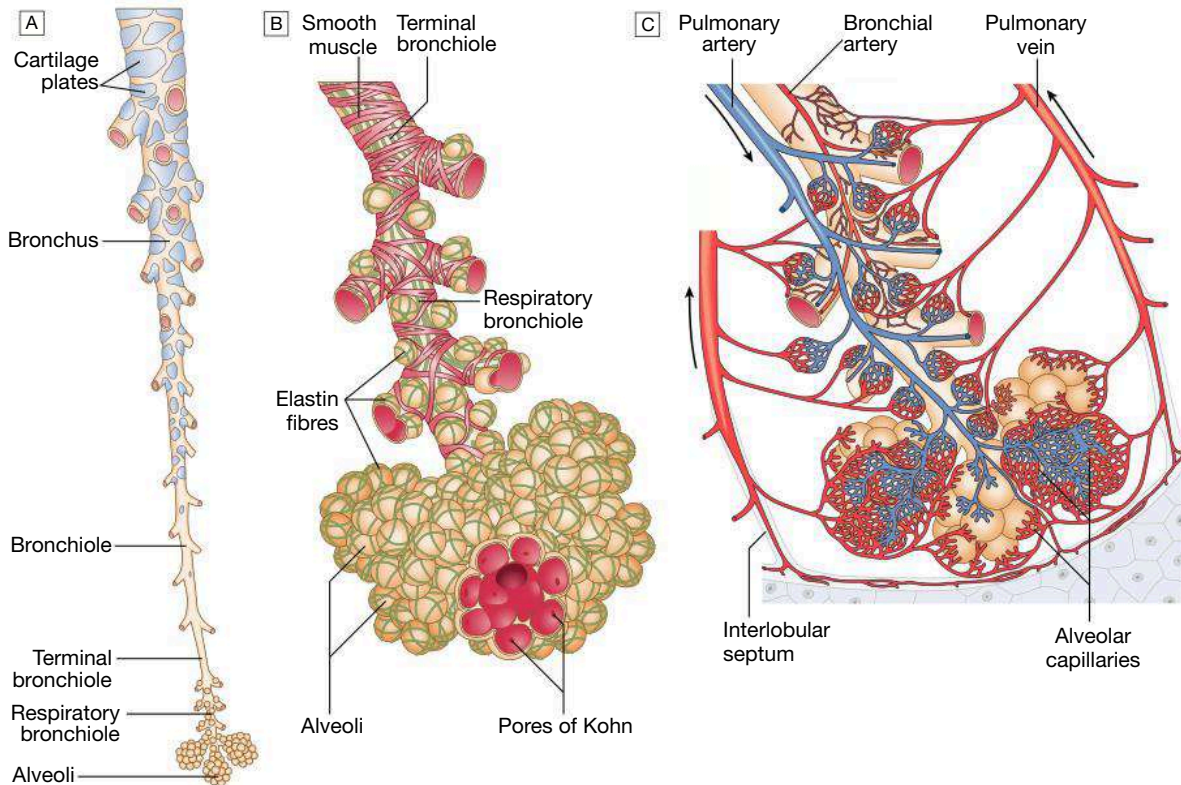

## Lung mechanics

Healthy alveolar walls contain a fine network of elastin and collagen fibres (see Fig. 17.2). The volume of the lungs at the end of a tidal ('normal') breath out is called the functional residual capacity (FRC). At this volume, the inward elastic recoil of the lungs (resulting from elastin fibres and surface tension in the alveolar lining fluid) is balanced by the resistance of the chest wall to inward distortion from its resting shape, causing negative pressure in the pleural space. Elastin fibres allow the lung to be easily distended at physiological lung volumes, but collagen fibres cause increasing stiffness as full inflation is approached, so that, in health, the maximum inspiratory volume is limited by the lung (rather than the chest wall). The weight of lung tissue compresses the dependent regions and

**Fig. 17.1** The major bronchial divisions and the fissures, lobes and segments of the lungs. The angle of the oblique fissure means that the left upper lobe is largely anterior to the lower lobe. On the right, the transverse fissure separates the upper from the anteriorly placed middle lobe, which is matched by the lingular segment on the left side. The site of a lobe determines whether physical signs are mainly anterior or posterior. Each lobe is composed of two or more bronchopulmonary segments that are supplied by the main branches of each lobar bronchus. **Bronchopulmonary segments:** **Right Upper lobe:** (1) Anterior, (2) Posterior, (3) Apical. **Middle lobe:** (1) Lateral, (2) Medial. **Lower lobe:** (1) Apical, (2) Posterior basal, (3) Lateral basal, (4) Anterior basal, (5) Medial basal. **Left Upper lobe:** (1) Anterior, (2) Apical, (3) Posterior, (4) Lingular. **Lower lobe:** (1) Apical, (2) Posterior basal, (3) Lateral basal, (4) Anterior basal.

**Fig. 17.2 Functional anatomy of the lung.** **A** The tapering, branching bronchus is armoured against compression by plates of cartilage. The more distal bronchioles are collapsible, but held patent by surrounding elastic tissue. **B** The unit of lung supplied by a terminal bronchiole is called an acinus. The bronchiolar wall contains smooth muscle and elastin fibres. The latter also run through the alveolar walls. Gas exchange occurs in the alveoli, which are connected to each other by the pores of Kohn. **C** Vascular anatomy of an acinus. Both the pulmonary artery (carrying desaturated blood) and the bronchial artery (systemic supply to airway tissue) run along the bronchus. The venous drainage to the left atrium follows the interlobular septa. From *www.Netter.com: Illustrations 155 (bronchus, acinus) and 191 (circulation), Elsevier*.

distends the uppermost parts, so a greater portion of an inhaled breath passes to the basal regions, which also receive the greatest blood flow as a result of gravity. Elastin fibres in alveolar walls maintain small airway patency by radial traction on the airway walls. Even in health, however, these small airways narrow during expiration because they are surrounded by alveoli at higher pressure, but are prevented from collapsing by radial elastic traction. The volume that can be exhaled is thus limited purely by the capacity of the expiratory muscles to distort the chest wall inwards. In emphysema, loss of alveolar walls leaves the small airways unsupported, and their collapse on expiration causes air trapping and limits expiration at a high end-expiratory volume.

## Control of breathing

The respiratory motor neurons in the posterior medulla oblongata are the origin of the respiratory cycle. Their activity is modulated by multiple external inputs in health and in disease (see Fig. 17.9):

- Central chemoreceptors in the ventrolateral medulla sense the pH of the cerebrospinal fluid (CSF) and are indirectly stimulated by a rise in arterial  $PCO_2$ .
- The carotid bodies sense hypoxaemia but are mainly activated by arterial  $PO_2$  values below 8 kPa (60 mmHg). They are also sensitised to hypoxia by raised arterial  $PCO_2$ .
- Muscle spindles in the respiratory muscles sense changes in mechanical load.
- Vagal sensory fibres in the lung may be stimulated by stretch, inhaled toxins or disease processes in the interstitium.
- Cortical (volitional) and limbic (emotional) influences can override the automatic control of breathing.

## Ventilation/perfusion matching and the pulmonary circulation

The regional distribution of ventilation and perfusion must be matched for optimal gas exchange within the lungs. At segmental and subsegmental level, hypoxia constricts pulmonary arterioles and airway  $CO_2$  dilates bronchi, helping to maintain good regional matching of ventilation and perfusion. Lung disease may create regions of relative under-ventilation or under-perfusion, which disturb this regional matching, causing respiratory failure. In addition to causing ventilation-perfusion mismatch, diseases that destroy capillaries or thicken the alveolar capillary membrane (e.g. emphysema or fibrosis) can impair gas diffusion directly.

The pulmonary circulation in health operates at low pressure (approximately 24/9 mmHg) and can accommodate large increases in flow with minimal rise in pressure, e.g. during exercise. Pulmonary hypertension occurs when vessels are destroyed by emphysema, obstructed by thrombus, involved in interstitial inflammation or thickened by pulmonary vascular disease. The right ventricle responds by hypertrophy, with right axis deviation and P pulmonale (tall, peaked p waves) on the electrocardiogram (ECG), and clinical features of right heart failure; the term 'cor pulmonale' is often used for these findings.

Changes in respiratory function associated with old age are shown in Box 17.1.

## Lung defences

### Upper airway defences

Large airborne particles are trapped by nasal hairs, and smaller particles settling on the mucosa are cleared towards the oropharynx by the columnar ciliated epithelium that covers the turbinates and septum

### 17.1 Respiratory function in old age

- **Reserve capacity:** a significant reduction in function can occur with ageing with only minimal effect on normal breathing, but the ability to combat acute disease is reduced.
- **Decline in FEV<sub>1</sub>:** the FEV<sub>1</sub>/FVC (forced expiratory volume/forced vital capacity) ratio falls by around 0.2% per year from 70% at the age of 40–45 years, due to a decline in elastic recoil in the small airways with age. Smoking accelerates this decline threefold on average. Symptoms usually occur only when FEV<sub>1</sub> drops below 50% of predicted.
- **Increasing ventilation–perfusion mismatch:** the reduction in elastic recoil causes a tendency for the small airways to collapse during expiration, particularly in dependent areas of the lungs, thus reducing ventilation.
- **Reduced ventilatory responses to hypoxia and hypercapnia:** older people may be less tachypnoeic for any given fall in PaO<sub>2</sub> or rise in PaCO<sub>2</sub>.
- **Impaired defences against infection:** due to reduced numbers of glandular epithelial cells, which lead to a reduction in protective mucus.
- **Decline in maximum oxygen uptake:** due to a combination of impairments in muscle, and the respiratory and cardiovascular systems. This leads to a reduction in cardiorespiratory reserve and exercise capacity.
- **Loss of chest wall compliance:** due to reduced intervertebral disc spaces and ossification of the costal cartilages; respiratory muscle strength and endurance also decline. These changes become important only in the presence of other respiratory disease.

(Fig. 17.3). During cough, expiratory muscle effort against a closed glottis results in high intrathoracic pressure, which is then released explosively. The flexible posterior tracheal wall is pushed inwards by the high surrounding pressure, which reduces tracheal cross-section and thus maximises the airspeed to achieve effective expectoration. The larynx also acts as a sphincter, closing to protect the airway during swallowing and vomiting.

#### Lower airway defences

The structure and function of the lower airways are maintained by close cooperation between the innate and adaptive immune responses. Traditionally, the healthy lower respiratory tract was considered to be sterile. However, molecular analysis has established that it harbours a diverse resident microbial population (the lung microbiome); understanding of the interactions between the immune system and the lung microbiome, and its role in health and disease, is in its infancy.

The innate response in the lungs is characterised by a number of non-specific defence mechanisms. Inhaled particulate matter is trapped in airway mucus and cleared by the mucociliary escalator. Tobacco smoke increases mucus secretion but reduces mucociliary clearance and predisposes towards lower respiratory tract infections, including pneumonia. Defective mucociliary transport is also a feature of several rare diseases including cystic fibrosis, primary ciliary dyskinesia and Young syndrome, which are characterised by repeated sino-pulmonary infections and bronchiectasis.

Airway secretions contain an array of antimicrobial peptides (AMPs, such as defensins and lysozyme), immunoglobulin A (IgA), antiproteases and antioxidants. Many assist with the opsonisation and killing of bacteria and the regulation of the proteolytic enzymes secreted by inflammatory cells. In particular,  $\alpha_1$ -antitrypsin regulates neutrophil elastase, and deficiency of this may be associated with premature emphysema.

Macrophages engulf microbes, organic dusts and other particulate matter. They cannot digest inorganic agents such as asbestos or silica, which cause their death and lead to the release of powerful proteolytic enzymes that damage the lung. Neutrophil numbers in the airway are low but the pulmonary circulation contains a marginated pool that may be recruited rapidly in response to bacterial infection.

Adaptive immunity is characterised by a specific response and immunological memory. Lung dendritic cells facilitate antigen presentation to T and B lymphocytes.

**Fig. 17.3 The mucociliary escalator.** Scanning electron micrograph of the respiratory epithelium showing large numbers of cilia (C) overlaid by the mucus 'raft' (M).

## Investigation of respiratory disease

A detailed history, thorough examination and basic haematological and biochemical tests usually indicate the likely diagnosis and differential. A number of other investigations are normally required to confirm the diagnosis and/or monitor disease activity.

### Imaging

#### The 'plain' chest X-ray

The chest X-ray (CXR) is one of the initial investigations performed on the majority of patients suspected of having respiratory disease. A posteroanterior (PA) film provides information on the lung fields, heart, mediastinum, vascular structures and thoracic cage (Fig. 17.4). A lateral film may provide additional information, particularly if pathology is suspected behind the heart or deep in the diaphragmatic sulci. An approach to interpreting the chest X-ray is given in Box 17.2; common abnormalities are listed in Box 17.3.

Increased shadowing may represent accumulation of fluid, lobar collapse or consolidation. Uncomplicated consolidation should not change the position of the mediastinum and the presence of an air bronchogram means that proximal bronchi are patent. Collapse (implying obstruction of the lobar bronchus) is accompanied by loss of volume and displacement of the mediastinum towards the affected side (Fig. 17.5).

The presence of ring shadows (thickened bronchi seen end-on), tram-line shadows (thickened bronchi side-on) or tubular shadows (bronchi filled with secretions) suggests bronchiectasis. The presence of pleural fluid is suggested by a dense basal shadow, which, in the erect patient, ascends towards the axilla. In a large pulmonary embolism, relative oligoemia may cause a lung field to appear abnormally dark.

#### Computed tomography

Computed tomography (CT) provides detailed images of the pulmonary parenchyma, mediastinum, pleura and bony structures. The displayed range of densities can be adjusted to highlight different structures such as the lung parenchyma, the mediastinal vascular structures or bone. Cross-sectional formatting allows recognition of the axial distribution of the disease, while coronal reformation displays the cranio-caudal distribution. In cases of suspected lung cancer, CT is central to both diagnosis and staging, and facilitates percutaneous needle biopsy. CT identifies the extent and appearance of pleural thickening (see Fig. 17.64) and reliably differentiates pleural and pericardial fat from pathology. High-resolution thin-section scanning provides detailed

images of the pulmonary parenchyma and is superior to chest X-ray for assessment of diffuse parenchymal lung disease (see Fig. 17.55), identifying airway thickening, bronchiectasis (see Fig. 17.29) and emphysema (see Fig. 17.27). The relative contribution of competing pathologies to a breathless patient may be assessed. Prone imaging may be used to differentiate the gravity-induced posterobasal attenuation seen in supine scans. CT pulmonary angiography (CTPA) has become the investigation of choice in the diagnosis of pulmonary thromboembolism (see Fig. 17.67), when it may either confirm the suspected embolism or highlight an alternative diagnosis. CTPA has largely replaced the radioisotope-based ventilation–perfusion ( $V/Q$ ) scan for this purpose. CT may assist in identifying cavitation and other features of infection (e.g. air crescent and halo signs in aspergillosis). Finally, CT may be used to monitor disease progression in established disease and for screening in certain high-risk populations.

### Positron emission tomography

Positron emission tomography (PET) scanners employ the radiotracer  $^{18}\text{F}$ -fluorodeoxyglucose (FDG) to quantify the rate of glucose metabolism by cells. The  $^{18}\text{F}$ FDG is rapidly taken up by metabolically active tissue, where it is phosphorylated and ‘trapped’ in the cell. The assessment of  $^{18}\text{F}$ FDG uptake may be qualitative (visual analysis) or semi-quantitative, using the standardised uptake value (SUV) (Fig. 17.6). FDG-PET is useful in the staging of mediastinal lymph nodes and distal metastatic disease in patients with lung cancer and in the investigation of pulmonary nodules. Co-registration of PET and CT (PET-CT) enhances localisation and characterisation of metabolically active deposits (see Fig. 17.6). FDG-PET may also differentiate benign from malignant pleural disease and can be used to assess the extent of extrapulmonary disease in sarcoidosis. However,  $^{18}\text{F}$ FDG uptake by a lesion is affected by a large number of parameters, including equipment used, the physics, and biological factors such as amount of body fat and brown fat uptake and the blood glucose level.

### 17.2 How to interpret a chest X-ray

<b>Name, date, orientation</b>	Films are posteroanterior (PA) unless marked AP to denote that they are anteroposterior
<b>Lung fields</b>	Equal translucency? Check horizontal fissure from right hilum to sixth rib at the anterior axillary line Masses? Consolidation? Cavitation?
<b>Lung apices</b>	Check behind the clavicles. Masses? Consolidation? Cavitation?
<b>Trachea</b>	Central (midway between the clavicular heads)? Paratracheal mass? Goitre?
<b>Heart</b>	Normal shape? Cardiothoracic ratio (should be < half the intrathoracic diameter) Retrocardiac mass?
<b>Hila</b>	Left should be higher than right Shape (should be concave laterally; if convex, consider mass or lymphadenopathy)? Density?
<b>Diaphragm</b>	Right should be higher than left Hyperinflation (no more than 10 ribs should be visible posteriorly above the diaphragm)?
<b>Costophrenic angles</b>	Acute and well defined (pleural fluid or thickening, if not)?
<b>Soft tissues</b>	Breast shadows in females Chest wall for masses or subcutaneous emphysema
<b>Bones</b>	Ribs, vertebrae, scapulae and clavicles Any fracture visible at bone margins or lucencies?

**Fig. 17.4 The normal chest X-ray.** The lung markings consist of branching and tapering lines radiating out from the hila. Where airways and vessels turn towards the film, they can appear as open or filled circles (see upper pole of right hilum). The scapulae may overlie the lung fields; trace the edge of bony structures to avoid mistaking them for pleural or pulmonary shadows. To check for hyperinflation, count the ribs; if more than 10 are visible posteriorly above the diaphragm, the lungs are hyperinflated. *From Innes JA. Davidson's Essentials of medicine. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2009.*

## i

## 17.3 Common chest X-ray abnormalities

**Pulmonary and pleural shadowing**

- Consolidation: infection, infarction, inflammation and, rarely, bronchoalveolar cell carcinoma
- Lobar collapse: mucus plugging, tumour, compression by lymph nodes
- Solitary nodule
- Multiple nodules: miliary tuberculosis (TB), dust inhalation, metastatic malignancy, healed varicella pneumonia, rheumatoid disease
- Ring shadows, tramlines and tubular shadows: bronchiectasis
- Cavitating lesions: tumour, abscess, infarct, pneumonia (*Staphylococcus/Klebsiella*), granulomatosis with polyangiitis (GPA)
- Reticular, nodular and reticulonodular shadows: diffuse parenchymal lung disease, infection
- Pleural abnormalities: fluid, plaques, tumour

**Increased translucency**

- Bullae
- Pneumothorax
- Oligaemia

**Hilar abnormalities**

- Unilateral hilar enlargement: TB, lung cancer, lymphoma
- Bilateral hilar enlargement: sarcoidosis, lymphoma, TB, silicosis

**Other abnormalities**

- Hiatus hernia
- Surgical emphysema

**Magnetic resonance imaging**

Conventional magnetic resonance imaging (MRI) of the lung parenchyma is seldom useful, although the technique is being used increasingly in distinguishing benign from malignant pleural disease and in delineating invasion of the chest wall or diaphragm by tumour.

The use of hyperpolarized  $^3\text{He}$  MRI is a developing method of assessing the distribution of ventilation within the lung.

**Ultrasound**

Transthoracic ultrasound is a point-of-care investigation used to assess the pleural space (see Fig. 17.15). In the hands of an experienced operator it can distinguish pleural fluid from pleural thickening, identify a pneumothorax and, by directly visualising the diaphragm and solid organs such as the liver, spleen and kidneys, may be used to guide pleural aspiration, biopsy and intercostal chest drain insertion. It is also used to guide needle biopsy of superficial lymph node or chest wall masses and provides useful information on the shape and movement of the diaphragm.

**Endoscopic examination****Laryngoscopy**

The larynx may be inspected directly with a fiberoptic laryngoscope in cases of suspected intermittent laryngeal obstruction (ILO), when paradoxical movement of the vocal cords may mimic asthma. Left-sided lung tumours may involve the left recurrent laryngeal nerve, paralysing the left vocal cord and leading to a hoarse voice and a 'bovine' cough. Continuous laryngoscopy during exercise tests allows the identification of exercise-induced ILO.

**Bronchoscopy**

The trachea and the first 3–4 generations of bronchi may be inspected using a flexible fiberoptic bronchoscope. This is usually performed under local anaesthesia with sedation, on an outpatient basis. Abnormal tissue

**Fig. 17.5** Radiological features of lobar collapse caused by bronchial obstruction. The dotted line in the drawings represents the normal position of the diaphragm. The dark pink area represents the extent of shadowing seen on the X-ray.

in the bronchial lumen or wall can be biopsied, and bronchial brushings, washings or aspirates can be taken for cytological or bacteriological examination. Small biopsy specimens of lung tissue, taken by forceps passed through the bronchial wall (transbronchial biopsies), may be

**Fig. 17.6** Computed tomography and positron emission tomography combined to reveal intrathoracic metastases. **A** In a patient with lung cancer, CT shows some posterior pleural thickening. **B** FDG-PET scanning reveals FDG uptake in two pleural lesions (arrows). **C** The lesions are highlighted in yellow in the combined PET-CT image. (CT = computed tomography; FDG =  $^{18}\text{F}$ -fluorodeoxyglucose; PET = positron emission tomography) (A–C) From <http://radiology.rsna.org>.

helpful in the diagnosis of bronchocentric disorders such as sarcoidosis and diffuse malignancy but are generally too small to be of diagnostic value in other diffuse parenchymal pulmonary disease.

Rigid bronchoscopy requires general anaesthesia and is reserved for specific situations, such as massive haemoptysis or removal of a foreign body (see Fig. 9.2), and can facilitate endobronchial laser therapy and stenting.

### Endobronchial ultrasound

Endobronchial ultrasound (EBUS) allows directed needle aspiration from peribronchial nodes and is used increasingly to stage lung cancer. It may also be useful in non-malignant conditions, such as mediastinal lymphadenopathy caused by tuberculosis or sarcoidosis. Lymph nodes down to the main carina can also be sampled using a mediastinoscope passed through a small incision at the suprasternal notch under general anaesthetic. Lymph nodes in the lower mediastinum may be biopsied via the oesophagus using an oesophageal endoscope equipped with an ultrasound transducer and biopsy needle (endoscopic ultrasound).

### Thoracoscopy

Thoracoscopy, which involves the insertion of an endoscope through the chest wall, facilitates biopsy under direct vision and is the gold standard for the evaluation of the pleural surfaces, characterisation of complex pleural effusion, and identification of exudate and haemorrhage. It is also used for accurate staging of apical tumours.

### Microbiological investigations

Sputum, pleural fluid, throat swabs, blood, and bronchial washings and aspirates can be examined for bacteria, fungi and viruses. The use of hypertonic saline to induce expectoration of sputum may obviate the need for more invasive procedures such as bronchoscopy. Molecular tests (nucleic acid amplification tests, NAATs) are being used increasingly as first-line diagnostic tests for respiratory viruses (including influenza and coronaviruses such as SARS-CoV-2), as well as bacterial pathogens (e.g. *Legionella*, *Mycoplasma*), for which they have largely replaced paired serology and antigen-based tests. NAATs are also gaining an increased role as first-line diagnostic tests for tuberculosis and for rapid identification of antimicrobial drug resistance.

### Immunological and serological tests

The presence of atopy can be detected by demonstrating an elevated level of immunoglobulin E (IgE), and the measurement of IgE directed against specific antigens. This can be useful to support the diagnosis of asthma and in identifying triggers. Many autoimmune diseases present with pulmonary involvement and autoantibodies may be identified in

the serum. IgG enzyme immunoassay or identification of serum precipitins (antibodies that form visible lines of precipitated glycoprotein when they encounter their specific antigen in an agarose gel) can be used to identify a reaction to fungi such as *Aspergillus* or to antigens involved in hypersensitivity pneumonitis, such as farmer's lung or bird fancier's lung. The presence of pneumococcal antigen in sputum, blood or urine may be of diagnostic importance in pneumonia. Respiratory viruses can be detected in nose/throat swabs by immunofluorescence and *Legionella* infection may be diagnosed by detection of a *Legionella* antigen in urine.  $\beta$ -1,3-D-glucan detection (in blood) is a marker of fungal infection (see Chapter 13) and *Aspergillus* galactomannan (in blood and bronchial lavage fluid) is used to diagnose invasive aspergillosis. Interferon-gamma release assays are useful in the detection of latent tuberculosis.

### Cytology and histopathology

Cytological examination of exfoliated cells in pleural fluid or bronchial brushings and washings, or of fine needle aspirates from lymph nodes or pulmonary lesions, can support a diagnosis of malignancy. A larger tissue biopsy is often necessary, however, as this allows immunohistochemistry and genetic testing to characterise the tumor and guide variant-specific therapy. Histopathology may also allow identification of microorganisms using conventional staining or NAATs. Differential cell counts in bronchial lavage fluid may help to distinguish pulmonary changes due to sarcoidosis, idiopathic pulmonary fibrosis or hypersensitivity pneumonitis.

### Respiratory function testing

Respiratory function tests are used to aid diagnosis, quantify functional impairment and monitor treatment or progression of disease. Airway narrowing, lung volume and gas exchange capacity are quantified and compared with normal values adjusted for age, gender, height and ethnic origin. In diseases characterised by airway narrowing (e.g. asthma, bronchitis and emphysema), maximum expiratory flow is limited by dynamic compression of small intrathoracic airways, some of which may close completely during expiration, limiting the volume that can be expired ('obstructive' defect). This causes hyperinflation of the chest, which can become extreme if elastic recoil is also lost due to parenchymal destruction, as in emphysema. In contrast, diseases that cause interstitial inflammation and/or fibrosis lead to progressive loss of lung volume ('restrictive' defect) with normal expiratory flow rates. Typical laboratory traces are illustrated in Figure 17.7.

### Measurement of airway obstruction

Airway narrowing is assessed by asking patients to breathe in fully, then blow out as hard and fast as they can into a peak flow meter or

a spirometer. Peak flow meters are useful for home monitoring of peak expiratory flow (PEF) in the detection and monitoring of asthma but results are effort-dependent. More accurate and reproducible measures are obtained by maximum forced expiration into a spirometer. The forced expired volume in 1 second (FEV<sub>1</sub>) is the volume exhaled in the first second, and the forced vital capacity (FVC) is the total volume exhaled. Airflow obstruction is defined as a FEV<sub>1</sub>/FVC ratio of less than 70%. In this situation, spirometry should be repeated following inhaled short-acting  $\beta_2$ -adrenoceptor agonists (e.g. salbutamol); an increase of > 12% and > 200 mL in FEV<sub>1</sub> or FVC indicates significant reversibility. A large improvement in FEV<sub>1</sub> (> 400 mL) and variability in peak flow over time are features of asthma.

Large airway narrowing (e.g. tracheal stenosis or compression; see Fig. 20.12) can be distinguished from small airway narrowing through plotting spirometry data as flow/volume loops. These display flow in relation to lung volume (rather than time) during maximum expiration and inspiration, and the pattern of flow reveals the site of airflow obstruction (Fig. 17.7B).

## Lung volumes

Spirometry can measure only the volume of gas that can be exhaled; it cannot measure the gas remaining in the lungs after a maximal expiration. All the gas in the lungs can be measured by rebreathing an inert non-absorbed gas (usually helium) and recording how much the test gas is diluted by lung gas at equilibrium. This measures the volume of intrathoracic gas that mixes freely with tidal breaths. Alternatively, lung volume may be measured by body plethysmography (see Chapter 9), which determines the pressure/volume relationship of the thorax. This method measures total intrathoracic gas volume, including poorly ventilated areas such as bullae. The terms used to describe lung volume are shown in Figure 17.7C.

## Transfer factor

To measure the capacity of the lungs to exchange gas, patients inhale a test mixture of 0.3% carbon monoxide, which is taken up avidly by haemoglobin in pulmonary capillaries. After a short breath-hold, the rate of disappearance of CO into the circulation is calculated from a sample of expirate, and expressed as the TL<sub>CO</sub> or carbon monoxide transfer factor. Helium is also included in the test breath to allow calculation of the volume of lung examined by the test breath. Transfer factor expressed per unit lung volume is termed K<sub>CO</sub>. Common respiratory function abnormalities are summarised in Box 17.4.

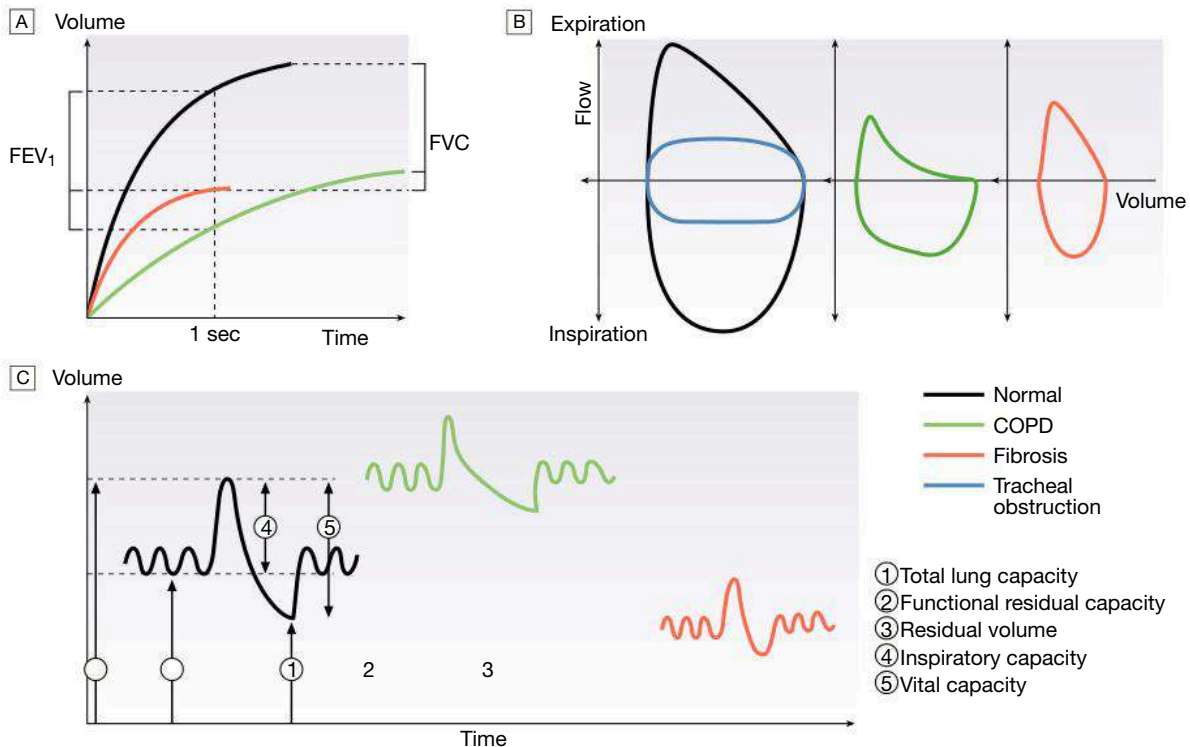

## Arterial blood gases and oximetry

The measurement of hydrogen ion concentration, PaO<sub>2</sub> and PaCO<sub>2</sub>, and derived bicarbonate concentration in an arterial blood sample is essential for assessing the degree and type of respiratory failure and for measuring acid–base status. This is discussed in detail on pages 496 and 630 (see Box 17.16). Interpretation of results is facilitated by blood gas diagrams (Fig. 17.8), which indicate whether any acidosis or alkalosis is due to acute or chronic respiratory derangements of PaCO<sub>2</sub> or to metabolic causes.

Pulse oximeters provide a continuous estimation of arterial oxygen saturation (SaO<sub>2</sub>, or SpO<sub>2</sub> if measured by pulse oximetry) (see p.177), thus allowing a real-time assessment of a patient's response to oxygen therapy.

## Exercise tests

Resting measurements may be unhelpful in early disease or in patients complaining only of exercise-induced symptoms. Spirometry testing before and after exercise can help to reveal exercise-induced asthma. Walk tests include the self-paced 6-minute walk and the externally

**Fig. 17.7** Respiratory function tests in health and disease. **A** Volume/time traces from forced expiration in health, chronic obstructive pulmonary disease (COPD) and fibrosis. COPD causes slow, prolonged and limited exhalation. In fibrosis, forced expiration results in rapid expulsion of a reduced forced vital capacity (FVC). Forced expiratory volume (FEV<sub>1</sub>) is reduced in both diseases but disproportionately so, compared to FVC, in COPD. **B** The same data plotted as flow/volume loops. In COPD, collapse of intrathoracic airways limits flow, particularly during mid- and late expiration. The blue trace illustrates large airway obstruction, which particularly limits peak flow rates. **C** Lung volume measurement. Volume/time graphs during quiet breathing with a single maximal breath in and out. COPD causes hyperinflation with increased residual volume. Fibrosis causes a proportional reduction in all lung volumes.

17.4 How to interpret respiratory function abnormalities				
	Asthma	Chronic bronchitis	Emphysema	Pulmonary fibrosis
FEV <sub>1</sub>	↓↓	↓↓	↓↓	↓
FVC	↓	↓	↓	↓↓
FEV <sub>1</sub> /FVC	↓	↓	↓	→/↑
TL <sub>co</sub>	→	→	↓↓	↓↓
K <sub>co</sub>	→/↑	→	↓	→/↓
TLC	→/↑	↑	↑↑	↓
RV	→/↑	↑	↑↑	↓

(RV = residual volume; TLC = total lung capacity; see text for other abbreviations)

**Fig. 17.8** Changes in blood  $[H^+]$ ,  $PaCO_2$  and plasma  $[HCO_3^-]$  in acid–base disorders. The rectangle indicates normal limits for  $[H^+]$  and  $PaCO_2$ . The bands represent 95% confidence limits of single disturbances in human blood. To determine the likely cause of an acid–base disorder, plot the values of  $[H^+]$  and  $PaCO_2$  from an arterial blood gas measurement. The diagram indicates whether any acidosis or alkalosis results primarily from a respiratory disorder of  $PaCO_2$  or from a metabolic derangement. From Flenley D. *Lancet* 1971; 1:1921, with permission from Elsevier.

paced incremental ‘shuttle’ test, where patients walk at increasing pace between two cones 10m apart. These provide simple, repeatable assessments of disability and response to treatment. Cardiopulmonary bicycle exercise testing, with measurement of metabolic gas exchange, ventilation and ECG changes, is useful for quantifying exercise limitation and detecting occult cardiovascular or respiratory limitation in a breathless patient.

## Presenting problems in respiratory disease

### Cough

Cough is the most frequent symptom of respiratory disease and is caused by stimulation of sensory nerves in the mucosa of the pharynx, larynx, trachea and bronchi. Acute sensitisation of the normal cough reflex occurs in a number of conditions and it is typically induced by changes in air temperature or exposure to irritants, such as cigarette

smoke or perfumes. Distinguishing characteristics of various causes of cough are detailed in [Box 17.5](#).

The explosive quality of a normal cough is lost in patients with respiratory muscle paralysis or vocal cord palsy. Paralysis of a single vocal cord gives rise to a prolonged, low-pitched, inefficient ‘bovine’ cough accompanied by hoarseness. Coexistence of an inspiratory noise (stridor) indicates partial obstruction of a major airway (e.g. laryngeal oedema, tracheal tumour, scarring, compression or inhaled foreign body) and requires urgent investigation and treatment. Sputum production is common in patients with acute or chronic cough, and its nature and appearance can provide clues to the aetiology.

### Aetiology

Acute transient cough is most commonly caused by viral tracheo-bronchial infection, post-nasal drip resulting from rhinitis or sinusitis, aspiration of a foreign body, or throat-clearing secondary to laryngitis or pharyngitis. When cough occurs in the context of more serious diseases, such as pneumonia, aspiration, congestive heart failure or pulmonary embolism, it is usually easy to diagnose from other clinical features.

Patients with chronic cough present more of a challenge and should be assessed with history, physical examination, chest X-ray and lung function studies.

Adults with chronic cough and a history of tobacco exposure should be considered for CT scanning if they have either an abnormal chest X-ray or a normal X-ray and other symptoms that might suggest lung cancer.

In the context of normal respiratory examination and investigations, extra-thoracic causes of cough need to be considered such as post-nasal drip secondary to nasal or sinus disease, gastro-oesophageal reflux disease or cough hypersensitivity. Use of angiotensin-converting enzyme (ACE) inhibitors can result in a chronic dry cough, taking up to 6 months to resolve following cessation. *Bordetella pertussis* infection in adults can result in cough lasting up to 3 months.

The presence of fine inspiratory crackles and a dry cough should prompt investigation for the possibility of an interstitial lung disease.

### Breathlessness

Breathlessness or dyspnoea is defined as the feeling of an uncomfortable need to breathe. It is unusual among sensations, as it has no defined receptors, no localised representation in the brain, and multiple causes both in health (e.g. exercise) and in diseases of the lungs, heart or muscles.

### Pathophysiology

Stimuli to breathing resulting from disease processes are shown in [Figure 17.9](#). Respiratory diseases can stimulate breathing and dyspnoea by:

- stimulating intrapulmonary sensory nerves (e.g. pneumothorax, interstitial inflammation and pulmonary embolus)
- increasing the mechanical load on the respiratory muscles (e.g. airflow obstruction or pulmonary fibrosis)
- causing hypoxia, hypercapnia or acidosis, which stimulate chemoreceptors.

In cardiac failure, pulmonary congestion reduces lung compliance and can also obstruct the small airways. Reduced cardiac output also limits oxygen supply to the skeletal muscles during exercise, causing early lactic acidemia and further stimulating breathing via the central chemoreceptors.

Breathlessness and the effects of treatment can be quantified using a symptom scale. Patients tend to report breathlessness in proportion to the sum of the above stimuli to breathing. Individual patients differ greatly in the intensity of breathlessness reported for a given set of circumstances, but breathlessness scores during exercise within individuals are reproducible and can be used to monitor the effects of therapy.

17.5 Cough		
Origin	Common causes	Clinical features
Pharynx	Post-nasal drip	History of chronic rhinitis
Larynx	Laryngitis, tumour, whooping cough, croup	Voice or swallowing altered, harsh or painful cough Paroxysms of cough, often associated with stridor
Trachea	Tracheitis	Raw retrosternal pain with cough
Bronchi	Bronchitis (acute) and chronic obstructive pulmonary disease (COPD)	Dry or productive, worse in mornings
	Asthma	Usually dry, worse at night
	Eosinophilic bronchitis	Features similar to asthma but airway hyper-reactivity absent
	Lung cancer	Persistent (often with haemoptysis)
Lung parenchyma	Tuberculosis	Productive (often with haemoptysis)
	Pneumonia	Dry initially, productive later Atypical pneumonias including COVID-19 often present with a dry cough
	Bronchiectasis	Productive, changes in posture induce sputum production
	Pulmonary oedema	Often at night (may be productive of pink, frothy sputum)
	Interstitial fibrosis	Dry and distressing
Drug side-effect	Angiotensin-converting enzyme (ACE) inhibitors	Dry cough
Aspiration	Gastro-oesophageal reflux disease (GORD)	History of acid reflux, heartburn, hiatus hernia Obesity

**Fig. 17.9 Respiratory stimuli contributing to breathlessness.** Mechanisms by which disease can stimulate the respiratory motor neurons in the medulla. Breathlessness is usually felt in proportion to the sum of these stimuli. Further explanation is given on page 181. (CSF = cerebrospinal fluid; V/Q = ventilation/perfusion ratio; IX = glossopharyngeal nerve)

## Differential diagnosis

Patients may present with either chronic exertional breathlessness or as an emergency with acute breathlessness, with prominent symptoms even at rest. The causes are classified in [Box 17.6](#).

### Chronic exertional breathlessness

The cause of breathlessness is often apparent from the clinical history. Key questions are detailed below.

#### How is your breathing at rest and overnight?

In COPD, there is a fixed, structural limit to maximum ventilation, and a tendency for progressive hyperinflation during exercise. Breathlessness is apparent mainly when walking and patients usually report minimal symptoms at rest and overnight. In contrast, patients with significant asthma are often woken from their sleep by breathlessness with chest tightness and wheeze.

Orthopnoea is common in COPD, as well as in heart disease, because airflow obstruction is made worse by cranial displacement of the diaphragm by the abdominal contents when recumbent, so many patients choose to sleep propped up. Thus it is not a useful differentiating symptom unless there is a clear history of previous angina or infarction to suggest cardiac disease.

#### How much can you do on a good day?

Noting 'breathless on exertion' is not enough; the approximate distance the patient can walk on the level should be documented, along with capacity to climb inclines or stairs. Variability within and between days is a hallmark of asthma; in mild asthma, the patient may be free of symptoms and signs when well. Gradual, progressive loss of exercise capacity over months and years, with consistent disability over days, is typical of COPD. When asthma is suspected, the degree of variability can be detected by home peak flow monitoring.

Relentless, progressive breathlessness that is also present at rest, often accompanied by a dry cough, suggests interstitial lung disease. Impaired left ventricular function can also cause chronic exertional breathlessness, cough and wheeze. A history of angina, hypertension or myocardial infarction raises the possibility of a cardiac cause. This may be confirmed by a displaced apex beat, a raised JVP and cardiac murmurs (although these signs can occur in severe hypoxic lung disease

with fluid retention). The chest X-ray may show cardiomegaly and an ECG and echocardiogram may provide evidence of left ventricular disease. Measurement of arterial blood gases may help, as, in the absence of an intracardiac shunt or pulmonary oedema, the  $PaO_2$  in cardiac disease is normal and the  $PaCO_2$  is low or normal.

#### Did you have breathing problems in childhood or at school?

When present, a history of childhood wheeze increases the likelihood of asthma, although this history may be absent in late-onset asthma. A history of atopic disease also increases the likelihood of asthma.

#### Do you have other symptoms along with your breathlessness?

Digital or perioral paraesthesiae and a feeling that 'I cannot get a deep enough breath in' are typical features of breathing pattern disorders but this cannot be diagnosed until other potential causes have been excluded. Additional symptoms include lightheadedness, central chest discomfort and occasionally carpopedal spasm due to acute respiratory alkalosis. These alarming symptoms may provoke further anxiety and exacerbate hyperventilation. Breathing pattern disorders rarely disturb sleep, can occur at rest, and may be provoked by stress. The Nijmegen questionnaire can be used to score some of the typical symptoms of breathing pattern disorders ([Box 17.7](#)). Arterial blood gases show normal (or high)  $PO_2$ , low  $PCO_2$  and alkalosis.

Pleuritic chest pain in a patient with chronic breathlessness, particularly if it occurs in more than one site over time, should raise suspicion of thromboembolic disease, which can occasionally present as chronic breathlessness with no other specific features and should always be considered before a diagnosis of breathing pattern disorder is made.

Morning headache is an important symptom in patients with breathlessness, as it may signal the onset of carbon dioxide retention and respiratory failure. This is particularly significant in patients with musculoskeletal disease impairing respiratory function (e.g. kyphoscoliosis or muscular dystrophy).

### Acute severe breathlessness

This is one of the most common and dramatic medical emergencies. Although respiratory causes are common, it can result from cardiac disease, metabolic disease or poisoning causing acidosis, or from psychogenic causes. The approach to patients with acute severe breathlessness is covered on page 181.

## 17.6 Causes of breathlessness

System	Acute dyspnoea	Chronic exertional dyspnoea
Cardiovascular	Acute pulmonary oedema*	Chronic heart failure Myocardial ischaemia (angina equivalent)
Respiratory	Acute severe asthma* Acute exacerbation of COPD* Pneumothorax* Bacterial and viral pneumonias* Pulmonary embolus* ARDS Inhaled foreign body (especially in children) Lobar collapse Laryngeal oedema (e.g. anaphylaxis)	COPD* Chronic asthma* Lung cancer Interstitial lung disease (sarcoidosis, fibrosing alveolitis, extrinsic allergic alveolitis, pneumoconiosis) Chronic pulmonary thromboembolism Lymphangitis carcinomatosa (may cause intolerable breathlessness) Large pleural effusion(s)
Others	Metabolic acidosis (e.g. diabetic ketoacidosis, lactic acidosis, uraemia, overdose of salicylates, ethylene glycol poisoning) Psychogenic hyperventilation (anxiety- or panic-related)	Severe anaemia Obesity Deconditioning

\*Denotes a common cause.

(ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease)

### 17.7 Factors suggesting psychogenic hyperventilation

- 'Inability to take a deep breath'
- Frequent sighing/erratic ventilation at rest
- Short breath-holding time in the absence of severe respiratory disease
- Difficulty in performing and/or inconsistent spirometry measures
- High score (over 26) on Nijmegen questionnaire
- Induction of symptoms during submaximal hyperventilation
- Resting end-tidal CO<sub>2</sub> <4.5%
- Associated digital and/or perioral paraesthesiae

### Chest pain

Chest pain can result from cardiac, respiratory, oesophageal or musculoskeletal disorders. The approach to this common symptom is covered on page 179.

### Finger clubbing

Finger clubbing describes painless swelling of the soft tissues of the terminal phalanges, causing increased longitudinal and lateral convexity of the nail (Fig. 17.10). Upward displacement of the proximal nail margin causes the anteroposterior diameter of the finger at that point to exceed that at the distal interphalangeal joint. It also removes the normal hyponychial angle between the proximal part of the nail and the adjoining skin. Clubbing usually affects the fingers symmetrically and commonly also involves the toes, but can be unilateral if caused by a proximal vascular condition, e.g. arteriovenous shunts for dialysis. Although clubbing is usually idiopathic, it can be associated with suppurative or malignant lung conditions (Box 17.8). Clubbing may recede if the underlying condition resolves, e.g. following lung transplantation for cystic fibrosis.

### Haemoptysis

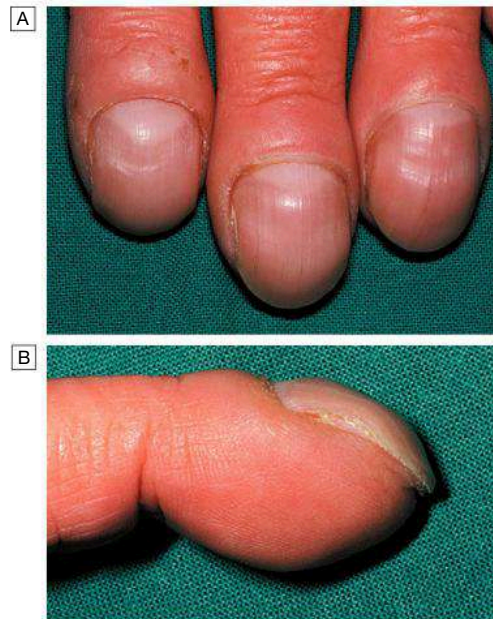

Coughing up blood is an alarming symptom and patients nearly always seek medical advice. Care should be taken to establish that it is true haemoptysis and not haematemesis, or gum or nose bleeding. Haemoptysis must always be assumed to have a serious cause until this is excluded (Box 17.9).

Many episodes of haemoptysis remain unexplained, even after full investigation, and are likely to be due to simple bronchial infection. A history of repeated small haemoptysis, or blood-streaking of sputum, is highly suggestive of lung cancer. Fever, night sweats and weight loss suggest tuberculosis. Pneumococcal pneumonia often causes 'rusty'-coloured sputum but can cause frank haemoptysis, as can all suppurative respiratory infections. Lung abscess, bronchiectasis and intracavitary mycetoma can cause catastrophic bronchial haemorrhage. Finally, pulmonary thromboembolism is a common cause of haemoptysis and should always be considered.

Physical examination may reveal additional clues. Finger clubbing suggests lung cancer or bronchiectasis; other signs of malignancy, such as cachexia, hepatomegaly and lymphadenopathy, should also be sought. Fever, pleural rub and signs of consolidation occur in pneumonia or pulmonary infarction; a minority of patients with pulmonary infarction also have unilateral leg swelling or pain suggestive of deep venous thrombosis. Rashes, haematuria and digital infarcts point to an underlying systemic disease such as a vasculitis, which may cause haemoptysis.

### Management

In severe acute haemoptysis the patient should be nursed upright (or on the side of the bleeding, if this is known), given high-flow oxygen and resuscitated as required. Bronchoscopy in the acute phase is difficult and often merely shows blood throughout the bronchial tree. Infusions of the antifibrinolytic agent tranexamic acid or the vasopressin precursor terlipressin may help to limit bleeding but evidence of efficacy is limited. If radiology shows an obvious central cause, then rigid bronchoscopy under general anaesthesia may allow intervention to stop bleeding; however, the

**Fig. 17.10** Finger clubbing. **A** Anterior view. **B** Lateral view. From Douglas G, Nicol F, Robertson C. *Macleod's Clinical examination*, 13th edn. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2013.

### 17.8 Differential diagnosis of finger clubbing

#### Congenital or familial (5%–10%)

#### Acquired

#### Thoracic (~80%)

- Chronic suppurative conditions:
  - Pulmonary tuberculosis
  - Bronchiectasis
  - Lung abscess
  - Empyema
  - Cystic fibrosis
- Tumours:
  - Lung cancer
  - Mesothelioma
  - Fibroma
- Pulmonary fibrosis

#### Cardiovascular

- Cyanotic congenital heart disease
- Infective endocarditis
- Arteriovenous shunts and aneurysms

#### Gastrointestinal

- Cirrhosis
- Inflammatory bowel disease
- Coeliac disease

#### Others

- Thyrotoxicosis (thyroid acropachy)
- Primary hypertrophic osteoarthropathy

source often cannot be visualised. Intubation with a divided endotracheal tube may allow protected ventilation of the unaffected lung to stabilise the patient. Bronchial arteriography and embolisation (Fig. 17.11), or even emergency surgery, can be life-saving in the acute situation.

In the vast majority of cases, however, the haemoptysis itself is not life-threatening and a logical sequence of investigations can be followed:

- Chest X-ray may provide evidence of a localised lesion such as tumour, pneumonia, mycetoma or tuberculosis
- Full blood count (FBC) and clotting screen
- CTPA may show underlying pulmonary thromboembolic disease or alternative causes not seen on the chest X-ray (e.g. pulmonary arteriovenous malformation or small or hidden tumours)
- Bronchoscopic biopsy (after acute bleeding has settled) if the CT scan suggests an abnormality that needs biopsy.

## 'Incidental' pulmonary nodule

A pulmonary nodule may be defined as a well or poorly circumscribed, approximately rounded structure that appears on imaging as a focal opacity less than 3 cm in diameter that is surrounded by aerated lung. 'Incidental' pulmonary nodules have become increasingly common with the increased use of CT scanning (Fig. 17.12). Nodules must not be dismissed as 'incidental', however, until either a treatable condition has been excluded or stability has been demonstrated for at least 2 years.

The list of potential causes of pulmonary nodules is extensive and most are benign (Box 17.10). Features on a CT scan consistent with a benign lesion include being less than 5 mm in diameter or less than 80 mm<sup>3</sup> in volume; diffuse, central, laminated or popcorn calcification; or the presence of macroscopic fat. In addition, perifissural lymph nodes and subpleural nodules with a lentiform or triangular shape do not require any further investigation.

In cases where a benign lesion cannot be confidently assumed, further assessment depends on both the appearance of the nodule and the clinical context. These assessments may be aided by the use of computer prediction models (Box 17.11).

A variety of diagnostic approaches may be considered, including bronchoscopy, percutaneous needle biopsy, FDG-PET, interval CT scanning or surgical resection of the lesion. Pulmonary nodules are invariably beyond the vision of the bronchoscope and, with the notable exception of pulmonary infection (e.g. tuberculosis), the yield from blind washings is low. If the nodule is favourably located and of sufficient size, percutaneous needle biopsy under ultrasound or CT guidance may be employed. The risk of pneumothorax is approximately 15% and around 7% require intercostal drainage, so this should be contemplated only in individuals with an FEV<sub>1</sub> of more than 35% predicted. Haemorrhage into the lung or pleural space, air embolism and tumour seeding are rare but recognised complications.

PET-CT scanning provides useful information about nodules of at least 1 cm in diameter. The presence of high metabolic activity is strongly suggestive of malignancy, while an inactive 'cold' nodule suggests benign disease. However, a high SUV is a marker of glucose metabolism, not malignancy, and PET-CT has significant limitations in regions with high endemic rates of infectious or granulomatous disease. False-negative results may occur with neuro-endocrine tumours and minimally invasive lepidic adenocarcinoma. Detection of neuro-endocrine tumours may be improved by the use of <sup>68</sup>Ga-DOTATOC in place of FDG.

**Fig. 17.11** Bronchial artery angiography. An angiography catheter has been passed via the femoral artery and aorta into an abnormally dilated right bronchial artery (arrows). Contrast is seen flowing into the lung. This patient had post-tuberculous bronchiectasis and presented with massive haemoptysis. Bronchial artery embolisation was successfully performed.

**Fig. 17.12** Thoracic CT scan showing a solitary pulmonary nodule identified in the right upper lobe (arrow).

### 17.9 Causes of haemoptysis

#### Bronchial disease

- Cancer\*
- Bronchiectasis\*
- Acute bronchitis\*
- Bronchial adenoma
- Foreign body

#### Parenchymal disease

- Tuberculosis\*
- Suppurative pneumonia
- Parasites (e.g. hydatid disease, flukes)
- Lung abscess
- Trauma
- Actinomycosis
- Mycetoma

#### Lung vascular disease

- Pulmonary infarction\*
- Goodpastur's disease
- Polyarteritis nodosa
- Idiopathic pulmonary haemosiderosis

#### Cardiovascular disease

- Acute left ventricular failure\*
- Mitral stenosis
- Aortic aneurysm

#### Blood disorders

- Leukaemia
- Haemophilia
- Anticoagulants

\*More common causes.

### 17.10 Causes of pulmonary nodules

#### Common causes

- Lung cancer
- Single metastasis
- Localised pneumonia
- Lung abscess
- Tuberculoma
- Pulmonary infarct

#### Uncommon causes

- Benign tumour
- Lymphoma
- Arteriovenous malformation
- Hydatid cyst
- Bronchogenic cyst
- Rheumatoid nodule
- Granulomatosis with polyangiitis (GPA)
- Pulmonary sequestration
- Pulmonary haematoma
- 'Pseudotumour' – fluid collection in a fissure
- Aspergilloma (usually surrounded by air crescent)
- *Cryptococcus*
- *Aspergillus* nodule

### 17.11 Clinical and radiographic features distinguishing benign from malignant nodules\*

Feature	Risk of malignancy	Feature	Risk of malignancy
<b>Characteristics of nodule</b>		<b>Characteristics of patient</b>	
Size	Nearly all >3 cm but fewer than 1% <4 mm are malignant	Age	Increases with age and is uncommon below age of 40
Margin	Usually smooth in benign lesions Spiculated suggests malignancy	Smoking history	Increases in proportion to duration and amount smoked
Calcification or fat	Laminated or central deposition of calcification suggests granuloma 'Popcorn' pattern suggests hamartoma Fat may suggest hamartoma or lipid granuloma	Other	Increased by history of lung cancer in first-degree relative and by exposure to asbestos, silica, uranium and radon
Location	70% of lung cancers occur in upper lobes Benign lesions are equally distributed throughout upper and lower lobes		

\*Linear or sheet-like lung opacities are unlikely to represent neoplasms and do not require follow-up. Some nodular opacities may be sufficiently typical of scarring for follow-up not to be warranted. Adapted from MacMahon H, Austin JH, Gamsu G, et al. Guidelines for management of small pulmonary nodules detected on CT scans: a statement from the Fleischner Society. *Radiology* 2005; 237:395–400.

If the nodule is small and inaccessible, interval CT scanning may be employed. A repeat CT scan at 3 months will reliably detect growth in larger nodules and may also demonstrate resolution. Further interval scans may be arranged depending on the clinical context (Fig. 17.13). Particular care must be taken with subsolid nodules, particularly if further imaging demonstrates the development of a new solid component, as these may represent a pre-malignant or an early invasive form of adenocarcinoma.

Nodules with a high clinical suspicion for malignancy despite benign or indeterminate biopsies may merit proceeding straight to surgical resection, as this represents the best chance of curative therapy for lung cancer. It is important for the logic underlying this approach to be discussed with the patient, consideration of frozen intra-operative histology, and the consequences of resection of a benign lesion explained.

Where the probability of cancer is low, the potential risk of further scanning must be considered. Subsequent scans often detect further nodules, increase the risk of false-positive findings and lead to unnecessary patient anxiety while exposing the individual to increased radiation.

## Pleural effusion

The accumulation of serous fluid within the pleural space is termed pleural effusion. Accumulations of pus, blood and chyle are termed empyema, haemothorax and chylothorax respectively. In general, pleural fluid accumulates because of either increased hydrostatic pressure or decreased osmotic pressure ('transudative' effusion, as seen in cardiac, liver or renal failure), or from increased microvascular pressure due to disease of the pleura or injury in the adjacent lung ('exudative' effusion). The causes of the majority of pleural effusions (Boxes 17.12 and 17.13) are identified by a thorough history, examination and relevant investigations.

### Clinical assessment

Symptoms (pain on inspiration and coughing) and signs of pleurisy (a pleural rub) often precede the development of an effusion, especially in patients with underlying pneumonia, pulmonary infarction or connective tissue disease. When breathlessness is the only symptom, however, the onset may be insidious, depending on the size and rate of accumulation. The physical signs are detailed on page 481.

### Investigations

#### Radiological investigations

The classical appearance of pleural fluid on the erect PA chest X-ray is of a curved shadow at the lung base, blunting the costophrenic angle and ascending towards the axilla. Fluid appears to track up the lateral chest

wall. In fact, fluid surrounds the whole lung at this level but casts a radiological shadow only where the X-ray beam passes tangentially across the fluid against the lateral chest wall. Around 200 mL of fluid is required in order for it to be detectable on a PA chest X-ray. Previous scarring or adhesions in the pleural space can cause localised effusions. Pleural fluid localised below the lower lobe ('subpulmonary effusion') simulates an elevated hemidiaphragm. Pleural fluid localised within an oblique fissure may produce a rounded opacity that may be mistaken for a tumour.

Ultrasound is more accurate than plain chest X-ray for determining the presence of fluid. A clear hypoechoic space is consistent with a transudate and the presence of moving, floating densities suggests an exudate. The presence of septation most likely indicates an evolving empyema or resolving haemothorax. CT scanning is indicated where there is concern for malignant disease or loculation is suspected.

### Pleural aspiration and biopsy

In some conditions (e.g. left ventricular failure), it should not be necessary to sample fluid unless atypical features are present; appropriate treatment should be administered and the effusion re-evaluated. In most other circumstances, however, diagnostic sampling is required. Simple aspiration provides information on the colour and texture of fluid and these alone may immediately suggest an empyema or chylothorax. The presence of blood is consistent with pulmonary infarction or malignancy but may result from a traumatic tap. Biochemical analysis allows classification into transudate or exudate (Box 17.14). Cytological examination can characterize the presence of inflammatory or malignant cells. Microbiological staining can detect bacteria and mycobacteria. If a diagnosis of tuberculosis is being considered, adenosine deaminase (ADA) should be measured (see p. 520). A low pH suggests infection but may also be seen in rheumatoid arthritis, ruptured oesophagus or advanced malignancy.

Ultrasound- or CT-guided pleural biopsy provides tissue for pathological and microbiological analysis. Where necessary, video-assisted thoracoscopy allows visualisation of the pleura and direct guidance of a biopsy.

### Management

Therapeutic aspiration may be required to palliate breathlessness but removing more than 1.5 L at a time is associated with a small risk of re-expansion pulmonary oedema. An effusion should never be drained to dryness before establishing a diagnosis, as biopsy may be precluded until further fluid accumulates. Treatment of an underlying cause such as heart failure, pneumonia, pulmonary embolism or subphrenic abscess will often be followed by resolution of the effusion. The management of pleural effusion in pneumonia, tuberculosis and malignancy is dealt with below.

## Empyema

An empyema is a collection of pus within the pleural space. Microscopically, neutrophil leucocytes are present in large numbers and bacteria may be identified on Gram's stain. An empyema may involve the whole pleural space or only part of it ('loculated' or 'encysted' empyema) and is usually unilateral. It is usually secondary to infection in a neighbouring structure, usually the lung, most commonly due to the bacterial pneumonia or tuberculosis. Over 40% of patients with community-acquired pneumonia develop an associated pleural effusion ('parapneumonic' effusion) and about 15% of these become secondarily infected. Other causes are infection of a haemothorax following trauma or surgery, oesophageal rupture, and rupture of a subphrenic abscess through the diaphragm.

Macroscopically, the pleural surfaces are covered with an inflammatory exudate. The pus can be under considerable pressure. Inadequate treatment can result in rupture into a bronchus, causing a bronchopleural fistula and pyopneumothorax, or tracking through the chest wall forming a subcutaneous abscess or sinus ('empyema necessitans').

### Clinical assessment

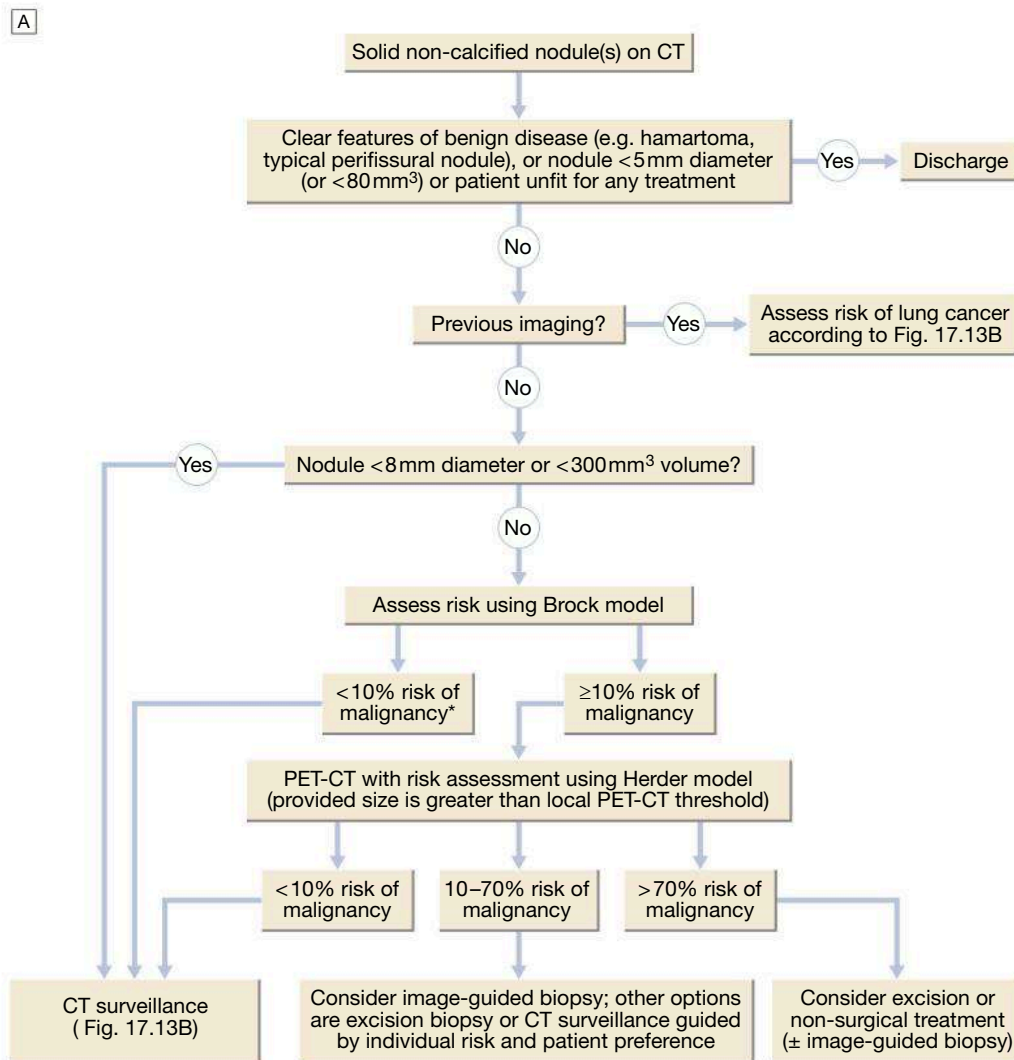

An empyema should be suspected in patients with pulmonary infection if there is severe pleuritic chest pain or persisting or recurrent pyrexia

despite appropriate antimicrobial treatment. In other cases, the primary infection may be so mild that it passes unrecognised and the first definite clinical features are due to the empyema itself. Once an empyema has developed, systemic features are prominent (Box 17.15).

### Investigations

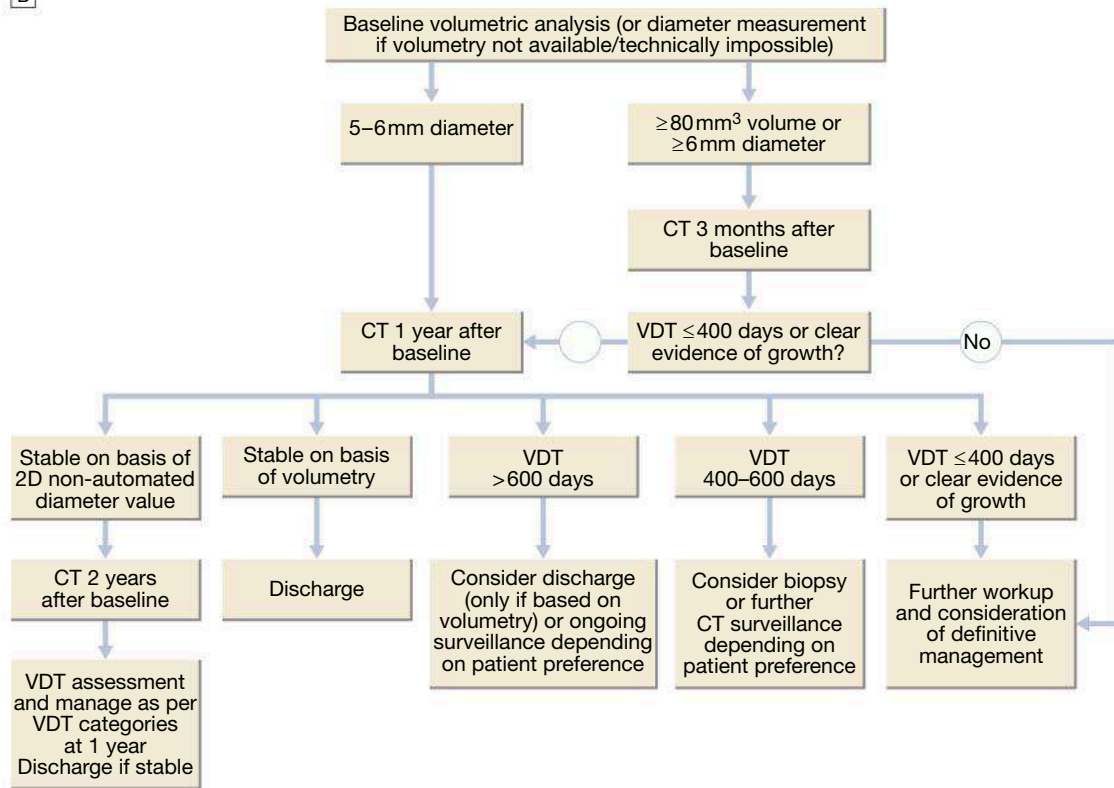

Chest X-ray appearances may be indistinguishable from those of pleural effusion, although pleural adhesions may confine the empyema to form a 'D'-shaped shadow against the inside of the chest wall (Fig. 17.14). When air is present as well as pus (pyopneumothorax), a horizontal 'fluid level' marks the air/liquid interface. Ultrasound shows the position of the fluid, the extent of pleural thickening and whether fluid is in a single collection or multiloculated, containing fibrin and debris (Fig. 17.15). CT provides information on the pleura, underlying lung parenchyma and patency of the major bronchi.

Ultrasound or CT is used to identify the optimal site for aspiration, which is best performed using a wide-bore needle. If the fluid is thick and turbid pus, empyema is confirmed. Other features suggesting empyema are a fluid glucose of less than 3.3 mmol/L (60 mg/dL), lactate dehydrogenase (LDH) of more than 1000 IU/L, or a fluid pH of less than 7.2. However, pH measurement should be avoided if pus is thick, as it damages blood gas machines. Bacterial culture may be negative if

**Fig. 17.13 Recommendations on the assessment of a solid pulmonary nodule.** **A** Initial approach to solid pulmonary nodules. The Brock model is an online calculator that can also be downloaded as an app (<https://brocku.ca/lung-cancer-risk-calculator>). The model integrates data on age, sex, family history of cancer, the presence of emphysema, nodule size, nodule type, nodule position, nodule count and speculation, and calculates the probability that a nodule will become malignant within a 2- to 4-year follow-up period. Herder is a similar model. \*Consider positron emission tomography-computed tomography (PET-CT) for larger nodules in young patients with low risk by Brock score, as this score was developed in a screening cohort (50–75 years) and so performance in younger patients is unproven. *Continues overleaf*

*May cause bilateral effusions.	

antibiotics have already been given. The distinction between tuberculous and non-tuberculous disease can be difficult and may require pleural biopsy, histology and microbiological tests.

### Management

An empyema will heal only if infection is eradicated and the empyema space is obliterated, allowing apposition of the visceral and parietal pleural layers. This can only occur if all the pus is removed from the pleural space. When the pus is sufficiently thin this is most easily achieved by the insertion of a wide-bore intercostal tube into the most dependent part of the empyema space. If the initial aspirate reveals turbid fluid or frank pus, or if loculations are seen on ultrasound, the tube should be put on suction (−5 to −10 cmH<sub>2</sub>O) and flushed regularly with 20 mL normal saline. Antibiotics should not be started until

they are deemed clinically necessary, and ideally not until a sample has been taken and the causative organism identified. If an organism is identified, the narrowest spectrum antibiotic that will cover that organism should be used. If not, empirical antibiotic treatment (e.g. intravenous co-amoxiclav 1.2 g 8-hourly or cefuroxime 1.5 g 12-hourly plus metronidazole 500 mg 8-hourly) should be used. Antibiotics should be continued until the infection has resolved and inflammatory markers have normalised, usually about 2–4 weeks. There is no consensus on the optimum duration of intravenous vs. oral antibiotics. The use of intrapleural fibrinolytics in combination with DNAase has been shown to be beneficial.

An empyema can be successfully treated with a combination of antibiotics and pleural drainage, but delays can result in a failure of these therapies, and a need for surgical intervention to clear the empyema cavity of pus and break down any adhesions. Surgical 'decortication' of the lung may also be required if gross thickening of the visceral pleura is preventing re-expansion of the lung. Surgery is also necessary if a bronchopleural fistula or empyema necessitans develops.

### Respiratory failure

The term 'respiratory failure' is used when pulmonary gas exchange fails to maintain normal arterial oxygen and carbon dioxide levels. Its classification into types I and II is defined by the absence or presence of hypercapnia (raised PaCO<sub>2</sub>).

#### Pathophysiology

When disease impairs ventilation of part of a lung (e.g. in asthma or pneumonia), perfusion of that region results in hypoxic and CO<sub>2</sub>-laden blood entering the pulmonary veins. Increased ventilation of neighbouring regions of normal lung can increase CO<sub>2</sub> excretion, correcting arterial CO<sub>2</sub> to normal, but cannot augment oxygen uptake because the haemoglobin flowing through these normal regions is already fully saturated.

### 17.13 Pleural effusion: main causes and features

Cause	Appearance of fluid	Type of fluid	Predominant cells in fluid	Other diagnostic features
<b>Tuberculosis</b>	Serous, usually amber-coloured	Exudate	Lymphocytes (occasionally polymorphs)	Positive tuberculin test Isolation of <i>Mycobacterium tuberculosis</i> from pleural fluid (20%) Positive pleural biopsy (80%) Raised adenosine deaminase
<b>Malignant disease</b>	Serous, often blood-stained	Exudate	Serosal cells and lymphocytes Often clumps of malignant cells	Positive pleural biopsy (40%) Evidence of malignancy elsewhere
<b>Cardiac failure</b>	Serous, straw-coloured	Transudate	Few serosal cells	Other signs of cardiac failure Response to diuretics
<b>Pulmonary infarction</b>	Serous or blood-stained	Exudate (rarely transudate)	Red blood cells Eosinophils	Evidence of pulmonary infarction Obvious source of embolism Factors predisposing to venous thrombosis
<b>Rheumatoid disease</b>	Serous Turbid if chronic	Exudate	Lymphocytes (occasionally polymorphs)	Rheumatoid arthritis: rheumatoid factor and anti-cyclic citrullinated peptide (anti-CCP) antibodies Cholesterol in chronic effusion; very low glucose in pleural fluid
<b>Systemic lupus erythematosus (SLE)</b>	Serous	Exudate	Lymphocytes and serosal cells	Other signs of SLE Antinuclear factor or anti-DNA positive
<b>Acute pancreatitis</b>	Serous or blood-stained	Exudate	No cells predominate	Higher amylase in pleural fluid than in serum
<b>Obstruction of thoracic duct</b>	Milky	Chyle	None	Chylomicrons

### 17.14 Light's criteria for distinguishing pleural transudate from exudate

Exudate is likely if one or more of the following criteria are met:

- Pleural fluid protein:serum protein ratio >0.5
- Pleural fluid LDH:serum LDH ratio >0.6
- Pleural fluid LDH > two-thirds of the upper limit of normal serum LDH

(LDH = lactate dehydrogenase)

### 17.15 Clinical features of empyema

#### Systemic features

- Pyrexia, usually high and remittent
- Rigors, sweating, malaise and weight loss
- Polymorphonuclear leucocytosis, high C-reactive protein

#### Local features

- Pleural pain; breathlessness; cough and sputum, usually because of underlying lung disease; copious purulent sputum if empyema ruptures into a bronchus (bronchopleural fistula)
- Clinical signs of pleural effusion

Admixture of blood from the under-ventilated and normal regions thus results in hypoxia with normocapnia, which is called 'type I respiratory failure'. Diseases causing this include all those that impair ventilation locally with sparing of other regions (Box 17.16).

Arterial hypoxia with hypercapnia (type II respiratory failure) is seen in conditions that cause generalised, severe ventilation-perfusion mismatch, leaving insufficient normal lung to correct  $PaCO_2$ , or any disease that reduces total ventilation. The latter includes not just diseases of the lung but also disorders affecting any part of the neuromuscular mechanism of ventilation (see Box 17.16). Acute type II respiratory failure is an emergency requiring immediate intervention. It is useful to distinguish between patients with high ventilatory drive (rapid respiratory rate and accessory muscle recruitment) who cannot move sufficient air, and those with reduced or inadequate respiratory effort.

**Fig. 17.14** Chest X-ray showing a 'D'-shaped shadow in the left mid-zone, consistent with an empyema. In this case, an intercostal chest drain has been inserted but the loculated collection of pus remains.

### Management of acute respiratory failure

Prompt diagnosis and management of the underlying cause is crucial. In type I respiratory failure, oxygen should be administered and titrated to maintain a normal arterial oxygen saturation ( $SaO_2$ ), which will usually relieve hypoxia by increasing the alveolar  $PO_2$  in poorly ventilated lung units. Occasionally, however (e.g. severe pneumonia affecting several lobes), mechanical ventilation may be needed to relieve hypoxia.

If inspiratory stridor is present then an upper or large airway issue should be considered. This can include acute upper airway obstruction, foreign body inhalation or laryngeal obstruction (angioedema, carcinoma or vocal cord paralysis). Depending on cause, the Heimlich manoeuvre, immediate intubation or emergency tracheostomy may be required.

More commonly, the problem is within the lungs, with severe generalised bronchial obstruction from COPD or asthma, acute respiratory distress syndrome (ARDS), or tension pneumothorax. Oxygen should be

administered to maintain the  $SaO_2$  within the target range of 94%–98%, or 88%–92% for those patients at risk of type II respiratory failure, pending a rapid examination of the respiratory system and measurement of arterial blood gases. Patients with the trachea deviated away from a silent and resonant hemithorax are likely to have tension pneumothorax, and air should be aspirated from the pleural space and a chest drain inserted as soon as possible. Patients with generalised wheeze, scanty breath sounds bilaterally or a history of asthma or COPD should be treated with salbutamol 2.5 mg nebulised with oxygen, repeated until bronchospasm is relieved. Failure to respond to initial treatment, declining conscious level and worsening respiratory acidosis ( $pH < 7.35$ ),  $PaCO_2 > 6.6$  kPa) on blood gases are all indications that supported ventilation is required.

A small proportion of patients with severe chronic lung disease and type II respiratory failure develop abnormal tolerance to raised  $PaCO_2$  and may become dependent on hypoxic drive to breathe. In these patients only, lower concentrations of oxygen (24%–28% by Venturi mask) should be used to avoid precipitating worsening respiratory depression (see below). In all cases, regular monitoring of arterial blood gases is important to assess progress.

Patients with acute type II respiratory failure who have reduced drive or conscious level may be suffering from sedative poisoning,  $CO_2$  narcosis or a primary failure of neurological drive (e.g. following intracerebral haemorrhage or head injury). History from a witness may be invaluable, and reversal of specific drugs with (for example) opiate antagonists is occasionally successful, but should not delay intubation and supported mechanical ventilation in appropriate cases.

**Fig. 17.15** Pleural ultrasound showing septation. Courtesy of Dr P. Sivasothy, Department of Respiratory Medicine, Addenbrooke's Hospital, Cambridge.

## Chronic and 'acute on chronic' type II respiratory failure

The most common cause of chronic type II respiratory failure is severe COPD. Although  $PaCO_2$  may be persistently raised, there is no persisting acidaemia because the kidneys retain bicarbonate, correcting arterial pH to normal. This 'compensated' pattern, which may also occur in chronic neuromuscular disease, kyphoscoliosis or other end-stage respiratory diseases, is maintained until there is a further acute illness (see [Box 17.16](#)), such as an exacerbation of COPD that precipitates an episode of 'acute on chronic' respiratory failure, with acidaemia and initial respiratory distress followed by drowsiness and eventually coma. These patients have lost their chemosensitivity to elevated  $PaCO_2$ , and so they may paradoxically depend on hypoxia for respiratory drive and are at risk of respiratory depression if given high concentrations of oxygen, e.g. during ambulance transfers or in emergency departments. Moreover, in contrast to acute severe asthma, some patients with 'acute on chronic' type II respiratory failure due to COPD may not appear distressed, despite being critically ill with severe hypoxaemia, hypercapnia and acidaemia. While the physical signs of  $CO_2$  retention (delirium, flapping tremor, bounding pulses and so on) can be helpful if present, they may not be, so measurement of arterial blood gases is mandatory in the assessment of initial severity and response to treatment.

### Management

The principal aims of treatment in acute on chronic type II respiratory failure are to achieve a safe  $PaO_2$  ( $> 7.0$  kPa (52 mmHg)) without increasing  $PaCO_2$  and acidosis, while identifying and treating the precipitating condition. In these patients, it is not necessary to achieve a normal  $PaO_2$ ; even a small increase will greatly improve tissue oxygen delivery, since their  $PaO_2$  values are often on the steep part of the oxygen dissociation curve (see [Fig. 9.10](#)). The risks of worsening hypercapnia and coma must be balanced against those of severe hypoxaemia, which include potentially fatal arrhythmias and hypoxic brain damage. Immediate treatment is shown in [Box 17.17](#). Patients who are conscious and have adequate respiratory drive may benefit from non-invasive ventilation (NIV), which has been shown to reduce mortality and the requirement for intubation, and shorten hospital stay in acidotic exacerbations of COPD. Patients who are drowsy and have low respiratory drive require an urgent decision regarding intubation and ventilation, as this is likely to be the only effective treatment, even though weaning off the ventilator may be difficult in severe disease. The decision is challenging, and important factors to consider include patient wishes, presence of a potentially remediable precipitating condition, prior functional capacity and quality of life. The

### 17.16 How to interpret blood gas abnormalities in respiratory failure

	Type I		Type II	
	Hypoxia ( $PaO_2 < 8.0$ kPa (60 mmHg)) Normal or low $PaCO_2$ ( $\leq 6$ kPa (45 mmHg))		Hypoxia ( $PaO_2 < 8.0$ kPa (60 mmHg)) Raised $PaCO_2$ ( $> 6$ kPa (45 mmHg))	
	Acute	Chronic	Acute	Chronic

(ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease)

various types of non-invasive (via a face or nasal mask) or invasive (via an endotracheal tube) ventilation are detailed on page 207. Respiratory stimulant drugs, such as doxapram, have been superseded by non-invasive or invasive ventilation.

### Home ventilation for chronic respiratory failure

NIV is of significant benefit in the long-term treatment of respiratory failure due to spinal deformity, neuromuscular disease and central alveolar hypoventilation. Some patients with advanced lung disease, e.g. COPD and cystic fibrosis, also benefit from NIV for respiratory failure. In these conditions, type II respiratory failure can develop slowly and insidiously. Morning headache (due to elevated  $PaCO_2$ ) and fatigue are common symptoms but, in many cases, the diagnosis is revealed only by sleep studies or morning blood gas analysis. In the initial stages, ventilation is insufficient for metabolic needs only during sleep, when there is a physiological decline in ventilatory drive. Over time, however,  $CO_2$  retention becomes chronic, with renal compensation of acidosis. Treatment by home-based NIV overnight is often sufficient to restore the daytime  $PCO_2$  to normal, and to relieve fatigue and headache. In advanced disease (e.g. muscular dystrophies or cystic fibrosis), daytime NIV may also be required.

### Lung transplantation

Lung transplantation is an established treatment for carefully selected patients with advanced lung disease unresponsive to medical treatment (Box 17.18). Single-lung transplantation may be used for selected patients with advanced emphysema or lung fibrosis. This is contraindicated in patients with chronic bilateral pulmonary infection, such as cystic fibrosis and bronchiectasis, because the transplanted lung is vulnerable to cross-infection in the context of post-transplant immunosuppression, and for these individuals bilateral lung transplantation is the standard procedure. Combined heart-lung transplantation is still occasionally needed for patients with advanced congenital heart disease, such as Eisenmenger syndrome, and is preferred by some surgeons for the treatment of primary pulmonary hypertension unresponsive to medical therapy.

The prognosis following lung transplantation is improving steadily with modern immunosuppressive drugs: According to the International Society for Heart and Lung Transplantation median survival for double lung transplantation is 7.8 years. Chronic rejection with obliterative bronchiolitis continues to afflict some recipients, however. Glucocorticoids are used to manage acute rejection, but drugs that inhibit cell-mediated immunity specifically, such as ciclosporin, mycophenolate and tacrolimus, are used to prevent chronic lung allograft dysfunction (CLAD). Azithromycin, statins and total lymphoid irradiation are employed to treat progressive CLAD, but late organ failure remains a significant problem.

The major factor limiting the availability of lung transplantation is the shortage of donor lungs.

## Obstructive pulmonary diseases

### Asthma

Asthma is a chronic inflammatory disorder of the airways, in which many cells and cellular elements play a role. Chronic inflammation is associated with airway hyper-responsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction within the lung that is often reversible, either spontaneously or with treatment.

The prevalence of asthma increased steadily over the latter part of last century. As asthma affects all age groups, it is one of the most common and important long-term respiratory conditions in terms of global years lived with disability (Fig. 17.16).

The development and course of asthma and the response to treatment are influenced by genetic determinants, while the rapid rise in

prevalence implies that environmental factors are critically important in the development and expression of the disease. The potential role of indoor and outdoor allergens, microbial exposure, diet, vitamins, breast-feeding, tobacco smoke, air pollution and obesity have been explored but no clear consensus has emerged.

### Pathophysiology

Airway hyper-reactivity (AHR) – the tendency for airways to narrow excessively in response to triggers that have little or no effect in normal individuals – is integral to the diagnosis of asthma and appears to be related, although not exclusively, to airway inflammation (Fig. 17.17). Other factors likely to be important in the behaviour of airway smooth muscle include the degree of airway narrowing and neurogenic mechanisms.

The relationship between atopy (the propensity to produce IgE) and asthma is well established and in many individuals there is a clear relationship between sensitisation and allergen exposure, as demonstrated by skin-prick reactivity or elevated serum-specific IgE. Common examples of allergens include house dust mites, pets, insect pests and fungi. Inhalation of an allergen into the airway is followed by early and late-phase bronchoconstrictor responses (Fig. 17.18). Allergic mechanisms are also implicated in some cases of occupational asthma.

In cases of NSAID-induced asthma, the ingestion of salicylates results in inhibition of the cyclo-oxygenase enzymes, preferentially shunting the metabolism of arachidonic acid through the lipoxygenase pathway with resultant production of the asthmogenic cysteinyl leukotrienes. In exercise-induced asthma, hyperventilation results in water loss from the pericellular lining fluid of the respiratory mucosa, which, in turn, triggers mediator release. Heat loss from the respiratory mucosa may also be important.

In persistent asthma, a chronic and complex inflammatory response ensues, characterised by an influx of numerous inflammatory cells, the transformation and participation of airway structural cells, and the secretion of an array of cytokines, chemokines and growth factors. Examination of the inflammatory cell profile in induced sputum samples demonstrates that, although asthma is predominantly characterised by

### 17.17 Assessment and management of 'acute on chronic' type II respiratory failure

#### Initial assessment

*Patient may not appear distressed, despite being critically ill*

- Conscious level (response to commands, ability to cough)
- $CO_2$  retention (warm periphery, bounding pulses, flapping tremor)
- Airways obstruction (wheeze, prolonged expiration, hyperinflation, intercostal indrawing, pursed lips)
- Cor pulmonale (peripheral oedema, raised jugular venous pressure, hepatomegaly, ascites)
- Background functional status and quality of life
- Signs of precipitating cause (see Box 17.16)

#### Investigations

- Arterial blood gases (severity of hypoxaemia, hypercapnia, acidaemia, bicarbonate)
- Chest X-ray

#### Management

- Maintenance of airway
- Treatment of specific precipitating cause
- Frequent physiotherapy  $\pm$  pharyngeal suction
- Nebulised bronchodilators
- Controlled oxygen therapy:
  - Start with 24% Venturi mask
  - Aim for a  $PaO_2 > 7$  kPa (52 mmHg) (a  $PaO_2 < 5$  (37 mmHg) is dangerous)
- Antibiotics if evidence of infection
- Diuretics if evidence of fluid overload

#### Progress

- If  $PaCO_2$  continues to rise or a safe  $PaO_2$  cannot be achieved without severe hypercapnia and acidaemia, mechanical ventilatory support may be required

airway eosinophilia, neutrophilic inflammation predominates in some patients while in others scant inflammation is observed ('pauci-granulocytic' asthma).

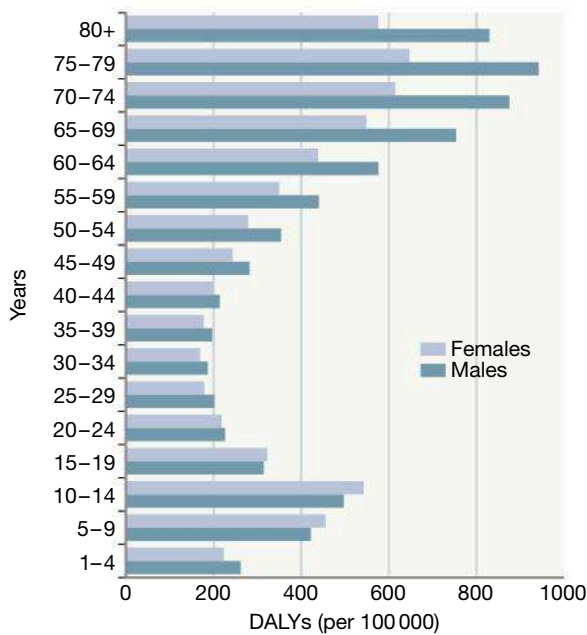

With increasing severity and chronicity of the disease, remodelling of the airway may occur, leading to fibrosis of the airway wall, fixed narrowing of the airway and a reduced response to bronchodilator medication.

**Clinical features**

Typical symptoms include recurrent episodes of wheezing, chest tightness, breathlessness and cough. Asthma is commonly mistaken for a cold or a persistent chest infection (e.g. longer than 10 days). Classical precipitants include exercise, particularly in cold weather, exposure to airborne allergens or pollutants, and viral upper respiratory tract infections. Wheeze apart, there is often very little to find on examination. An inspection for nasal polyps and eczema should be performed. Rarely, a vasculitic rash may suggest eosinophilic granulomatosis with polyangiitis (EGPA, formerly known as Churg–Strauss syndrome).

Patients with mild intermittent asthma are usually asymptomatic between exacerbations. Individuals with persistent asthma report ongoing breathlessness and wheeze but these are variable, with symptoms fluctuating over the course of one day, or from day to day or month to month.

17.18 Indications for lung transplantation	
<b>Parenchymal lung disease</b>	
• Cystic fibrosis	• Langerhans cell histiocytosis
• Emphysema	• Lymphangioleiomyomatosis
• Pulmonary fibrosis	
• Obliterative bronchiolitis	
<b>Pulmonary vascular disease</b>	
• Primary pulmonary hypertension	• Veno-occlusive disease
• Thromboembolic pulmonary hypertension	• Eisenmenger syndrome

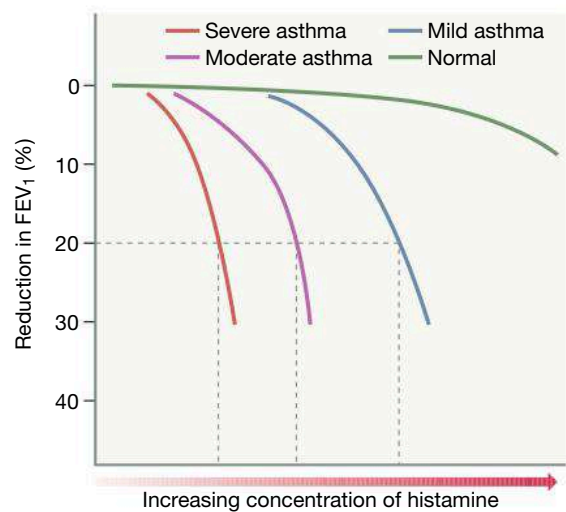

**Fig. 17.16** The burden of asthma, measured by disability life years (DALYs) per 100 000 population. The burden of asthma is greatest in children approaching adolescence and in old age. The burden is similar in males and females at ages below 30–34 but at older ages the burden is higher in males. From *The Global Asthma Report 2014*. Copyright 2014 The Global Asthma Network.

Asthma characteristically displays a diurnal pattern, with symptoms and lung function being worse in the early morning. Particularly when poorly controlled, symptoms such as cough and wheeze disturb sleep. Cough may be the dominant symptom in some patients, and the lack of wheeze or breathlessness may lead to a delay in reaching the diagnosis of so-called 'cough-variant asthma'.

Some patients with asthma have a similar inflammatory response in the upper airway. Careful enquiry should be made as to a history of sinusitis, sinus headache, a blocked or runny nose and loss of sense of smell.

Although the aetiology of asthma is often elusive, an attempt should be made to identify any agents that may contribute to the appearance or aggravation of the condition. Particular enquiry should be made about potential allergens, such as exposure to pets or other animals, pest infestation, exposure to moulds following water damage to a home or building, and any potential occupational agents.

In some circumstances, asthma is triggered by prescription drugs. Beta-adrenoceptor antagonists (β-blockers), even when administered topically as eye drops, may induce bronchospasm, as may aspirin and

**Fig. 17.17** Airway hyper-reactivity in asthma. This is demonstrated by bronchial challenge tests with sequentially increasing concentrations of either histamine, or methacholine or mannitol. The reactivity of the airways is expressed as the concentration or dose of either chemical required to produce a specific decrease (usually 20% or 15%) in the forced expired volume in 1 second (FEV<sub>1</sub>) (PC<sub>20</sub> [histamine and methacholine challenges] or PD<sub>15</sub> [mannitol challenges], respectively). (PC = concentration of drug; PD = dose of drug)

**Fig. 17.18** Changes in peak flow following allergen challenge. A similar biphasic response is observed following a variety of different challenges. Occasionally, an isolated late response is seen with no early reaction.

other non-steroidal anti-inflammatory drugs (NSAIDs). The classical NSAID-induced asthma patient is female and presents in middle age with asthma, rhinosinusitis and nasal polyps. Aspirin-sensitive patients may also report symptoms following alcohol and foods containing salicylates. Other medications implicated include the oral contraceptive pill, cholinergic agents and prostaglandin  $F_{2\alpha}$ . Betel nuts contain arecoline, which is structurally similar to methacholine and can aggravate asthma. An important minority of patients develop a particularly severe form of asthma and this appears to be more common in women. Allergic triggers are less important and airway neutrophilia predominates.

## Diagnosis

The diagnosis of asthma is predominantly clinical and is based on the combination of history, lung function and 'other' tests, which allows high, intermediate or low probability of asthma to emerge. The approach may vary from patient to patient and may need to be re-evaluated following the introduction of treatment.

Supportive evidence is provided by the demonstration of variable air-flow obstruction, preferably by using spirometry (Box 17.19) to measure  $FEV_1$  and FVC. This identifies the obstructive defect, defines its severity, and provides a baseline for bronchodilator reversibility (Fig. 17.19). If spirometry is not available, a peak flow meter may be used. Symptomatic patients should be instructed to record peak flow readings after rising in the morning and before retiring in the evening. A diurnal variation in PEF of more than 20% (the lowest values typically being recorded in the morning) is considered diagnostic and the magnitude of variability provides some indication of disease severity (Fig. 17.20).

It is not uncommon for patients whose symptoms are suggestive of asthma to have normal lung function. In these circumstances, the demonstration of AHR by challenge tests may be useful to confirm the diagnosis (see Fig. 17.17). AHR has a high negative predictive value but positive results may be seen in other conditions such as COPD, bronchiectasis and cystic fibrosis. Exercise tests are useful when symptoms are predominantly related to exercise (Fig. 17.21). Measurement of exhaled nitric oxide (FeNO) is a useful test for glucocorticoid-naïve patients as a measure of eosinophilic airways inflammation. An elevated FeNO value (adults >50ppb; children >35ppb) supports the diagnosis of asthma and suggests that the patient's symptoms are highly likely to respond to glucocorticoids.

The diagnosis may be supported by the presence of peripheral blood eosinophilia or atopy demonstrated by skin-prick tests or measurement of total and allergen-specific IgE. X-ray appearances are often normal, but lobar collapse may be seen if mucus occludes a large bronchus and, if accompanied by the presence of flitting infiltrates, may suggest that asthma has been complicated by allergic bronchopulmonary aspergillosis.

## Management

### Setting goals

Asthma is a chronic condition but may be controlled with appropriate treatment in the majority of patients. The goal of treatment should be to obtain and maintain complete control (Box 17.20) but aims may be modified according to the circumstances and the patient. Unfortunately, surveys consistently demonstrate that the majority of individuals with asthma report suboptimal control, perhaps reflecting the poor expectations of

patients and their clinicians. Pregnancy raises some issues in asthma management, which are shown in Box 17.21.

### Self-management

Patients should be encouraged to take responsibility for managing their own disease. A key aspect of self-management is education, ensuring that the patient understands the relationship between symptoms and inflammation, key symptoms such as nocturnal waking and the indications for medication. The patient must also be able to use the prescribed inhalers and understand the importance of concordance with therapy. Written action plans can be helpful in developing self-management skills and they can be guided by symptoms or PEF.

**Fig. 17.19** Reversibility test. Forced expiratory manoeuvres before and 20 minutes after inhalation of a  $\beta_2$ -adrenoceptor agonist. Note the increase in forced expiratory volume in 1 second ( $FEV_1$ ) from 1.0 to 2.5L.

**Fig. 17.20** Serial recordings of peak expiratory flow (PEF) in a patient with asthma. Note the sharp overnight fall (morning dip) and subsequent rise during the day. Following the introduction of glucocorticoids, there is an improvement in PEF rate and reduction of morning dipping.

### 17.19 How to make a diagnosis of asthma

Compatible clinical history *plus either/or*:

- $FEV_1 \geq 12\%$  (and 200 mL) increase following administration of a bronchodilator/trial of glucocorticoids. Greater confidence is gained if the increase is >15% and >400 mL
- >20% diurnal variation on  $\geq 3$  days in a week for 2 weeks on PEF diary
- $FEV_1 \geq 15\%$  decrease after 6 mins of exercise

( $FEV_1$  = forced expiratory volume in 1 sec; PEF = peak expiratory flow)

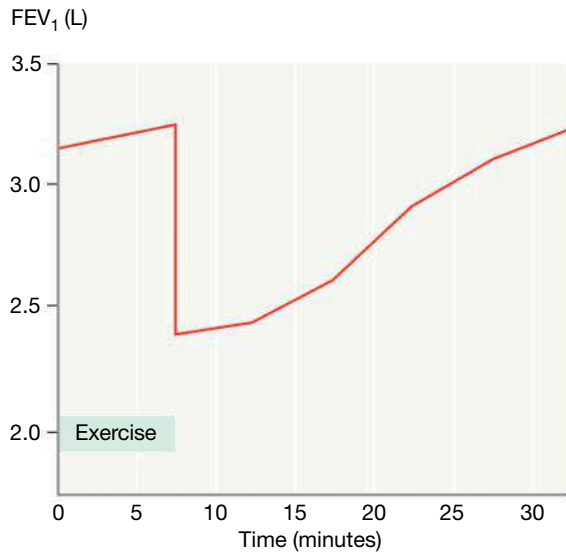

**Avoidance of aggravating factors**

This is particularly important in the management of occupational asthma but may also be relevant in atopic patients, for whom removing or reducing exposure to relevant antigens may effect improvement. House dust mite exposure may be reduced by replacing carpets with floorboards and using mite-impermeable bedding, but these measures have not demonstrated major improvements in asthma control. Many patients are sensitised to several ubiquitous aeroallergens, making avoidance strategies impracticable. Measures to reduce fungal exposure may be applicable in specific circumstances and medications known to precipitate or aggravate asthma should be avoided. Smoking cessation (p.90) is particularly important, as smoking not only encourages sensitisation but also induces a relative glucocorticoid resistance in the airway.

**The stepwise approach to the management of asthma**

Prior to any step up in a patient’s asthma therapy they should be reviewed to ensure that aggravating factors have been addressed, concordance assessed and inhaler technique checked.

Once asthma control is established, the dose of inhaled (or oral) glucocorticoid should be titrated to the lowest dose at which effective

**Fig. 17.21 Exercise-induced asthma.** Serial recordings of forced expiratory volume in 1 second (FEV<sub>1</sub>) in a patient with bronchial asthma before and after 6 minutes of strenuous exercise. Note initial rise on completion of exercise, followed by sudden fall and gradual recovery. Adequate warm-up exercise or pre-treatment with a β<sub>2</sub>-adrenoceptor agonist, nedocromil sodium or a leukotriene antagonist can protect against exercise-induced symptoms.

control is maintained. Decreasing the dose of glucocorticoid by around 25%–50% every 3 months is a reasonable strategy for most patients.

The stepwise approach is summarized in Figure 17.22.

**Step 1: Regular preventer**

The initial therapy for a patient diagnosed with asthma would be a low-dose inhaled glucocorticoid (ICS). For adults, a starting dose equivalent to beclometasone dipropionate (BDP) 400 µg per day is reasonable, although higher doses may be required in smokers.

A variety of different inhaled devices are available and the choice of device should be guided by patient preference and competence in its use. The metered-dose inhaler remains the most widely prescribed (Fig. 17.23).

**Step 2: Initial add-on therapy**

If the asthma remains poorly controlled despite regular preventer therapy, the next step should be addition of a long-acting beta agonist (LABA). This should be done via a combination ICS/LABA inhaler to prevent inadvertent administration of LABA monotherapy and risk of asthma death.

Combination ICS/LABA inhalers containing the fast-acting LABA formoterol can be used as a maintenance and reliever (MART) inhaler allowing for auto-titration of therapy in response to symptoms.

**Step 3: Additional add-on therapies**

If asthma control remains poor despite initial add-on therapy, the patient should have a detailed asthma review. There are a number of options to consider at this stage:

**17.21 Asthma in pregnancy**

- **Clinical course:** women with well-controlled asthma usually have good pregnancy outcomes. Pregnancy in women with more severe asthma can precipitate worsening control and lead to increased maternal and neonatal morbidity.
- **Labour and delivery:** 90% have no symptoms.
- **Safety data:** good for β<sub>2</sub>-agonists, inhaled glucocorticoids, theophyllines, oral prednisolone and chromones.
- **Oral leukotriene receptor antagonists:** no evidence that these harm the fetus and they should not be stopped in women who have previously demonstrated significant improvement in asthma control prior to pregnancy.
- **Glucocorticoids:** women on maintenance prednisolone >7.5 mg/day should receive hydrocortisone 100 mg 3–4 times daily during labour.
- **Prostaglandin F<sub>2α</sub>:** may induce bronchospasm and should be used with extreme caution.
- **Breastfeeding:** use medications as normal.
- **Uncontrolled asthma:** associated with maternal (hyperemesis, hypertension, pre-eclampsia, vaginal haemorrhage, complicated labour) and fetal (intrauterine growth restriction and low birth weight, preterm birth, increased perinatal mortality, neonatal hypoxia) complications.

<b>i 17.20 Levels of asthma control</b>			
Characteristic	Controlled	Partly controlled (any present in any week)	Uncontrolled
Daytime symptoms	None (≤twice/week)	>twice/week	} ≥3 features of partly controlled asthma present in any week
Limitations of activities	None	Any	
Nocturnal symptoms/awakening	None	Any	
Need for rescue/'reliever' treatment	None (≤twice/week)	>twice/week	
Lung function (PEF or FEV <sub>1</sub> )	Normal	<80% predicted or personal best (if known) on any day	
Exacerbation	None	≥1/year	1 in any week

(FEV<sub>1</sub> = forced expiratory volume in 1 sec; PEF = peak expiratory flow)

- If there has been no response to the LABA, then it should be stopped and an increase of the ICS to a medium dose (800µg) considered.
- If there is benefit from the LABA, but control is poor then the ICS should be increased to a medium dose, alternatively trial of a leukotriene antagonist (LTRA) or a slow-release theophylline preparation should be considered.

**Step 4: High-dose therapies**

In adults, the dose of inhaled glucocorticoid should be trialled up to a high dose (2000µg BDP) (or equivalent) daily. Trials of LTRA, long-acting antimuscarinic agents (LAMA), theophyllines or a slow-release oral β<sub>2</sub>-agonist may be considered. If the trial of add-on therapy is ineffective, it should be discontinued.

**Step 5: Continuous or frequent use of oral glucocorticoids**

At this stage, oral prednisolone (usually administered as a single daily dose in the morning) should be prescribed at the lowest dose necessary to control symptoms and the patients should be referred for specialist severe asthma assessment. Patients who are on long-term glucocorticoid tablets (>3 months) or are receiving more than three or four courses per year will be at risk of systemic side-effects (p. 684). The risk of osteoporosis in this group can be reduced by giving bisphosphonates. These patients should be considered for biologic therapy to minimise long-term harm from oral glucocorticoids.

Omalizumab (anti-IgE) therapy may be considered for those patients with severe IgE-driven atopic asthma. Benralizumab (anti-IL5r), mepolizumab (anti-IL5), reslizumab (anti-IL5) or dupilumab (anti-IL4/13) could be considered for patients with eosinophilic forms of asthma.

**Exacerbations of asthma**

The course of asthma may be punctuated by exacerbations with increased symptoms, deterioration in lung function, and an increase in airway inflammation. Exacerbations are most commonly precipitated by viral infections but moulds, pollens (particularly following thunderstorms) and air pollution are also implicated. Most attacks are characterised by

a gradual deterioration over several hours to days but some appear to occur with little or no warning: so-called brittle asthma. An important minority of patients appear to have a blunted perception of airway narrowing and fail to appreciate the early signs of deterioration.

**Management of mild to moderate exacerbations**

Doubling the dose of inhaled glucocorticoids does not prevent an impending exacerbation. Short courses of at least 5 days of ‘rescue’ glucocorticoids (prednisolone 40–50mg/day) are therefore often required to regain control. Tapering of the glucocorticoid dose to withdraw treatment is not necessary, unless it has been given for more than 3 weeks.

Indications for ‘rescue’ courses include:

- symptoms and PEF progressively worsening day by day, with a fall of PEF below 75% of the patient’s personal best recording
- onset or worsening of sleep disturbance by asthma
- persistence of morning symptoms until midday

- Remove the cap and shake the inhaler
- Breathe out gently and place the mouthpiece into the mouth
- Incline the head backwards to minimise oropharyngeal deposition
- Simultaneously, begin a slow deep inspiration, depress the canister and continue to inhale
- Hold the breath for 10 seconds

Fig. 17.23 How to use a metered-dose inhaler.

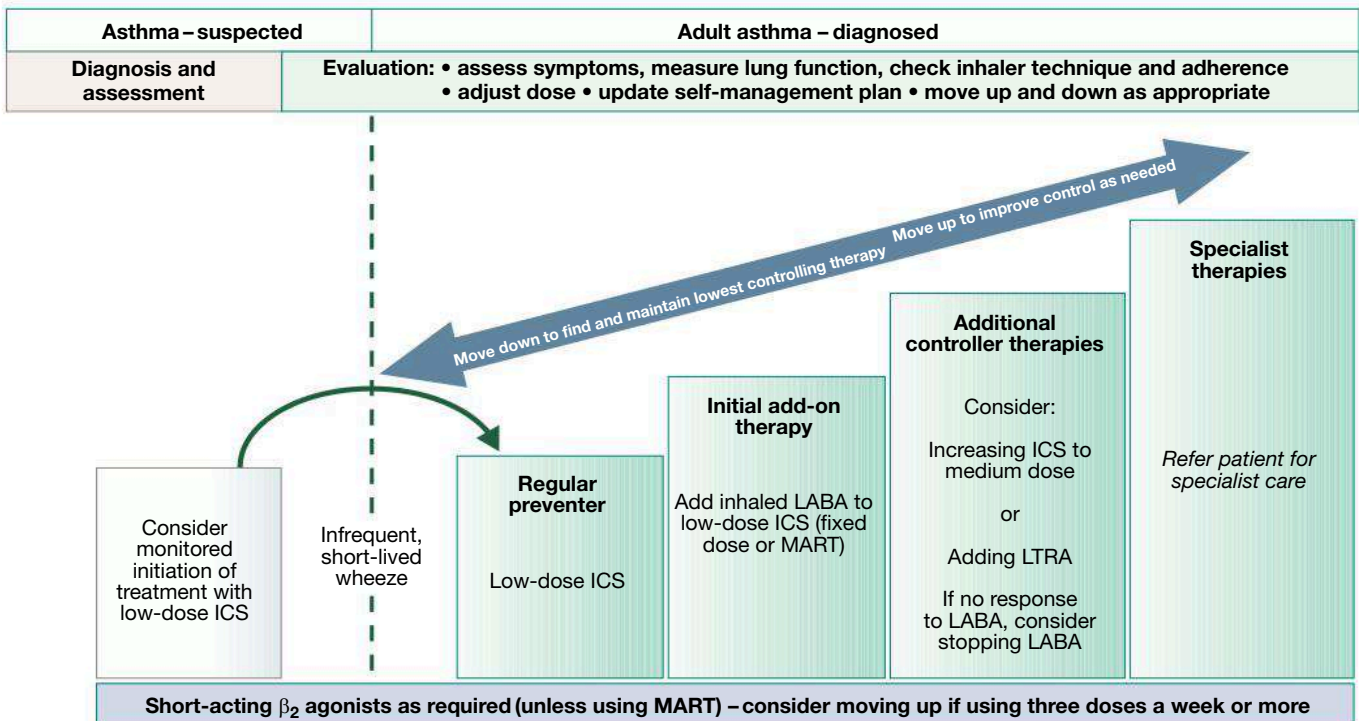

Fig. 17.22 Management approach in adults based on asthma control. - progressively diminishing response to an inhaled bronchodilator
- symptoms that are sufficiently severe to require treatment with nebulised bronchodilators

### Management of acute severe asthma

Box 17.22 highlights the immediate assessment requirements in acute asthma. Measurement of PEF is mandatory, unless the patient is too ill to cooperate, and is most easily interpreted when expressed as a percentage of the predicted normal or of the previous best value obtained on optimal treatment (Fig. 17.24). Arterial blood gas analysis is essential for those patients with life-threatening or near-fatal asthma to determine the

17.22 Immediate assessment of acute severe asthma

<b>Life-threatening features</b>	
<ul style="list-style-type: none"> <li>• PEF &lt;33% predicted (&lt;100 L/min)</li> <li>• <math>SpO_2</math> &lt;92% or <math>PaO_2</math> &lt;8 kPa (60 mmHg) (especially if being treated with oxygen)</li> <li>• Normal or raised <math>PaCO_2</math></li> <li>• Silent chest</li> </ul>	<ul style="list-style-type: none"> <li>• Cyanosis</li> <li>• Feeble respiratory effort</li> <li>• Bradycardia or arrhythmias</li> <li>• Hypotension</li> <li>• Exhaustion</li> <li>• Delirium</li> <li>• Coma</li> </ul>
<b>Near-fatal asthma</b>	
<ul style="list-style-type: none"> <li>• Raised <math>PaCO_2</math> and/or requiring mechanical ventilation with raised inflation pressures</li> </ul>	
(PEF = peak expiratory flow)	

$PaCO_2$ , a normal or elevated level being particularly dangerous. A chest X-ray is not immediately necessary, unless pneumothorax is suspected. Treatment includes the following measures:

- **Oxygen.** Controlled supplemental oxygen should be administered to maintain  $SaO_2$  94%–98%. The presence of a high  $PaCO_2$  should not be taken as an indication to reduce oxygen concentration but as a warning sign of a severe or life-threatening attack. Failure to achieve appropriate oxygenation is an indication for assisted ventilation.
- **High doses of inhaled bronchodilators.** Short-acting  $\beta_2$ -agonists are the agent of choice. They can be administered either via multiple doses of a metered-dose inhaler via a spacer device, or via a nebuliser driven by oxygen. Ipratropium bromide provides further bronchodilator therapy and should be added to if there is a failure to respond to salbutamol or in life-threatening attacks.
- **Systemic glucocorticoids.** These reduce the inflammatory response, reduce mortality, subsequent hospital admission and requirement for bronchodilators. They should be administered to all patients with an acute severe attack. They can usually be administered orally as prednisolone but intravenous hydrocortisone may be used in patients who are vomiting or unable to swallow.

There is no evidence base for the use of intravenous fluids but many patients are dehydrated due to high insensible water loss and may benefit. Potassium supplements may be necessary to counteract hypokalaemia caused by repeated doses of beta-agonists.

If patients fail to improve, a number of further options may be considered, including intravenous magnesium for patients with life-threatening or near-fatal attacks and intravenous aminophylline, although cardiac and therapeutic drug level monitoring is recommended.

PEF should be recorded 15–30 minutes after starting therapy and thereafter according to response every 4–6 hours and pulse oximetry should be monitored to ensure that  $SaO_2$  94%–98% is maintained.

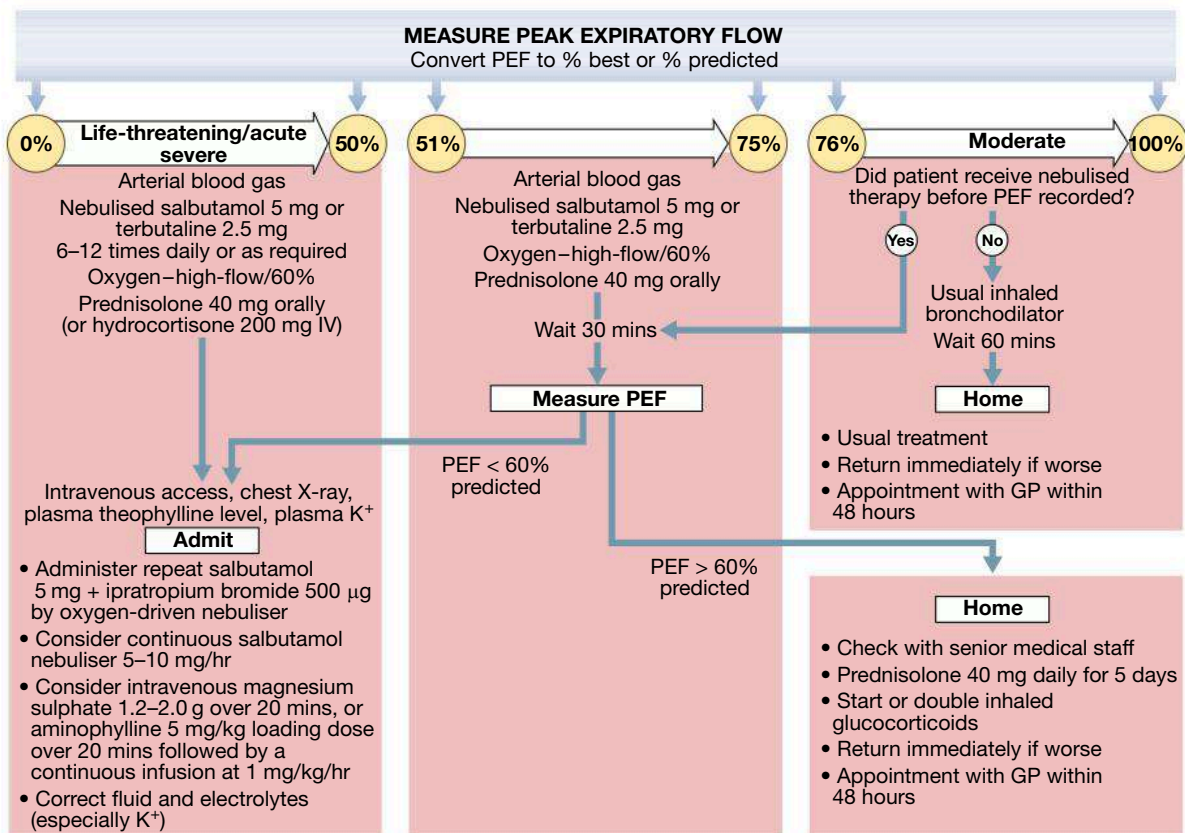

Fig. 17.24 Immediate treatment of patients with acute severe asthma. (GP = general practitioner; IV = intravenous; PEF = peak expiratory flow)

Repeat arterial blood gases are necessary if the initial  $PaCO_2$  measurements were normal or raised, the  $PaO_2$  was below 8 kPa (60 mmHg) or the patient deteriorates. Box 17.23 lists the indications for endotracheal intubation and intermittent positive pressure ventilation (IPPV).

### Prognosis

The outcome from acute severe asthma is generally good but a considerable number of deaths occur in young people and many are preventable. Failure to recognise the severity of an attack, on the part of either the assessing physician or the patient, contributes to delay in delivering appropriate therapy and to under-treatment.

Prior to discharge, patients should be stable on discharge medication (nebulised therapy should have been discontinued for at least 24 hours) and the PEF should have reached 75% of predicted or personal best. The acute attack should prompt a look for and avoidance of any trigger factors, the delivery of asthma education and the provision of a written self-management plan. The patient should be offered an appointment with a general practitioner or asthma nurse within 2 working days of discharge, and follow-up at a specialist hospital clinic within a month.

## Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is defined as a preventable and treatable disease characterised by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities, usually caused by significant exposure to noxious particles or gases. The spectrum of COPD includes chronic bronchitis and emphysema. Chronic bronchitis is defined as cough and sputum for at least 3 consecutive months in each of 2 consecutive years. Emphysema is abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their

walls. Exacerbations and comorbidities contribute to the overall severity in individual patients. Extrapulmonary effects include weight loss and skeletal muscle dysfunction (see Fig. 17.25). Commonly associated comorbid conditions include cardiovascular disease, cerebrovascular disease, the metabolic syndrome, osteoporosis, depression and lung cancer.

COPD prevalence is directly related to the prevalence of risk factors in the community, such as tobacco smoking, coal dust exposure or the use of biomass fuels, and to the age of the population being studied.

Risk factors are shown in Box 17.24. Cigarette smoking represents the most significant risk factor for COPD and the risk of developing the condition relates to both the amount and duration of smoking. It is unusual to develop COPD with less than 10 pack years (1 pack year=20 cigarettes daily per year) and not all smokers develop the condition, suggesting that individual susceptibility factors are important.

### Pathophysiology

COPD has both pulmonary and systemic components (Fig. 17.25). The presence of airflow limitation combined with premature airway closure leads to gas trapping and hyperinflation, adversely affecting pulmonary and chest wall compliance. Pulmonary hyperinflation also results, which flattens the diaphragmatic muscles and leads to an increasingly horizontal alignment of the intercostal muscles, placing the respiratory muscles at a mechanical disadvantage. The work of breathing is therefore markedly increased – first on exercise, when the time for expiration is further shortened, but then, as the disease advances, at rest.

Emphysema (Fig. 17.26) may be classified by the pattern of the enlarged airspaces: centriacinar, panacinar and paraseptal. Some individuals develop bullae; permanent air-filled spaces within the lung that are more than 1 cm in diameter. This results in impaired gas exchange and respiratory failure.

### Clinical features

COPD should be suspected in any patient over 40 years old who presents with symptoms of chronic bronchitis and/or breathlessness. Depending on the presentation, important differential diagnoses include asthma, tuberculosis, bronchiectasis and congestive cardiac failure.

Cough and associated sputum production are usually the first symptoms, and are often referred to as a 'smoker's cough'. Haemoptysis may complicate exacerbations of COPD but should not be attributed to COPD without thorough investigation.

Breathlessness usually prompts presentation to a health professional. The level should be quantified for future reference, often by documenting what the patient can manage before stopping; scales such as the modified Medical Research Council (mMRC) dyspnoea scale may be useful (Box 17.25). In advanced disease, enquiry should be made as to the presence of oedema (which may be seen for the first time during an exacerbation) and morning headaches (which may suggest hypercapnia).

Physical signs are non-specific, correlate poorly with lung function, and are seldom obvious until the disease is advanced. Breath sounds are typically quiet; crackles may accompany infection but, if persistent, raise the possibility of bronchiectasis. Finger clubbing is not a feature of COPD and should trigger further investigation for lung cancer or fibrosis. Right heart failure may develop in patients with advanced COPD, particularly if there is coexisting sleep apnoea or thromboembolic disease. However, even in the absence of right heart failure, COPD patients often have pitting oedema from salt and water retention caused by renal hypoxia and hypercapnia. This is known as 'cor pulmonale', but the term is a misnomer in such patients, as they do not have heart failure. Fatigue, anorexia and weight loss may point to the development of lung cancer or tuberculosis, but are common in patients with severe COPD. Body mass index (BMI) is of prognostic significance. Depression and anxiety are also common.

Two classical phenotypes have been described: 'pink puffers' and 'blue bloaters'. The former are typically thin and breathless, and maintain a normal  $PaCO_2$  until the late stage of disease. The latter develop

#### 17.23 Indications for assisted ventilation in acute severe asthma

- Coma
- Respiratory arrest
- Deterioration of arterial blood gas tensions despite optimal therapy:
  - $PaO_2 < 8$  kPa (60 mmHg) and falling
  - $PaCO_2 > 6$  kPa (45 mmHg) and rising
  - pH low and falling ( $H^+$  high and rising)
- Exhaustion, delirium, drowsiness

#### 17.24 Risk factors for development of chronic obstructive pulmonary disease

##### Environmental factors

- Tobacco smoke: accounts for 95% of cases in the UK
- Indoor air pollution: cooking with biomass fuels in confined areas in low-income countries
- Occupational exposures, such as coal dust, silica and cadmium
- Low birth weight: may reduce maximally attained lung function in young adult life
- Lung growth: childhood infections or maternal smoking may affect growth of lung during childhood, resulting in a lower maximally attained lung function in adult life
- Infections: recurrent infection may accelerate decline in  $FEV_1$ ; persistence of adenovirus in lung tissue may alter local inflammatory response, predisposing to lung damage; HIV infection is associated with emphysema
- Low socioeconomic status
- Cannabis smoking

##### Host factors

- Genetic factors: alpha-1-antitrypsin deficiency; other COPD susceptibility genes are likely to be identified
- Airway hyper-reactivity

( $FEV_1$  = forced expiratory volume in 1 sec)

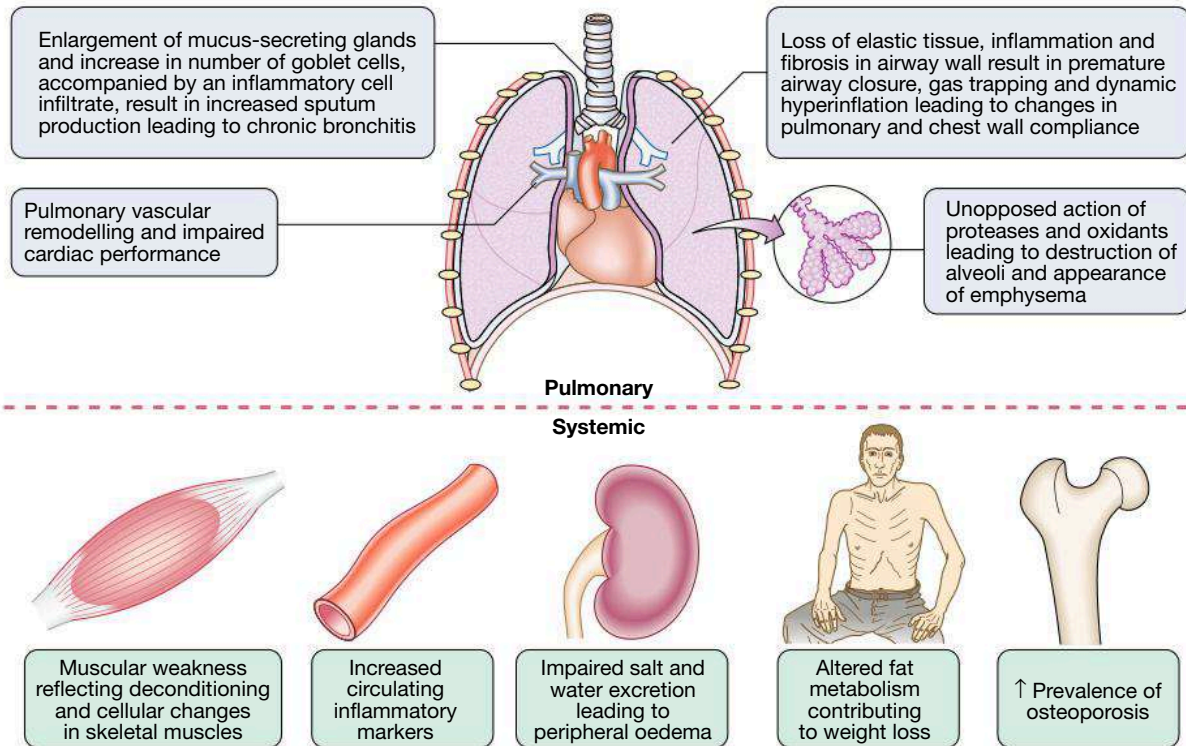

Fig. 17.25 The pulmonary and systemic features of chronic obstructive pulmonary disease.

(or tolerate) hypercapnia earlier and may develop oedema and secondary polycythaemia. In practice, these phenotypes often overlap.

### Investigations

Although there are no reliable radiographic signs that correlate with the severity of airflow limitation, a chest X-ray is essential to identify alternative diagnoses such as cardiac failure, lung cancer and the presence of bullae. A blood count is useful to exclude anaemia or document polycythaemia, and all patients should be tested for alpha-1-antitrypsin deficiency.

The diagnosis requires objective demonstration of airflow obstruction by spirometry and is established when the post-bronchodilator  $FEV_1/FVC$  is  $<70\%$ . The severity of COPD may be defined in relation to the post-bronchodilator  $FEV_1$  (Box 17.26).

Measurement of lung volumes provides an assessment of hyperinflation. This is generally performed by helium dilution technique (p. 488); however, in patients with severe COPD, and in particular large bullae, body plethysmography is preferred because the use of helium may under-estimate lung volumes. The presence of emphysema is suggested by a low gas transfer. Exercise tests provide an objective assessment of exercise tolerance and provide a baseline on which to judge the response to bronchodilator therapy or rehabilitation programmes; they may also be valuable when assessing prognosis. Pulse oximetry may prompt referral for a domiciliary oxygen assessment if less than 93%.

The assessment of health status by the St George's Respiratory Questionnaire (SGRQ) is commonly used for research. In practice, the COPD Assessment Test and the COPD Control Questionnaire are easier to administer. High-resolution computed tomography (HRCT) is likely to play an increasing role in the assessment of COPD, as it allows the detection, characterisation and quantification of emphysema (Fig. 17.27) and is more sensitive than the chest X-ray at detecting bullae. It is also used to guide lung volume reduction surgery.

### Assessment of severity

The severity of COPD has traditionally been defined in relation to the  $FEV_1\%$  predicted. However, assessing the impact of COPD on individual

Fig. 17.26 The pathology of emphysema. **A** Normal lung. **B** Emphysematous lung, showing gross loss of the normal surface area available for gas exchange. (B) Courtesy of the British Lung Foundation.

patients in terms of the symptoms and limitations in activity that they experience and whether they suffer frequent or significant exacerbations may provide a more clinically relevant assessment and help guide management.

### 17.25 Modified Medical Research Council (mMRC) dyspnoea scale

Grade	Degree of breathlessness related to activities
0	No breathlessness, except with strenuous exercise
1	Breathlessness when hurrying on the level or walking up a slight hill
2	Walks slower than contemporaries on level ground because of breathlessness or has to stop for breath when walking at own pace
3	Stops for breath after walking about 100 m or after a few minutes on level ground
4	Too breathless to leave the house, or breathless when dressing or undressing

### 17.26 Spirometric classification of COPD severity based on post-bronchodilator FEV<sub>1</sub>

PD FEV <sub>1</sub> /FVC	FEV <sub>1</sub> % predicted	Severity of airflow obstruction post-bronchodilator		
		ATS/ERS (2004)	GOLD (2020)	NICE Clinical Guideline 101 (2010)
<0.7	≥80%	Mild	Stage I – mild	Stage I – mild <sup>1</sup>
<0.7	50%–79%	Moderate	Stage II – moderate	Stage II – moderate
<0.7	30%–49%	Severe	Stage III – severe	Stage III – severe
<0.7	<30%	Very severe	Stage IV – very severe	Stage IV – very severe <sup>2</sup>

<sup>1</sup>Mild COPD should not be diagnosed on lung function alone if the patient is asymptomatic. <sup>2</sup>Or FEV<sub>1</sub> < 50% with respiratory failure.

(ATS/ERS = American Thoracic Society/European Respiratory Journal; FEV<sub>1</sub> = forced expiratory volume in 1 sec; GOLD = Global Initiative for Chronic Obstructive Lung Disease; PD = post-bronchodilator)

## Management

The management of COPD focuses on improving breathlessness, reducing the frequency and severity of exacerbations, and improving health status and prognosis.

### Reducing exposure to noxious particles and gases

Sustained smoking cessation in mild to moderate COPD is accompanied by a reduced decline in FEV<sub>1</sub> compared to persistent smokers, and cessation remains the only strategy that impacts favourably on the natural history of COPD. Complete cessation is accompanied by an improvement in lung function and deceleration in the rate of FEV<sub>1</sub> decline (Fig. 17.28). In regions where the indoor burning of biomass fuels is important, the introduction of non-smoking cooking devices or alternative fuels should be encouraged.

### Pulmonary rehabilitation

Exercise should be encouraged at all stages and patients should be reassured that breathlessness, while distressing, is not dangerous.

Fig. 17.27 Gross emphysema. High-resolution computed tomogram showing emphysema, most evident in the right lower lobe.

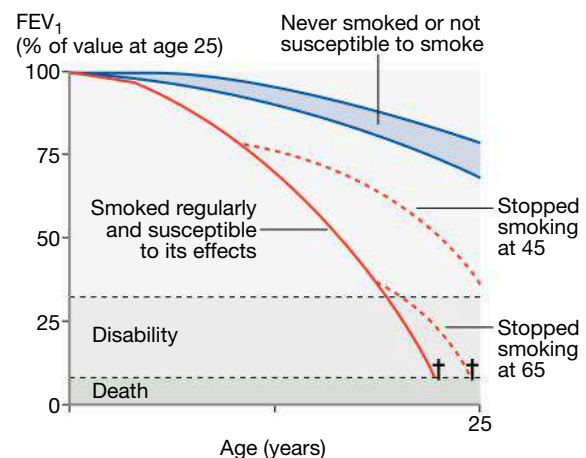

Fig. 17.28 Model of annual decline in FEV<sub>1</sub> with accelerated decline in susceptible smokers. When smoking is stopped, subsequent loss is similar to that in healthy non-smokers. (FEV<sub>1</sub> = forced expiratory volume in 1 second)

Multidisciplinary programmes that incorporate physical training, disease education and nutritional counselling reduce symptoms, improve health status and enhance confidence. Most programmes include two to three sessions per week, last between 6 and 12 weeks, and are accompanied by demonstrable and sustained improvements in exercise tolerance and health status.

### Bronchodilators

Bronchodilator therapy is central to the management of breathlessness. Choice should be informed by patient preference and inhaler assessment. Short-acting bronchodilators are used as relievers and may be used as sole treatment for patients with very mild disease but combination longer-acting bronchodilators are preferred. Long-acting beta-agonists (LABA) and long-acting muscarinic-antagonists (LAMA) are available in single agent or combination inhalers. Nebulised short-acting bronchodilators can be used in those unable to take inhalers. Significant improvements in breathlessness may be reported despite minimal changes in FEV<sub>1</sub>, probably reflecting improvements in lung emptying that reduce dynamic hyperinflation and ease the work of breathing. Oral bronchodilator therapy, such as theophylline, is only recommended when other long-acting bronchodilators are not available. Their use is limited by side-effects, unpredictable metabolism and drug interactions; hence the requirement to monitor plasma levels.

### Combined inhaled glucocorticoids and bronchodilators

Those with frequent exacerbations and/or persistent breathlessness despite long-acting bronchodilators, may benefit from inhaled

glucocorticoids (usually abbreviated to ICS, for 'inhaled corticosteroids'), in the form of either a LABA/LAMA/ICS or LABA/ICS combination inhaler. These combined therapies improve lung function, reduce the frequency and severity of exacerbations and improve quality of life. However, these advantages may be accompanied by an increased risk of pneumonia, particularly in older people. Combination ICS inhalers are likely to reduce the frequency of exacerbations in patients with eosinophilia, and should be used in patients with a history of asthma.

### Oral anti-inflammatories

Oral glucocorticoids are useful during exacerbations but maintenance therapy contributes to osteoporosis and impaired skeletal muscle function, and should be avoided. Oral glucocorticoid trials assist in the diagnosis of asthma but do not predict response to inhaled glucocorticoids in COPD. Roflumilast, a phosphodiesterase-4 inhibitor, improves lung function and reduces moderate to severe exacerbations in patients with severe or very severe COPD. Azithromycin 500 mg three times weekly can reduce the number of exacerbations, but non-tuberculous mycobacterial infections must first be excluded, and LFTs, QTC and hearing should be monitored.

### Other maintenance measures

Patients with COPD should be offered pneumococcal vaccination and annual influenza vaccination. Obesity, poor nutrition, depression and social isolation should be identified and, if possible, addressed. Chest physiotherapy techniques and devices and mucolytic agents ease sputum expectoration and may reduce exacerbations.

### Oxygen therapy and home ventilation

Long-term domiciliary oxygen therapy (LTOT) improves survival in selected patients with COPD complicated by severe hypoxaemia (arterial  $PaO_2 < 7.3$  kPa (55 mmHg); [Box 17.27](#)). It is most conveniently provided by an oxygen concentrator and patients should be instructed to use oxygen for a minimum of 15 hours a day; greater benefits are seen in those who use it for more than 20 hours a day. The aim of therapy is to increase the  $PaO_2$  to at least 8 kPa (60 mmHg) or  $SaO_2$  to at least 90%. Ambulatory oxygen therapy should be considered in patients who desaturate on exercise and show objective improvement in exercise capacity and/or dyspnoea with oxygen. Oxygen flow rates should be adjusted to maintain  $SaO_2$  above 90%. Home non-invasive ventilation improves quality of life and prolongs time to readmission in patients with persistent hypercapnia.

### Surgical intervention

Bullectomy may be considered when large bullae compress surrounding normal lung tissue. Patients with predominantly upper lobe emphysema, preserved gas transfer and no evidence of pulmonary hypertension may benefit from lung volume reduction surgery (LVRS). LVRS involves resection of peripheral emphysematous lung tissue with the aim of reducing hyperinflation and decreasing the work of breathing. Both bullectomy and LVRS can be performed thoroscopically, minimising morbidity. Bronchoscopic LVRS involves the use of one-way valves, lung coils or thermal ablation to collapse down areas of ineffective emphysematous lung. This enables the neighbouring areas of healthier lung to expand

### 17.27 Prescription of long-term oxygen therapy in COPD

Arterial blood gases are measured in clinically stable patients on optimal medical therapy on at least two occasions 3 weeks apart:

- $PaO_2 < 7.3$  kPa (55 mmHg) irrespective of  $PaCO_2$
- $PaO_2 7.3$ – $8$  kPa (55–60 mmHg) plus pulmonary hypertension, peripheral oedema or polycythaemia (haematocrit  $> 55\%$ )
- the patient has stopped smoking

Use at least 15 hrs/day at the necessary flow rate to achieve a  $PaO_2 > 8$  kPa (60 mmHg) without unacceptable rise in  $PaCO_2$

and work more efficiently. Lung transplantation may benefit carefully selected patients with advanced disease.

### Palliative care

Addressing end-of-life needs is an important aspect of care in advanced COPD. Hand-held electric fans and morphine preparations may be used for palliation of breathlessness and low-dose benzodiazepines may reduce anxiety. Decisions regarding resuscitation and escalation of care should be addressed in advance of critical illness.

### Prognosis

COPD has a variable natural history but is usually progressive. The prognosis is inversely related to age and directly related to the post-bronchodilator  $FEV_1$ . Additional poor prognostic indicators include weight loss and pulmonary hypertension. A composite score comprising the body mass index (B), the degree of airflow obstruction (O), a measurement of dyspnoea (D) and exercise capacity (E) (BODE index) may assist in predicting death from respiratory and other causes ([Box 17.28](#)). Respiratory failure, pneumonia, cardiac disease and lung cancer represent common modes of death.

Specific challenges with the diagnosis and management of obstructive pulmonary disease in older people are shown in [Box 17.29](#).

### Acute exacerbations of COPD

Acute exacerbations of COPD (AECOPD) are characterised by an increase in symptoms and deterioration in lung function and health status. They become more frequent as the disease progresses and are usually triggered by infection or a change in air quality. They may be

### 17.28 Calculation of the BODE index

Variable	Points on BODE index			
	0	1	2	3
$FEV_1$	$\geq 65$	50–64	36–49	$\leq 35$
Distance walked in 6 mins (m)	$\geq 350$	250–349	150–249	$\leq 149$
mMRC dyspnoea scale*	0–1	2	3	4
Body mass index	$> 21$	$\leq 21$		

A patient with a BODE index of 0–2 has a mortality rate of 20% at 4 years, whereas a patient with a BODE index of 7–10 has a mortality rate of 82% at 4 years.

\*See [Box 17.25](#).  
(BODE – see text;  $FEV_1$  = forced expiratory volume in 1 sec)

### 17.29 Obstructive pulmonary disease in old age

- **Asthma:** may appear de novo in old age, so airflow obstruction should not always be assumed to be due to COPD.
- **Peak expiratory flow recordings:** older people with poor vision have difficulty reading PEF meters.
- **Perception of bronchoconstriction:** impaired by age, so an older patient's description of symptoms may not be a reliable indicator of severity.
- **Stopping smoking:** the benefits on the rate of loss of lung function decline with age but remain valuable up to the age of 80.
- **Metered-dose inhalers:** many older people cannot use these because of difficulty coordinating and triggering the device. Aids are available, and frequent demonstration and re-instruction in the use of all devices are required.
- **Mortality rates for acute asthma:** higher in old age, partly because patients under-estimate the severity of bronchoconstriction and also develop a lower degree of tachycardia and pulsus paradoxus for the same degree of bronchoconstriction.
- **Treatment decisions:** advanced age in itself is not a barrier to intensive care or mechanical ventilation in an acute episode of asthma or COPD, but this decision may be difficult and should be shared with the patient (if possible), the relatives and the wider medical team.

accompanied by the development of respiratory failure and/or fluid retention and represent an important cause of death.

Many patients can be managed at home with the use of increased bronchodilator therapy, a short course of oral glucocorticoids and, if appropriate, antibiotics. The presence of cyanosis, peripheral oedema or an alteration in consciousness should prompt referral to hospital. In other patients, consideration of comorbidity and social circumstances may influence decisions regarding hospital admission.

### Oxygen therapy

In patients with an exacerbation of severe COPD, high concentrations of oxygen may cause respiratory depression and worsening acidosis. Controlled oxygen at 24% or 28% should be used with the aim of maintaining  $\text{SaO}_2$  of 88%–92% or  $\text{PaO}_2$  of more than 8 kPa (60 mmHg) without worsening acidosis.

### Bronchodilators

Nebulised short-acting  $\beta_2$ -agonists combined with an anticholinergic agent (e.g. salbutamol and ipratropium) are routinely administered. However, the latter is only appropriate if the patient is unable to take their LAMA inhaler. Nebulisers can be driven with oxygen, but due to concern regarding oxygen sensitivity, they are more safely driven by compressed air with supplemental oxygen delivered by nasal cannula.

### Glucocorticoids

Oral prednisolone reduces symptoms and improves lung function. Doses of 30 mg for 5 days are currently recommended but weaning courses are required if the patient has had a recent course of steroids. Prophylaxis against osteoporosis should be considered in patients who receive repeated courses of glucocorticoids.

### Antibiotic therapy

The role of bacteria in exacerbations remains controversial. There is little evidence for the routine administration of antibiotics, but they are recommended for patients reporting an increase in sputum purulence, sputum volume or breathlessness. In most cases simple regimens are advised, such as an aminopenicillin, a tetracycline or a macrolide. However, local practice will depend on local guidance and epidemiology.

### Non-invasive ventilation

Non-invasive ventilation (NIV) reduces mortality and invasive ventilation rates in patients with an acute exacerbation of COPD complicated by mild to moderate respiratory acidosis ( $\text{pH} < 7.35$  and  $\text{PaCO}_2 > 6.5$  kPa). It should be considered when respiratory acidosis is not corrected within an hour of identification, despite optimal medical therapy, including controlled oxygen therapy with a target saturation of 88%–92%. Invasive ventilation should be considered in patients with deteriorating acidosis despite optimal NIV settings, those unable to tolerate or wear the interface (e.g. due to facial injury) and those who cannot protect their airway.

### Additional therapy

Exacerbations may be accompanied by the development of peripheral oedema; this usually responds to diuretics. Hospital admission provides a good opportunity to address smoking cessation, mobility and sputum clearance, inhaler technique and concordance, nutrition and swallowing concerns.

### Discharge

Discharge from hospital may be contemplated once patients are clinically stable on their usual maintenance medication. Hospital-at-home teams may provide short-term nebuliser loan, improving discharge rates and providing additional support for the patient.

## Bronchiectasis

Bronchiectasis means abnormal dilatation of the bronchi. Chronic suppurative airway infection with sputum production, progressive scarring and lung damage occur, whatever the cause.

## Aetiology and pathology

Bronchiectasis may result from a congenital defect affecting airway ion transport or ciliary function, such as cystic fibrosis (see below), or may be acquired secondary to damage to the airways by a destructive infection, inhaled toxin or foreign body. The result is chronic inflammation and infection in the airways. Box 17.30 shows the common causes, of which tuberculosis is the most common worldwide.

Localised bronchiectasis may occur due to the accumulation of pus beyond an obstructing bronchial lesion, such as enlarged tuberculous hilar lymph nodes, a bronchial tumour or an inhaled foreign body.

The bronchiectatic cavities may be lined by granulation tissue, squamous epithelium or normal ciliated epithelium. There may also be inflammatory changes in the deeper layers of the bronchial wall and hypertrophy of the bronchial arteries. Chronic inflammatory and fibrotic changes are usually found in the surrounding lung tissue, causing progressive destruction of the normal lung architecture in advanced cases.

## Clinical features

The symptoms are shown in Box 17.31.

Physical signs in the chest may be unilateral or bilateral. If the bronchiectatic airways do not contain secretions and there is no associated lobar collapse, there are no abnormal physical signs. When there are large amounts of sputum in the bronchiectatic spaces, numerous coarse crackles may be heard over the affected areas. Collapse with retained secretions blocking a proximal bronchus may lead to locally diminished breath sounds, while advanced disease may cause scarring and overlying bronchial breathing. Acute haemoptysis is an important complication of bronchiectasis; management is described on page 492.

### 17.30 Causes of bronchiectasis

#### Congenital

- Cystic fibrosis
- Ciliary dysfunction syndromes:
  - Primary ciliary dyskinesia (immotile cilia syndrome)
  - Kartagener syndrome (sinusitis and transposition of the viscera)
- Primary hypogammaglobulinaemia

#### Acquired: children

- Severe infections in infancy (especially whooping cough, measles)
- Primary tuberculosis
- Inhaled foreign body

#### Acquired: adults

- Suppurative pneumonia
- Pulmonary tuberculosis
- Allergic bronchopulmonary aspergillosis complicating asthma
- Bronchial tumours

### 17.31 Symptoms of bronchiectasis

- **Cough:** chronic, daily, persistent
- **Sputum:** copious, continuously purulent
- **Pleuritic pain:** when infection spreads to involve pleura, or with segmental collapse due to retained secretions
- **Haemoptysis:**
  - Streaks of blood common, larger volumes with exacerbations of infection
  - Massive haemoptysis requiring bronchial artery embolisation sometimes occurs
- **Infective exacerbation:** increased sputum volume with fever, malaise, anorexia
- **Halitosis:** frequently accompanies purulent sputum
- **General debility:** difficulty maintaining weight, anorexia, exertional breathlessness

## Investigations

In addition to common respiratory pathogens, sputum culture may reveal *Pseudomonas aeruginosa* and *Staphylococcus aureus*, fungi such as *Aspergillus* and non-tuberculous mycobacteria.

Mild bronchiectasis may not be apparent on a plain chest X-ray. In advanced disease, thickened airway walls, cystic bronchiectatic spaces and associated areas of pneumonic consolidation or collapse may be visible. CT is much more sensitive and shows thickened, dilated airways (Fig. 17.29).

If the patient is suspected of having a ciliary dysfunction syndrome a nasal FeNO sample should be taken as a screening test, then consideration of nasal brush biopsy and genetic testing. The nasal biopsies should be assessed for ciliary beat frequency and structural ciliary abnormalities assessed by electron microscopy.

## Management

### Physiotherapy

Patients should be shown how to perform regular daily physiotherapy to assist the drainage of excess bronchial secretions. This reduces the amount of cough and sputum and prevents recurrent episodes of bronchopulmonary infection. Patients should lie in a position in which the lobe to be drained is uppermost. Deep breathing, followed by forced expiratory manoeuvres (the 'active cycle of breathing' technique), helps to move secretions in the dilated bronchi towards the trachea, from which they can be cleared by vigorous coughing. Devices that increase airway pressure either by a constant amount (positive expiratory pressure mask) or in an oscillatory manner (flutter valve) aid sputum clearance in some patients and a variety of techniques should be tried to find the one that suits the individual. The optimum duration and frequency of physiotherapy depend on the amount of sputum but 5–10 minutes twice daily is a minimum for most patients.

### Antibiotic therapy

For most patients with bronchiectasis, the appropriate antibiotics are the same as those used in COPD but larger doses and longer courses are required. When secondary infection occurs with staphylococci and Gram-negative bacilli, in particular *Pseudomonas* species, antibiotic therapy becomes more challenging and should be guided by microbiological sensitivities. For *Pseudomonas*, oral ciprofloxacin (500–750 mg twice daily) or an intravenous anti-pseudomonal  $\beta$ -lactam (e.g. piperacillin–tazobactam or ceftazidime) will be required. Haemoptysis in bronchiectasis often responds to treatment of the underlying infection, although percutaneous embolisation of the bronchial circulation by an

**Fig. 17.29** Computed tomogram of bronchiectasis. Extensive dilatation of the bronchi, with thickened walls (arrows) in both lower lobes.

interventional radiologist may be necessary in the event of massive or repeated haemoptysis.

### Surgical treatment

Excision of bronchiectatic areas is indicated in only a small proportion of cases. These are usually patients in whom the bronchiectasis is confined to a single lobe or segment on CT. Unfortunately, many of those in whom medical treatment proves unsuccessful are also unsuitable for surgery because of either extensive bilateral bronchiectasis or coexisting severe airflow obstruction. In progressive forms of bronchiectasis, resection of destroyed areas of lung that are acting as a reservoir of infection should be considered only as a last resort.

### Prognosis

The disease is progressive when associated with ciliary dysfunction or cystic fibrosis, and eventually causes respiratory failure. In other patients, the prognosis can be relatively good if physiotherapy is performed regularly and antibiotics are used aggressively.

### Prevention

As bronchiectasis commonly starts in childhood following measles, whooping cough or a primary tuberculous infection, adequate prevention and treatment of these conditions is essential. Early recognition and treatment of bronchial obstruction is also important.

## Cystic fibrosis

### Genetics, pathogenesis and epidemiology

Cystic fibrosis (CF) is the most common life-limiting genetic disease in people of predominantly European descent, with autosomal recessive inheritance, a carrier rate of 1 in 25, and an incidence of about 1 in 2500 live births in this population, although worldwide the incidence of CF varies widely. CF is the result of pathogenic variants affecting a gene on the long arm of chromosome 7, which codes for a chloride channel known as cystic fibrosis transmembrane conductance regulator (*CFTR*); this influences salt and water movement across epithelial cell membranes. The most common pathogenic *CFTR* variant in northern European and American populations is  $\Delta F508$ , but over 2000 pathogenic variants of this gene have now been identified. The genetic defect causes increased sodium and chloride content in sweat and increased resorption of sodium and water from respiratory epithelium (Fig. 17.30). Relative dehydration of the airway epithelium is thought to predispose to chronic bacterial infection, ciliary dysfunction and bronchiectasis. The gene defect also causes disorders in the gut epithelium, pancreas, liver and reproductive tract (see below).

In the 1960s, few patients with CF survived infancy. In modern practice, however, life expectancy has been increased by aggressive treatment of airway infection and nutritional support and in many high income countries there are now more adults than children with CF. Until recently, the diagnosis was most commonly made from the clinical picture (bowel obstruction, failure to thrive, steatorrhoea and/or chest symptoms in a young child), supported by sweat electrolyte testing and genotyping. Patients with unusual phenotypes were commonly missed, however, and late diagnosis led to poorer outcomes. Neonatal screening for CF using immunoreactive trypsin and genetic testing of newborn blood samples is now routine in the UK and should reduce delayed diagnosis and improve outcomes. Pre-implantation and/or prenatal testing may be offered to those known to be at high risk.

### Clinical features

The lungs are macroscopically normal at birth, but bronchiolar inflammation and infections usually lead to bronchiectasis in childhood. At this stage, the lungs are most commonly infected with *Staph. aureus*, while in adulthood, many patients become colonised with antibiotic resistant Gram-negative bacilli. Recurrent exacerbations of bronchiectasis, initially in the upper lobes but subsequently throughout both lungs, cause progressive lung damage, resulting ultimately in death from respiratory failure.

**Fig. 17.30 Cystic fibrosis: basic defect in the pulmonary epithelium.** **A** The cystic fibrosis gene (*CFTR*) codes for a chloride channel (1) in the apical (luminal) membrane of epithelial cells in the conducting airways. This is normally controlled by cyclic adenosine monophosphate (cAMP) and indirectly by β<sub>2</sub>-adrenoceptor stimulation, and is one of several apical ion channels that control the quantity and solute content of airway-lining fluid. Normal channels appear to inhibit the adjacent epithelial sodium channels (2). **B** In cystic fibrosis, one of many cystic fibrosis gene defects causes absence or defective function of this chloride channel (3). This leads to reduced chloride secretion and loss of inhibition of sodium channels, with excessive sodium resorption (4) and dehydration of the airway lining. The resulting abnormal airway-lining fluid predisposes to infection by mechanisms still to be fully explained.

Other clinical manifestations are shown in [Box 17.32](#). Most men with CF are infertile due to failure of development of the vas deferens, but microsurgical sperm aspiration and in vitro fertilisation are possible. Genotype is a poor predictor of disease severity in individuals; even siblings with matching genotypes may have different phenotypes. This suggests that other 'modifier genes', as yet unidentified, influence clinical outcome.

## Management

### Treatment of CF lung disease

The management of CF lung disease is that of severe bronchiectasis. All patients with CF who produce sputum should perform chest physiotherapy daily, and more frequently during exacerbations. While infections with *Staph. aureus* can often be managed with oral antibiotics, intravenous treatment (frequently self-administered at home through an implanted subcutaneous vascular access device) is usually needed for *Pseudomonas* infections.

Over time patients with CF become chronically infected with antibiotic-resistant organisms. These include *P. aeruginosa*, *Stenotrophomonas maltophilia* and *Burkholderia cepacia* complex, which may require prolonged treatment with combinations of intravenous antibiotics. The impact of non-tuberculous mycobacteria is less clear, with the exception of *Mycobacterium abscessus*. This organism, which is often pan-resistant, may be transmitted between patients with CF causing progressive lung destruction and potentially precluding lung transplantation. Fungi such as *Aspergillus fumigatus* may cause infection or allergic bronchopulmonary aspergillosis.

There has been a rapid advance in the maintenance therapies for patients with CF, including mucolytic therapies, long-term inhaled antibiotics, anti-inflammatory agents and more recently CFTR modulator therapies ([Box 17.33](#)) (see below).

For advanced CF lung disease, home oxygen and NIV may be necessary to treat respiratory failure. Ultimately, lung transplantation can produce dramatic improvements but is limited by donor organ availability and the long-term issues associated with CLAD.

The transition from paediatric to adult CF care raises specific management issues in adolescence, which are summarized in [Box 17.34](#).

### Treatment of non-respiratory manifestations of CF

There is a clear link between good nutrition and prognosis in CF. Malabsorption occurs in 85% of patients due to exocrine pancreatic failure and is treated with oral pancreatic enzymes and vitamin supplements.

## 17.32 Clinical features and complications of cystic fibrosis

### Respiratory

- Progressive airway obstruction
- Infective exacerbations of bronchiectasis
- Respiratory failure
- Spontaneous pneumothorax
- Allergic bronchopulmonary aspergillosis
- Haemoptysis
- Lobar collapse due to secretions
- Pulmonary hypertension
- Nasal polyps

### Gastrointestinal and hepatic

- Malabsorption and steatorrhoea
- Distal intestinal obstruction syndrome
- Increased risk of gastrointestinal malignancy
- Cystic fibrosis-associated liver disease (CFLD), including biliary cirrhosis, portal hypertension, varices and splenomegaly
- Gallstones

### Others

- Diabetes (25% of adults)
- Delayed puberty
- Male infertility
- Stress incontinence due to repeated forced cough
- Psychosocial problems
- Osteoporosis
- Arthropathy
- Cutaneous vasculitis

The increased calorie requirements of patients with CF are met by supplemental feeding, including nasogastric or gastrostomy tube feeding if required. Diabetes eventually develops in over 25% of patients and needs insulin therapy. Osteoporosis secondary to malabsorption and chronic ill health should be sought and treated.

### CFTR modulator therapies

CFTR modulators are small molecules designed to target specific *CFTR* variants. 'Correctors' act by correcting CFTR misfolding, thereby improving trafficking to the cell surface; and 'potentiators' act by improving the function of CFTR that is already at the cell surface.

Ivacaftor, a CFTR potentiator, is an oral treatment for the 5% of patients with the G551D variant and a number of other gating variants. It causes sustained improvements in FEV<sub>1</sub> and weight, and normalization of the sweat chloride levels. Newer combinations of CFTR correctors and potentiators (lumacaftor/ivacaftor and elexacaftor/tezacaftor/ivacaftor) are now treating patients with the more common ΔF 508 variant and represent a

17.33 Treatments that reduce chest exacerbations and/or improve lung function in cystic fibrosis	
Therapy	Drugs
Mucolytic therapies	Nebulised recombinant human DNase 2.5 mg daily Nebulised hypertonic saline (7%) 4 mL twice daily Inhaled mannitol 400 mg twice daily
Inhaled antibiotics	Nebulised tobramycin 300 mg twice daily, alternate months Inhaled powder tobramycin 28 mg twice daily, given alternate months Nebulised colistin 1 MU twice daily Nebulised colistin 2 MU twice daily Inhaled colistin 1.6 MU twice daily Nebulised aztreonam 75 mg three times daily alternate months Nebulised levofloxacin 240 mg twice daily, alternate months
Anti-inflammatory therapy	Azithromycin 250 mg/500 mg once a day three times weekly
CFTR modulator therapy	Ivacaftor Ivacaftor/lumacaftor Ivacaftor/tezacaftor Ivacaftor/tezacaftor/elexacaftor

(CFTR = cystic fibrosis transmembrane conductance regulator; FEV<sub>1</sub> = forced expiratory volume in 1 sec; FVC = forced vital capacity)

17.34 Cystic fibrosis (CF) in adolescence	
<b>Issues for the patient</b>	
<ul style="list-style-type: none"> <li>• Move to adult CF centre – loss of trusted paediatric team</li> <li>• Feelings of being different from peers due to chronic illness</li> <li>• Demanding treatments that conflict with social and school life</li> <li>• Pressure to take responsibility for self-care</li> <li>• Relationship/fertility concerns</li> </ul>	
<b>Issues for the patient's parents</b>	
<ul style="list-style-type: none"> <li>• Loss of control over patient's treatment – feeling excluded</li> <li>• Loss of trusted paediatric team</li> <li>• Need to develop trust in adult team</li> <li>• Feelings of helplessness when adolescent rebels or will not take treatment</li> </ul>	
<b>Issues for the CF team</b>

step forward in therapy. Other strategies under development for the treatment of CF including delivery of somatic gene therapy via liposome or viral vectors, and the use of gene-editing technology such as CRISPR.

## Infections of the respiratory system

Infections of the upper and lower respiratory tract are a major cause of morbidity and mortality, particularly in patients at the extremes of age and those with pre-existing lung disease or immune suppression. Features that are specific to older people are shown in [Box 17.35](#).

### Upper respiratory tract infection

Upper respiratory tract infections (URTIs), such as coryza (the common cold), acute pharyngitis and acute tracheobronchitis, are the most

### 17.35 Respiratory infection in old age

- **Increased risk of and from respiratory infection:** because of reduced immune responses, increased closing volumes, reduced respiratory muscle strength and endurance, altered mucus layer, poor nutritional status and the increased prevalence of chronic lung disease.
- **Predisposing factors:** other medical conditions may predispose to infection, e.g. swallowing difficulties due to stroke increase the risk of aspiration pneumonia.
- **Atypical presentation:** older patients often present with delirium, rather than breathlessness or cough.
- **Mortality:** the vast majority of deaths from pneumonia in high-income countries occur in older people.
- **Influenza:** has a much higher morbidity and mortality rate. Vaccination significantly reduces morbidity and mortality in old age but uptake is poor.
- **COVID-19:** increasing age is recognized as a highly significant risk factor for morbidity and mortality.
- **Tuberculosis:** most cases in old age represent reactivation of previous, often unrecognized, disease and may be precipitated by glucocorticoid therapy, diabetes mellitus and the factors above. Cryptic miliary tuberculosis is an occasional alternative presentation. Older people more commonly suffer adverse effects from antituberculous chemotherapy and require close monitoring.

common of all communicable diseases and represent the most frequent cause of short-term absenteeism from work and school. The vast majority of such infections are caused by viruses and, in adults, are usually short-lived and rarely serious.

Acute coryza is the most common URTI and is usually caused by rhinovirus infection. The usual symptoms are general malaise, nasal discharge, sneezing and cough. Involvement of the pharynx causes a sore throat, and that of the larynx a hoarse or 'lost' voice. If complicated by tracheitis or bronchitis, chest tightness and wheeze typical of asthma occur. Specific investigation is rarely warranted and treatment is symptomatic. Symptoms usually resolve quickly, but if repeated URTIs 'go to the chest', a more formal diagnosis of asthma ought to be considered. A variety of viruses causing URTI may also trigger exacerbations of asthma or COPD and aggravate other lung diseases.

*Bordetella pertussis*, the cause of whooping cough (pertussis), is an important cause of URTI. Vaccination confers protection and is usually offered in infancy, but its efficacy wanes in adult life and the infection is easily spread. Adults usually experience a mild illness similar to acute coryza but some individuals develop paroxysms of coughing that can persist for weeks to months, earning whooping cough the designation of 'the cough of 100 days'. The diagnosis may be confirmed by bacterial culture, polymerase chain reaction (PCR) from a nasopharyngeal swab or serological testing. If the illness is recognised early in the clinical course, macrolide antibiotics may ameliorate the course. Pertussis is a reportable disease in the UK.

Rhinosinusitis typically manifests as a combination of nasal congestion, blockage or discharge and may be accompanied by facial pain/pressure or loss of smell. Examination usually confirms erythematous swollen nasal mucosa and pus may be evident. Nasal polyps should be sought and dental infection excluded. Treatment with topical glucocorticoids, nasal decongestants and regular nasal douching is usually sufficient and, although bacterial infection is often present, antibiotics are indicated only if symptoms persist for more than 5 days. Persistent symptoms or recurrent episodes should prompt a referral to an ear, nose and throat specialist.

Viral respiratory tract infections with the potential to cause more severe disease (including COVID-19) are discussed in Chapter 13.

### Pneumonia

Pneumonia is as an acute respiratory illness associated with recently developed radiological pulmonary shadowing that may be segmental, lobar or multilobar. The context in which pneumonia develops is highly suggestive of the likely organism(s) involved; therefore, pneumonias are

usually classified as community- or hospital-acquired, or those occurring in immunocompromised hosts. 'Lobar pneumonia' is a radiological and pathological term referring to homogeneous consolidation of one or more lung lobes, often with associated pleural inflammation; bronchopneumonia refers to more patchy alveolar consolidation associated with bronchial and bronchiolar inflammation, often affecting both lower lobes.

### Community-acquired pneumonia

Figures from the UK suggest that an estimated 5–11/1000 adults suffer from community-acquired pneumonia (CAP) each year, accounting for around 5%–12% of all lower respiratory tract infections. CAP may affect all age groups but is commonest at the extremities of age.

Most cases are spread by droplet infection, and while CAP may occur in previously healthy individuals, several factors may impair the effectiveness of local defences and predispose to CAP (Box 17.36). *Streptococcus pneumoniae* (Fig. 17.31) remains the most common infecting agent, and thereafter the likelihood that other organisms may be involved depends on the age of the patient and the clinical context. Viral infections are recognised as important causes of CAP in children and their contribution to adult CAP is increasingly recognized. The common causative organisms are shown in Box 17.37.

#### Clinical features

Pneumonia, particularly lobar pneumonia, usually presents as an acute illness. Systemic features, such as fever, rigors, shivering and malaise, predominate and delirium may be present. The appetite is invariably lost and headache frequently reported.

Pulmonary symptoms include cough, which at first is characteristically short, painful and dry, but later is accompanied by the expectoration of mucopurulent sputum. Rust-coloured sputum may be produced by patients with *Strep. pneumoniae* infection and the occasional patient may report haemoptysis. Pleuritic chest pain may be a presenting feature and on occasion may be referred to the shoulder or anterior abdominal wall. Upper abdominal tenderness is sometimes apparent in patients with lower lobe pneumonia or those with associated hepatitis. Less typical presentations may be seen in childhood and old age.

While different organisms often give rise to a similar clinical and radiological picture, it may be possible to infer the likely agent from the clinical context. *Mycoplasma pneumoniae* is more common in young

people and rare in old age, whereas *Haemophilus influenzae* is more common in older people, particularly those with underlying lung disease. *Legionella pneumophila* occurs in local outbreaks centred on contaminated cooling towers in hotels, hospitals and other industries. *Staphylococcus aureus* is more common following an episode of influenza. *Klebsiella pneumoniae* has a specific association with alcohol abuse and often presents with a particularly severe bacteraemic illness and cavitation on the chest X-ray. Recent foreign travel raises the possibility of infections that may otherwise be unusual in the UK, e.g. Middle East respiratory syndrome (MERS), melioidosis (South-east Asia and northern Australia) and endemic fungal infection (North, Central or South America). Certain occupations may be associated with exposure to specific bacteria (p. 546).

Clinical examination should first focus on the respiratory and pulse rates, blood pressure and an assessment of the mental state, as these are important in assessing the severity of the illness. In the UK, severity is assessed using the CURB-65 score, which takes into account both examination and investigation findings (Fig. 17.32). Chest signs vary, depending on the inflammatory response, which proceeds through stages of acute exudation, red and then grey hepatisation, and finally resolution. When consolidated, the lung is typically dull to percussion and, as conduction of sound is enhanced, auscultation reveals bronchial breathing and whispering pectoriloquy; crackles are heard throughout. An assessment of the state of nutrition is important, particularly in old age and frailty. The presence of herpes labialis may point to streptococcal infection, as may the finding of 'rusty' sputum. The differential diagnosis of pneumonia is shown in Box 17.38.

#### Investigations

The object of investigations, which are summarised in Box 17.39, is to confirm the diagnosis, assess severity and identify the development of complications.

#### Management

The most important aspects of management are oxygenation, fluid balance and antibiotic therapy. In severe or prolonged illness, nutritional support may be required.

#### 17.36 Factors that predispose to pneumonia

- Cigarette smoking
- Upper respiratory tract infections
- Alcohol
- Glucocorticoid therapy
- Old age
- Recent influenza infection
- Pre-existing lung disease
- HIV
- Indoor air pollution

#### 17.37 Organisms causing community-acquired pneumonia

##### Bacteria

- *Streptococcus pneumoniae*
- *Mycoplasma pneumoniae*
- *Legionella pneumophila*
- *Chlamydia pneumoniae*
- *Haemophilus influenzae*
- *Staphylococcus aureus*
- *Chlamydia psittaci*
- *Coxiella burnetii* (Q fever)
- *Klebsiella pneumoniae* (Freidländer's bacillus)

##### Viruses

- Influenza, parainfluenza
- Measles
- Herpes simplex
- Varicella
- Adenovirus
- Cytomegalovirus
- Coronaviruses (SARS-CoV-2 and MERS-CoV)

(MERS = Middle East respiratory syndrome; SARS = severe acute respiratory syndrome)

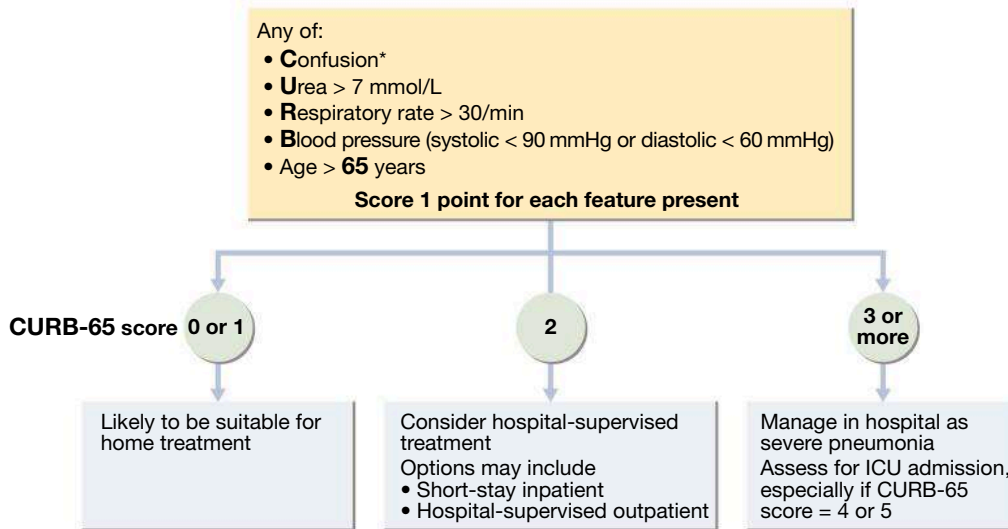

Fig. 17.31 Gram stain of sputum showing Gram-positive diplococci characteristic of *Streptococcus pneumoniae* (arrows).

#### 17.38 Differential diagnosis of pneumonia

- Pulmonary infarction
- Pulmonary/pleural tuberculosis
- Pulmonary oedema (can be unilateral)
- Pulmonary eosinophilia
- Malignancy: bronchoalveolar cell carcinoma
- Cryptogenic organising pneumonia/bronchiolitis obliterans organising pneumonia (COP/BOOP)

**Fig. 17.32** Hospital CURB-65. \*Defined as a mental test score of 8 or less, or new disorientation in person, place or time. (ICU = intensive care unit; urea of 7 mmol/L  $\cong$  20 mg/dL)

### Oxygen

Oxygen should be administered to all patients with tachypnoea, hypoxaemia, hypotension or acidosis to maintain the target oxygen saturations specified on p. 195. Continuous positive airway pressure (CPAP) should be considered in those who remain hypoxic despite high-concentration oxygen therapy, and these patients should be managed in a high-dependency or intensive care environment where mechanical ventilation is available. Indications for referral to an intensive care unit are summarised in [Box 17.40](#).

### Fluid balance

Intravenous fluids should be considered in those with severe illness, in older patients and those with vomiting. It may be appropriate to discontinue hypertensive agents temporarily, particularly if there is evidence of acute kidney injury secondary to sepsis. Otherwise, an adequate oral intake of fluid should be encouraged. Vasopressor support may be required in patients with shock.

### Antibiotic treatment

Prompt administration of appropriate antibiotics improves the outcome. The initial choice of antibiotic is guided by clinical context, severity assessment, local knowledge of antibiotic resistance patterns and antibiotic guidelines. Current regimens are detailed in [Box 17.41](#). In most patients with uncomplicated pneumonia a 5-day course is adequate, although treatment is usually required for longer in patients with pneumonia due to *Legionella pneumophila*, *Staph. aureus* or *Klebsiella pneumoniae*.

### Treatment of pleural pain

It is important to relieve pleural pain in order to allow the patient to breathe normally and cough efficiently. For the majority, simple analgesia with paracetamol, co-codamol or NSAIDs is sufficient. In some patients, opiates may be required but must be used with extreme caution in individuals with poor respiratory function.

### Physiotherapy

Physiotherapy is not usually indicated in patients with CAP, although it may be helpful to assist expectoration in patients who suppress cough because of pleural pain.

### Prognosis

Most patients respond promptly to antibiotic therapy. Fever may persist for several days, however, and the chest X-ray often takes several weeks or even months to resolve, especially in old age. Delayed recovery

suggests either that a complication has occurred ([Box 17.42](#)) or that the diagnosis is incorrect (see [Box 17.38](#)). Alternatively, the pneumonia may be secondary to a proximal bronchial obstruction or recurrent aspiration. The mortality rate of adults with non-severe pneumonia is very low (<1%); hospital death rates are typically between 5% and 10% but may be as high as 50% in severe illness.

### Discharge and follow-up

The decision to discharge a hospitalised patient depends on the home circumstances and the likelihood of complications. A chest X-ray need not be repeated before discharge in patients making a satisfactory clinical recovery. Clinical review by general practitioner or hospital should be arranged around 6 weeks later and a chest X-ray obtained if there are persistent symptoms, physical signs or reasons to suspect underlying malignancy, such as tobacco exposure.

### Prevention

Current smokers should be advised to stop. Influenza and pneumococcal vaccination should be offered to patients at highest risk of pneumonia (e.g. those over 65 or with chronic lung, heart, liver or kidney disease, diabetes or immunosuppression). Causes of pneumonia that have important public health implications must be notified to the appropriate health authority for appropriate investigation and follow-up (see [Box 6.11](#)). In resource-poor settings, tackling malnourishment and indoor air pollution, and encouraging immunisation against measles, pertussis and *Haemophilus influenzae* type b, are particularly important in children.

### Hospital-acquired pneumonia

Hospital-acquired pneumonia (HAP) is defined as an episode of pneumonia that presents at least 48 hours after admission to hospital and was not incubating at the time of admission. It is the second most common healthcare-associated infection (HAI) after surgical-site infections and the leading cause of HAI-associated death. Older patients are particularly at risk, as are patients in intensive care units. The term ventilator-associated pneumonia (VAP) is used to describe pneumonia that develops in a person who is mechanically ventilated. The factors predisposing to the development of HAP are listed in [Box 17.43](#).

### Clinical features and investigation

The diagnosis should be considered in any hospitalised patient who develops purulent sputum (or endotracheal secretions), new radiological infiltrates, an otherwise unexplained increase in oxygen requirement, a core temperature >38.3°C, and a leucocytosis or leucopenia. The clinical

## 17.39 Investigations in community-acquired pneumonia\*

### Blood

#### Full blood count

- Very high ( $>20 \times 10^9/L$ ) or low ( $<4 \times 10^9/L$ ) white cell count: marker of severity
- Neutrophil leucocytosis  $>15 \times 10^9/L$ : suggests bacterial aetiology
- Haemolytic anaemia: occasional complication of *Mycoplasma*

#### Urea and electrolytes

- Urea  $>7$  mmol/L ( $\sim 20$  mg/dL): marker of severity
- Hyponatraemia: marker of severity

#### Liver function tests

- Abnormal if basal pneumonia inflames liver
- Hypoalbuminaemia: marker of severity

#### Procalcitonin

- A high procalcitonin is more suggestive of bacterial than viral infection (see Ch. 6)

#### C-reactive protein/erythrocyte sedimentation rate

- Non-specifically elevated

#### Blood culture

- Bacteraemia: marker of severity

#### Arterial blood gases

- Measure when  $SpO_2 < 93\%$  or when clinical features are severe, to assess ventilatory failure or acidosis

### Sputum

#### Sputum samples

- Gram stain (see Fig. 17.31), culture and antimicrobial sensitivity testing

#### Pharyngeal swab

- NAAT for respiratory viruses (e.g. influenza, parainfluenza, coronaviruses) and bacteria (e.g. *Mycoplasma pneumoniae*)

#### Urine

- Pneumococcal and/or *Legionella* antigen

### Chest X-ray

#### Lobar pneumonia

- Patchy opacification evolves into homogeneous consolidation of affected lobe
- Air bronchogram (air-filled bronchi appear lucent against consolidated lung tissue) may be present (Fig. 17.33)

#### Bronchopneumonia

- Typically patchy and segmental shadowing

#### Complications

- Para-pneumonic effusion, intrapulmonary abscess or empyema

#### *Staphylococcus aureus*

- Suggested by multilobar shadowing, cavitation, pneumatoceles and abscesses

#### Plural fluid

- Always aspirate and culture when present in more than trivial amounts, preferably with ultrasound guidance

\*These investigations are for moderate- to high-severity community-acquired pneumonia (CAP). Low-severity CAP is usually managed empirically without the need for blood tests and microbiological investigations, unless the patient has risk factors for underlying disease or an atypical clinical course. (NAAT = nucleic acid amplification test)

features and radiographic signs are variable and non-specific, however, raising a broad differential diagnosis that includes pulmonary embolism, ARDS, pulmonary oedema, pulmonary haemorrhage and drug toxicity. Therefore, in contrast to CAP, microbiological confirmation should be sought whenever possible. Adequate sputum samples may be difficult to obtain and physiotherapy should be considered to aid expectoration. In patients who are mechanically ventilated, bronchoscopy-directed protected brush specimens, bronchoalveolar lavage (BAL) or endotracheal aspirates may be obtained.

**Fig. 17.33** Pneumonia of the right middle lobe. **A** Posteroanterior view: consolidation in the right middle lobe with characteristic opacification beneath the horizontal fissure and loss of normal contrast between the right heart border and lung. **B** Lateral view: consolidation confined to the anteriorly situated middle lobe.

## 17.40 Indications for referral to intensive care

- CURB score of 4–5 (see Fig. 17.32), failing to respond rapidly to initial management
- Persisting hypoxia ( $PaO_2 < 8$  kPa (60 mmHg)), despite high concentrations of oxygen
- Progressive hypercapnia
- Severe acidosis
- Circulatory shock
- Reduced conscious level

### Management

The principles of management are similar to those of CAP, focusing on adequate oxygenation, appropriate fluid balance and antibiotics. The choice of empirical antibiotic therapy is considerably more challenging, however, given the diversity of pathogens and the potential for drug resistance.

The organisms implicated in early-onset HAP (occurring within 4–5 days of admission) are similar to those involved in CAP. The initial choice of agents is most appropriately guided by knowledge of local patterns of microbiology and antibiotic resistance (Box 17.44). If the infecting organism is identified, antibiotic therapy should be refined, with the narrowest possible spectrum agent(s) being used. The most appropriate duration of antibiotic therapy has not been established and is a matter of clinical judgement. Physiotherapy is important to aid expectoration in less mobile patients and adequate nutritional support is often required.

i	17.41 Antibiotic treatment for community-acquired pneumonia (CAP) <sup>1</sup>
	<b>Low severity CAP (CURB-65 score 0–1)</b>
	<ul style="list-style-type: none"> <li>Amoxicillin 500 mg 3 times daily orally (or IV if necessary<sup>2</sup>)</li> </ul>
	<b>If patient is allergic to penicillin</b>
	<ul style="list-style-type: none"> <li>Doxycycline 200 mg loading dose then 100 mg/day orally <i>or</i> clarithromycin 500 mg twice daily orally</li> </ul>
	<b>Moderate severity CAP (CURB-65 score 2)</b>
	<ul style="list-style-type: none"> <li>Amoxicillin 500 mg–1 g 3 times daily orally (or IV if oral medication not possible<sup>2</sup>) <i>or</i> benzylpenicillin 1.2 g 4 times daily IV</li> <li><i>plus</i> clarithromycin 500 mg twice daily orally/IV</li> </ul>
	<b>If patient is allergic to penicillin</b>
	<ul style="list-style-type: none"> <li>Doxycycline 200 mg loading dose then 100 mg/day orally <i>or</i> levofloxacin 500 mg/day orally</li> </ul>
	<b>Severe CAP (CURB-65 score 3–5)</b>
	<ul style="list-style-type: none"> <li>Co-amoxiclav 1.2 g 3 times daily IV <i>or</i> cefuroxime 1.5 g 3 times daily IV <i>or</i> ceftriaxone 1–2 g daily IV</li> <li><i>plus</i> clarithromycin 500 mg twice daily IV</li> <li><i>or</i> benzylpenicillin 1.2 g 4 times daily IV <i>plus</i> levofloxacin 500 mg twice daily IV</li> </ul>
	<b>If <i>Legionella</i> is strongly suspected</b>
	<ul style="list-style-type: none"> <li>Consider adding levofloxacin 500 mg twice daily IV</li> </ul>
	<sup>1</sup> Antibiotic use in individual patients should take into account local guidance and antibiotic sensitivity patterns.
	<sup>2</sup> Reasons would include impaired consciousness, impaired swallowing reflex and functional or anatomical reasons for malabsorption. (CURB – see Fig. 17.32; IV = intravenous)
	<i>Adapted from British Thoracic Society Guidelines.</i>

### Prevention

Despite appropriate management, the mortality from HAP is high (approximately 30%), mandating prevention whenever possible. Good hygiene is paramount, particularly with regard to hand-washing and any equipment used. Steps should be taken to minimise the chances of aspiration and to limit the use of stress ulcer prophylaxis with proton pump inhibitors. Oral antiseptic (chlorhexidine 2%) may be used to decontaminate the upper airway and some intensive care units employ selective decontamination of the digestive tract when the anticipated requirement for ventilation will exceed 48 hours.

### Suppurative pneumonia, aspiration pneumonia and pulmonary abscess

These conditions are considered together, as their aetiology and clinical features overlap. Suppurative pneumonia is characterised by destruction of the lung parenchyma by the inflammatory process. Although micro-abscess formation is a characteristic histological feature, 'pulmonary abscess' is usually taken to refer to lesions in which there is a large localised collection of pus, or a cavity lined by chronic inflammatory tissue, from which pus has escaped by rupture into a bronchus.

Suppurative pneumonia and pulmonary abscess often develop after the inhalation of septic material during operations on the nose, mouth or throat, under general anaesthesia, or of vomitus during anaesthesia or coma, particularly if oral hygiene is poor. Additional risk factors for aspiration pneumonia include bulbar or vocal cord palsy, achalasia or oesophageal reflux, and alcoholism. Aspiration tends to localise to dependent areas of the lung, such as the apical segment of the lower lobe in a supine patient. These conditions may also complicate local bronchial obstruction from a neoplasm or foreign body.

Infections are usually due to a mixture of anaerobes and aerobes in common with the typical flora encountered in the mouth and upper respiratory tract. Isolates of *Prevotella melaninogenica*, *Fusobacterium necrophorum*, anaerobic or microaerophilic cocci and *Bacteroides fragilis* may be identified. When suppurative pneumonia or a pulmonary abscess occurs in a previously healthy lung, the most likely infecting organisms are *Staph. aureus* or *K. pneumoniae*. *Actinomyces* spp. cause chronic suppurative pulmonary infections, which may be associated with poor dental hygiene.

i	17.42 Complications of pneumonia
	<ul style="list-style-type: none"> <li>Para-pneumonic effusion – common</li> <li>Empyema</li> <li>Retention of sputum causing lobar collapse</li> <li>Deep vein thrombosis and pulmonary embolism</li> <li>Pneumothorax, particularly with <i>Staphylococcus aureus</i></li> <li>Suppurative pneumonia/lung abscess</li> <li>ARDS, renal failure, multi-organ failure</li> <li>Ectopic abscess formation (<i>Staphylococcus aureus</i>)</li> <li>Hepatitis, pericarditis, myocarditis, meningoenzephalitis</li> <li>Arrhythmias (e.g. atrial fibrillation)</li> <li>Pyrexia due to drug hypersensitivity</li> </ul>
	(ARDS = acute respiratory distress syndrome)

i	17.43 Factors predisposing to hospital-acquired pneumonia
	<b>Reduced host defences against bacteria</b>
	<ul style="list-style-type: none"> <li>Reduced immune defences (e.g. glucocorticoid treatment, diabetes, malignancy)</li> <li>Reduced cough reflex (e.g. post-operative)</li> <li>Disordered mucociliary clearance (e.g. anaesthetic agents)</li> <li>Bulbar or vocal cord palsy</li> </ul>
	<b>Aspiration of nasopharyngeal or gastric secretions</b>
	<ul style="list-style-type: none"> <li>Immobility or reduced conscious level</li> <li>Vomiting, dysphagia (N.B. stroke disease), achalasia or severe reflux</li> <li>Nasogastric intubation</li> </ul>
	<b>Bacteria introduced into lower respiratory tract</b>
	<ul style="list-style-type: none"> <li>Endotracheal intubation/tracheostomy</li> <li>Infected ventilators/nebulisers/bronchoscopes</li> <li>Dental or sinus infection</li> </ul>
	<b>Bacteraemia</b>
	<ul style="list-style-type: none"> <li>Abdominal sepsis</li> <li>Intravenous cannula infection</li> <li>Infected emboli</li> </ul>

Bacterial infection of a pulmonary infarct or a collapsed lobe may also produce a suppurative pneumonia or lung abscess. The organism(s) isolated from the sputum include *Strep. pneumoniae*, *Staph. aureus*, *Streptococcus pyogenes*, *H. influenzae* and, in some cases, anaerobic bacteria. In many cases, however, no pathogen can be isolated, particularly when antibiotics have been given.

Some strains of *Staph. aureus*, often community-acquired MRSA (CA-MRSA), produce the cytotoxin Panton–Valentine leukocidin (PVL). PVL-producing strains are mainly responsible for suppurative skin infection but also cause a rapidly progressive severe necrotising pneumonia.

Lemierre syndrome is a rare cause of pulmonary abscesses. The usual causative agent is the anaerobe *Fusobacterium necrophorum*. The illness typically commences as a sore throat, painful swollen neck, fever, rigor, haemoptysis and dyspnoea; spread into the jugular veins leads to thrombosis and metastatic dispersal of the organisms.

Injection drug-users are at particular risk of developing haematogenous lung abscess, often in association with endocarditis affecting the pulmonary and tricuspid valves. These abscesses are usually caused by staphylococci and streptococci, and occasionally by fungi such as *Candida* spp.

A non-infective form of aspiration pneumonia – exogenous lipid pneumonia – may follow the aspiration of animal, vegetable or mineral oils.

The clinical features of suppurative pneumonia are summarised in [Box 17.45](#).

### Investigations

Radiological features of suppurative pneumonia include homogeneous lobar or segmental opacity consistent with consolidation or collapse. Abscesses are characterised by cavitation and a fluid level. Occasionally, a pre-existing emphysematous bulla becomes infected and appears as a cavity containing an air–fluid level.

17.44 Antibiotics for adults aged 18 years and over with hospital-acquired pneumonia	
Antibiotic	Dosage and course length
<b>First-choice oral antibiotic for non-severe symptoms or signs and not at higher risk of resistance<sup>1</sup></b>	
Co-amoxiclav	500/125 mg 8-hourly for 5 days then review
<b>Alternative oral antibiotics for non-severe symptoms or signs and not at higher risk of resistance, if penicillin allergy or if co-amoxiclav unsuitable<sup>2</sup></b>	
Options include:	
Doxycycline	200 mg on first day, then 100 mg daily for 4 days (5-day course) then review
Cefalexin (caution in penicillin allergy)	500 mg 3 times or twice daily (can be increased to 1 g to 1.5 g 4 or 3 times daily) for 5 days then review
Co-trimoxazole	960 mg twice daily for 5 days then review
Levofloxacin (only if switching from IV levofloxacin with specialist advice; consider safety issues)	500 mg daily or twice daily for 5 days then review
<b>First-choice IV antibiotics if severe symptoms or signs (e.g. of sepsis) or at higher risk of resistance. Review IV antibiotics by 48 hrs and consider switching to oral antibiotics as above for a total of 5 days then review<sup>2</sup></b>	
Options include:	
Piperacillin with tazobactam	4.5 g 3 times daily (increased to 4.5 g 4 times daily if severe infection)
Ceftazidime	2 g 3 times daily
Ceftriaxone	2 g once daily
Cefuroxime	750 mg 4 or 3 times daily (increased to 1.5 g 4 or 3 times daily if severe infection)
Meropenem	0.5 g to 1 g 3 times daily
Ceftazidime with avibactam	2/0.5 g 3 times daily
Levofloxacin (consider safety issues)	500 mg daily or twice daily (use higher dosage if severe infection)
<b>Antibiotics to be added if suspected or confirmed MRSA infection (dual therapy with an IV antibiotic listed above)</b>	
Vancomycin	15 mg/kg to 20 mg/kg 3 times or twice daily IV, adjusted according to serum vancomycin concentration (a loading dose of 25 mg/kg to 30 mg/kg can be used in seriously ill people); maximum 2 g per dose
Teicoplanin	Initially 6 mg/kg twice daily for 3 doses, then 6 mg/kg daily
Linezolid (if vancomycin cannot be used; specialist advice only)	600 mg twice daily or IV

<sup>1</sup>Guided by microbiological results when available. <sup>2</sup>Choice should be based on specialist microbiological advice and local resistance data.

Adapted from National Institute for Health and Care Excellence (NICE). *Pneumonia (hospital-acquired): antimicrobial prescribing*. NICE Guideline [NG139], September 2019. <https://www.nice.org.uk/guidance/ng139>.

## Management

Aspiration pneumonia can usually be treated with amoxicillin and metronidazole. Further modification of antibiotics should be informed by clinical response and microbiological results. CA-MRSA is usually susceptible to a variety of oral non- $\beta$ -lactam antibiotics, such as trimethoprim-sulfamethoxazole, clindamycin, tetracyclines and linezolid. Parenteral therapy with vancomycin or linezolid can also be considered. *Fusobacterium necrophorum* is highly susceptible to  $\beta$ -lactam antibiotics and to metronidazole, clindamycin and third-generation cephalosporins. Prolonged treatment for 4–6 weeks may be required in some patients with lung abscess. Established pulmonary actinomycosis requires 6–12 months' treatment with intravenous or oral penicillin, or with a tetracycline in penicillin-allergic patients.

Physiotherapy is of great value, especially when suppuration is present in the lower lobes or when a large abscess cavity has formed. In most patients there is a good response to treatment, and although residual fibrosis and bronchiectasis are common sequelae, these seldom give rise to serious morbidity. Surgery should be contemplated if no improvement occurs despite optimal medical therapy. Removal or treatment of any obstructing endobronchial lesion is essential.

## 17.45 Clinical features of suppurative pneumonia

### Symptoms

- Cough with large amounts of sputum, sometimes fetid and blood-stained
- Pleural pain common
- Sudden expectoration of copious amounts of foul sputum if abscess ruptures into a bronchus

### Clinical signs

- High remittent pyrexia
- Profound systemic upset
- Digital clubbing may develop quickly (10–14 days)
- Consolidation on chest examination; signs of cavitation rarely found
- Pleural rub common
- Rapid deterioration in general health, with marked weight loss if not adequately treated

### ***Pneumonia in the immunocompromised patient***

Patients immunocompromised by drugs or disease (particularly human immunodeficiency virus (HIV) infection) are at increased risk of pulmonary infection and pneumonia is the most common cause of death in this group. The majority of infections are caused by the same pathogens that cause

pneumonia in immunocompetent individuals, but in patients with more profound immunosuppression less common organisms, or those normally considered to be of low virulence or non-pathogenic, may become 'opportunistic' pathogens. Depending on the clinical context, clinicians should consider the possibility of Gram-negative bacteria, especially *P. aeruginosa*, viruses, fungi, mycobacteria, and less common organisms such as *Nocardia* spp. Infection is often due to more than one organism.

### Clinical features

These typically include fever, cough and breathlessness but are influenced by the degree of immunosuppression, and the presentation may be less specific in the more profoundly immunosuppressed. The onset of symptoms tends to be swift in those with a bacterial infection but more gradual in patients with opportunistic organisms such as *Pneumocystis jirovecii* and mycobacterial infections. In *P. jirovecii* pneumonia, symptoms of cough and breathlessness can be present several days or weeks before the onset of systemic symptoms or the appearance of radiographic abnormality. The clinical features of invasive pulmonary aspergillosis are dealt with on p. 525.

### Investigations

The approach is informed by the clinical context and severity of the illness. Invasive investigations, such as bronchoscopy, BAL, trans-bronchial biopsy or surgical lung biopsy, are often impractical, as many patients are too ill to undergo these safely; however, 'induced sputum' (p. 487) offers a relatively safe method of obtaining microbiological samples. HRCT can be helpful:

- focal unilateral airspace opacification favours bacterial infection, mycobacteria or *Nocardia*
- bilateral opacification favours *P. jirovecii* pneumonia, fungi, viruses and unusual bacteria, e.g. *Nocardia*
- cavitation may be seen with *N. asteroides*, mycobacteria and fungi
- the presence of a 'halo sign' (a zone of intermediate attenuation between the nodule and the lung parenchyma) may suggest aspergillosis or other invasive fungal infection
- pleural effusions suggest pyogenic bacterial infections and are uncommon in *P. jirovecii* pneumonia.

$\beta$ -1,3-D-glucan levels are characteristically elevated in *P. jirovecii* pneumonia.

### Management

In theory, treatment should be based on an established aetiological diagnosis; in practice, however, the causative agent is frequently unknown. Factors that favour a bacterial aetiology include neutropenia, rapid onset and deterioration. In these circumstances, broad-spectrum antibiotic therapy should be commenced immediately, e.g. a third-generation cephalosporin, or a quinolone, plus an antistaphylococcal antibiotic, or an antipseudomonal penicillin plus an aminoglycoside. Thereafter, treatment may be tailored according to the results of investigations and the clinical response. Depending on the clinical context and response to treatment, antifungal or antiviral therapies may be added. The management of *P. jirovecii* infection is detailed on page 361 and that of invasive aspergillosis on page 527.

## Tuberculosis

### Epidemiology

Tuberculosis (TB) is caused by infection with *Mycobacterium tuberculosis* (MTB), which is part of a complex of organisms including *M. bovis* (reservoir cattle) and *M. africanum* (reservoir humans). The resurgence in TB in the UK observed over the latter part of the 20th century has been reversed. Following a 44% drop between 2011 and 2018, the number of new cases of TB in England has dropped to the lowest levels since records began in 1960. Nevertheless, its impact on world health remains significant. An estimated 10 million new cases were recorded in 2018, with the majority of these presenting in the world's poorest nations, which struggle to cover the costs associated with management and control

programmes (Fig. 17.34). In the same year, 1.5 million men, women and children died of TB, compared to 1 million of HIV/AIDS, making TB the worldwide leading cause of death from a single infectious agent that year.

### Pathology and pathogenesis

*M. tuberculosis* is spread by the inhalation of aerosolised droplet nuclei from other infected patients. Once inhaled, the organisms lodge in the alveoli and initiate the recruitment of macrophages and lymphocytes. Macrophages undergo transformation into epithelioid and Langhans cells, which aggregate with the lymphocytes to form the classical tuberculous granuloma (Fig. 17.35). Numerous granulomas aggregate to form a primary lesion or 'Ghon focus' (a pale yellow, caseous nodule, usually a few millimetres to 1–2 cm in diameter), which is characteristically situated in the periphery of the lung. Spread of organisms to the hilar lymph nodes is followed by a similar pathological reaction, and the combination of the primary lesion and regional lymph nodes is referred to as the 'primary complex of Ranke'. Reparative processes encase the primary complex in a fibrous capsule, limiting the spread of bacilli. If no further complications ensue, this lesion eventually calcifies and is clearly seen on a chest X-ray. Lymphatic or haematogenous spread may occur before containment is established, however, seeding secondary foci in other organs, including lymph nodes, serous membranes, meninges, bones, liver, kidneys and lungs, which may lie dormant for years. The only clue that infection is

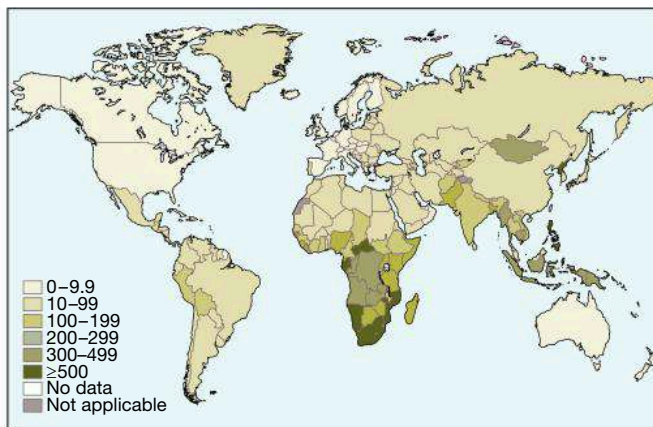

Fig. 17.34 Worldwide incidence of tuberculosis (2019). Estimated new cases (all forms) per 100 000 population. From *Global tuberculosis report 2020*. Geneva: World Health Organization; 2020.

Fig. 17.35 Tuberculous granuloma. Normal lung tissue is lost and replaced by a mass of fibrous tissue with granulomatous inflammation characterised by large numbers of macrophages and multinucleate giant cells (white arrow). The central area of this focus shows caseous degeneration (black arrow). Courtesy of Dr William Wallace, Department of Pathology, Royal Infirmary of Edinburgh.

present may be the appearance of a cell-mediated, delayed-type hypersensitivity reaction to tuberculin, demonstrated by tuberculin skin testing or an interferon-gamma release assay (IGRA): so-called latent TB infection (LTBI). If these controlling processes fail, primary progressive disease ensues (Fig. 17.36). The estimated lifetime risk of developing active disease after infection is 10%, with roughly half of this risk occurring in the first 2 years after infection. Factors predisposing to TB are summarised in Box 17.46 and the natural history of infection with TB is summarised in Box 17.47.

### Clinical features: pulmonary disease

#### Primary pulmonary TB

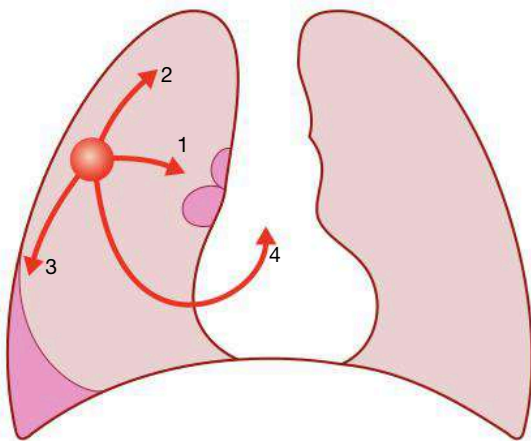

Primary TB refers to the infection of a previously uninfected (tuberculin-negative) individual. A few patients develop a self-limiting febrile illness but clinical disease occurs only if there is a hypersensitivity reaction or progressive infection (Box 17.48). Progressive primary disease may appear during the course of the initial illness or after a latent period of weeks or months.

#### Miliary TB

Blood-borne dissemination gives rise to miliary TB, which may present acutely but more frequently is characterised by 2–3 weeks of fever, night sweats, anorexia, weight loss and a dry cough. Hepatosplenomegaly may develop and the presence of a headache may indicate coexistent tuberculous meningitis. Auscultation of the chest is frequently normal but in more advanced disease widespread crackles are evident. Fundoscopy may show choroidal tubercles. The classical appearances on chest X-ray are of fine 1–2 mm lesions ('millet seed') distributed throughout the lung fields, although occasionally the appearances are coarser. Anaemia and leucopenia reflect bone marrow involvement.

#### Post-primary pulmonary TB

Post-primary disease refers to exogenous ('new' infection) or endogenous (reactivation of a dormant primary lesion) infection in a person who has been sensitised by earlier exposure. It is most frequently pulmonary and characteristically occurs in the apex of an upper lobe, where the oxygen tension favours survival of the strictly aerobic organism. The onset is usually insidious, developing slowly over several weeks. Systemic symptoms include fever, night sweats, malaise and loss of appetite and weight, and are accompanied by progressive pulmonary symptoms (Box 17.49). Radiological changes include ill-defined opacification in one

**Fig. 17.36 Primary pulmonary tuberculosis.** (1) Spread from the primary focus to hilar and mediastinal lymph glands to form the 'primary complex', which heals spontaneously in most cases. (2) Direct extension of the primary focus – progressive pulmonary tuberculosis. (3) Spread to the pleura – tuberculous pleurisy and pleural effusion. (4) Blood-borne spread: *few bacilli* – pulmonary, skeletal, renal, genitourinary infection, often months or years later; *massive spread* – miliary pulmonary tuberculosis and meningitis.

or both of the upper lobes, and as progression occurs, consolidation, collapse and cavitation develop to varying degrees (Fig. 17.37). It is often difficult to distinguish active from quiescent disease on radiological criteria alone but the presence of a miliary pattern or cavitation favours active disease. In extensive disease, collapse may be marked and results in significant displacement of the trachea and mediastinum. Occasionally, a caseous lymph node may drain into an adjoining bronchus, leading to tuberculous pneumonia.

### Clinical features: extrapulmonary disease

Extrapulmonary TB accounts for 20% of cases in those who are HIV-negative but is more common in HIV-positive patients.

#### Lymphadenitis

Lymph nodes are the most common extrapulmonary site of disease. Cervical and mediastinal glands are affected most frequently, followed by axillary and inguinal, and more than one region may be involved. Disease may represent primary infection, spread from contiguous sites or reactivation. Supraclavicular lymphadenopathy is often the result of spread from mediastinal disease. The nodes are usually painless and initially mobile but become matted together with time. When caseation and liquefaction occur, the swelling becomes fluctuant and may discharge through the skin with the formation of a 'collar-stud' abscess and sinus formation. Approximately half of cases fail to show any constitutional features, such as fevers or night sweats. During or after treatment, paradoxical enlargement, development of new nodes and suppuration may all occur but without evidence of continued infection; surgical excision is

### 17.46 Factors increasing the risk of tuberculosis

#### Patient-related

- Age (children > young adults < old age)
- First-generation immigrants from high-prevalence countries
- Close contacts of patients with smear-positive pulmonary TB
- Overcrowding (prisons, collective dormitories); homelessness (shelters and hostels)
- Chest X-ray evidence of primary TB infection
- Primary infection <1 year previously
- Smoking: cigarettes, bidis (Indian cigarettes made of tobacco wrapped in temburni leaves) and cannabis

#### Associated diseases

- Immunosuppression: HIV (reduced by ART), anti-tumour necrosis factor (TNF) and other biologic therapies, high-dose glucocorticoids, cytotoxic agents
- Malignancy (especially lymphoma and leukaemia)
- Diabetes mellitus
- Chronic kidney disease
- Silicosis
- Gastrointestinal disease associated with malnutrition (gastrectomy, jejunio-ileal bypass, cancer of the pancreas, malabsorption)
- Deficiency of vitamin D or A
- Recent measles in children

### 17.47 Natural history of untreated primary tuberculosis

Time from infection	Manifestations
3–8 weeks	Primary complex, positive tuberculin skin test
3–6 months	Meningeal, miliary and pleural disease
Up to 3 years	Gastrointestinal, bone and joint, and lymph node disease
Around 8 years	Renal tract disease
From 3 years onwards	Post-primary disease due to reactivation or re-infection

*Adapted from Davies PDO, ed. Clinical tuberculosis. London: Hodder Arnold; 1998.*

17.48 Features of primary tuberculosis	
<b>Infection (4–8 weeks)</b>	
<ul style="list-style-type: none"> <li>Influenza-like illness</li> <li>Skin test conversion</li> </ul>	<ul style="list-style-type: none"> <li>Primary complex</li> </ul>
<b>Disease</b>	
<ul style="list-style-type: none"> <li>Lymphadenopathy: hilar (often unilateral), paratracheal or mediastinal</li> <li>Collapse (especially right middle lobe)</li> <li>Consolidation (especially right middle lobe)</li> <li>Obstructive emphysema</li> </ul>	<ul style="list-style-type: none"> <li>Cavitation (rare)</li> <li>Pleural effusion</li> <li>Miliary disease</li> <li>Meningitis</li> <li>Pericarditis</li> </ul>
<b>Hypersensitivity</b>	
<ul style="list-style-type: none"> <li>Erythema nodosum</li> <li>Phlyctenular conjunctivitis</li> </ul>	<ul style="list-style-type: none"> <li>Dactylitis</li> </ul>

17.49 Clinical presentations of pulmonary tuberculosis	
<ul style="list-style-type: none"> <li>Chronic cough, often with haemoptysis</li> <li>Pyrexia of unknown origin</li> <li>Unresolved pneumonia</li> <li>Exudative pleural effusion</li> </ul>	<ul style="list-style-type: none"> <li>Asymptomatic (diagnosis on chest X-ray)</li> <li>Weight loss, general debility</li> <li>Spontaneous pneumothorax</li> </ul>

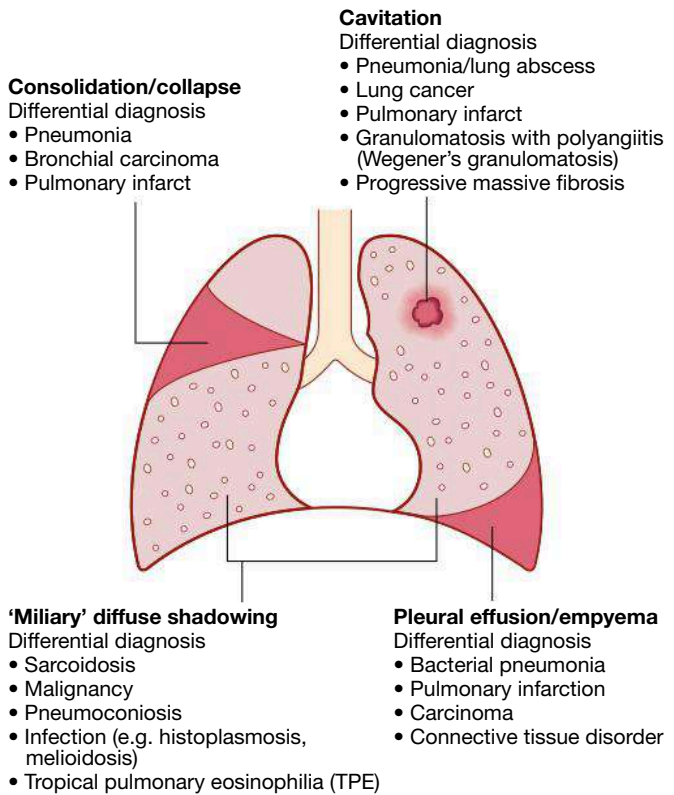

rarely necessary. In non-immigrant children in the UK, most mycobacterial lymphadenitis is caused by opportunistic mycobacteria, especially of the *M. avium* complex.

### Pleural tuberculosis

Tuberculous pleural effusions are common. Patients present with pleuritic chest pain in addition to the classic clinical features of pulmonary TB. Effusions are caused by both primary and reactivated TB, but can also result from a delayed hypersensitivity reaction to TB in the pleural cavity. Pseudochylothorax, due to compression from TB lymphadenitis, and empyema occur infrequently. Pleural fluid analysis demonstrates a lymphocytic exudate, with low glucose and pH. Pleural fluid smear and culture have sensitivities of only 10% and 25% respectively, however pleural tissue culture increases this to 80%. Raised adenosine deaminase has high sensitivity but low specificity as it occurs in malignancy and empyema also. Effusion volume fluctuates during treatment, even when successful. Therapeutic drainage is performed when necessary and steroids are sometimes used as an alternative.

### Gastrointestinal tuberculosis

TB can affect any part of the bowel and patients may present with a wide range of symptoms and signs (Fig. 17.38). Upper gastrointestinal tract involvement is rare and is usually an unexpected histological finding in an endoscopic or laparotomy specimen. Ileocaecal disease accounts for approximately half of abdominal TB cases. Fever, night sweats, anorexia and weight loss are usually prominent and a right iliac fossa mass may be palpable. Up to 30% of cases present with an acute abdomen. Ultrasound or CT may reveal thickened bowel wall, abdominal lymphadenopathy, mesenteric thickening or ascites. Diagnosis rests on obtaining histology by either colonoscopy or mini-laparotomy. The main differential diagnosis is Crohn's disease. Tuberculous peritonitis is characterised by abdominal distension, pain and constitutional symptoms. The ascitic fluid is exudative and cellular, with a predominance of lymphocytes. Laparoscopy reveals multiple white 'tubercles' over the peritoneal and omental surfaces. Low-grade hepatic dysfunction is common in miliary disease, in which biopsy reveals granulomas.

**Fig. 17.37** Chest X-ray: major manifestations and differential diagnosis of pulmonary tuberculosis. Less common manifestations include pneumothorax, acute respiratory distress syndrome (ARDS), cor pulmonale and localised emphysema.

### Pericardial disease

Disease occurs in two forms: pericardial effusion and constrictive pericarditis (see Fig. 17.38 and p. 476). Fever and night sweats are rarely prominent and the presentation is usually insidious, with breathlessness and abdominal swelling. Coexistent pulmonary disease is very rare, with the exception of pleural effusion. Pulsus paradoxus, a raised JVP, hepatomegaly, prominent ascites and peripheral oedema are common to both types. Pericardial effusion is associated with increased pericardial dullness and a globular enlarged heart on chest X-ray, and pericardial calcification occurs in around 25% of cases. Constriction is associated with an early third heart sound and, occasionally, atrial fibrillation. Diagnosis is based on clinical, radiological and echocardiographic findings. The effusion is frequently blood-stained. Open pericardial biopsy can be performed where there is diagnostic uncertainty. The addition of glucocorticoids to antituberculous chemotherapy has been shown to be beneficial in constrictive pericarditis.

### Central nervous system disease

Meningeal disease represents the most important form of central nervous system (CNS) TB. Unrecognised and untreated, it is rapidly fatal. Even when appropriate treatment is prescribed, mortality rates of 30% have been reported, while survivors may be left with neurological sequelae. Clinical features, investigations and management are described on p.1173.

### Bone and joint disease

The spine is the most common site for bony TB (Pott disease), which usually presents with chronic back pain and typically involves the lower thoracic and lumbar spine (see Fig. 17.38). The infection starts as a discitis and then spreads along the spinal ligaments to involve the adjacent anterior vertebral bodies, causing angulation of the vertebrae with subsequent kyphosis. Paravertebral and psoas abscess formation is common and the disease may present with a large (cold) abscess in the inguinal region. CT or MRI is valuable in gauging the extent of disease, the degree of cord compression, and the site for needle biopsy or open exploration,

**Fig. 17.38** Systemic presentations of extrapulmonary tuberculosis.

if required. The major differential diagnosis is malignancy, which tends to affect the vertebral body and leave the disc intact. Important complications include spinal instability or cord compression.

TB can affect any joint but most frequently involves the hip or knee. Presentation is usually insidious, with pain and swelling; fever and night sweats are uncommon. Radiological changes are often non-specific but, as disease progresses, reduction in joint space and erosions appear. Poncet arthropathy is an immunologically mediated polyarthritis that usually resolves within 2 months of starting treatment.

#### Genitourinary disease

Fever and night sweats are rare with renal tract TB and patients are often only mildly symptomatic for many years. Haematuria, frequency and dysuria are often present, with sterile pyuria found on urine microscopy and culture. In women, infertility from endometritis, or pelvic pain and swelling from salpingitis or a tubo-ovarian abscess occurs occasionally. In men, genitourinary TB may present as epididymitis or prostatitis.

#### Investigations

The presence of an otherwise unexplained cough for more than 3 weeks, particularly in regions where TB is prevalent, or typical chest X-ray or CT changes (Fig. 17.39) should prompt further investigation (Box 17.50). Direct microscopy of a sputum smear remains the most important first step. At least two sputum samples (including at least one obtained in the early morning) from a spontaneously produced deep cough should be obtained. Induced sputum may be used in those unable to expectorate. In selected cases, bronchoscopy and lavage or aspiration of a lymph node by EBUS may be used.

Light-emitting diode fluorescent microscopy with auramine staining (Fig. 17.40) is increasingly replacing the more traditional standard light microscopy and Ziehl–Neelsen stain. A positive smear is sufficient for the presumptive diagnosis of TB but definitive diagnosis requires either

**Fig. 17.39** Typical changes of tuberculosis. The chest X-ray shows bilateral upper lobe airspace shadowing with cavitation.

culture or the detection of *M. tuberculosis* DNA. The probability of visualising acid-fast bacilli is proportional to the bacillary burden in the sputum. Smear-negative sputum should also be cultured, as only 10–100 viable organisms are required for sputum to be culture-positive. A diagnosis of smear-negative TB may be considered in advance of culture if the chest X-ray appearances are typical of TB.

The slow growth of MTB on solid (typically between 4 and 6 weeks) and liquid (typically around 2 weeks) culture media has prompted the development of rapid NAATs. For example, the Cepheid GeneXpert MTB/RIF has the capacity to detect MTB (and certain molecular markers of rifampicin resistance) in less than 2 hours. However, while it is specific to MTB, it is not sufficiently sensitive to have replaced culture.

The diagnosis of extrapulmonary TB can be more challenging. There are generally fewer organisms (particularly in meningeal or pleural fluid), so culture, histopathological examination of tissue and/or NAAT may be required. Stimulation of T cells by mycobacterial antigens leads to increased levels of adenosine deaminase (ADA) in pleural, pericardial, cerebrospinal and ascitic fluid, so measuring ADA in these fluids may support a diagnosis of TB, but should not replace culture. IGRA and tuberculin skin tests have low sensitivity and specificity, are not routinely used in the diagnosis of active TB infection.

### Drug sensitivity testing

The rapid detection of drug resistance is central both to the management of the individual with TB and to control of the disease in the population. The gold standard remains culture. Molecular tests are increasingly used to provide rapid drug sensitivity testing (DST), particularly with regard to the

detection of rifampicin resistance, which is important because rifampicin forms the cornerstone of 6-month chemotherapy. Rapid identification of rifampicin resistance is provided by Xpert MTB/RIF. Line probe assays (LPAs) use PCR and reverse hybridisation to detect genetic sequences linked to resistance to both rifampicin and isoniazid, and increasingly to resistance to pyrazinamide, ethambutol and second-line agents.

Whole genome sequencing is now being used routinely in resource-rich settings both for identification of mycobacterium and to predict antimicrobial susceptibility, at least to first-line agents.

### Management

#### Chemotherapy

The treatment of TB is based on the principle of an initial intensive phase to reduce the bacterial population rapidly, followed by a continuation phase to destroy any remaining bacteria (Box 17.51). Standard treatment involves 6 months' treatment with isoniazid and rifampicin, supplemented in the first 2 months with pyrazinamide and ethambutol. Fixed-dose tablets combining two, three or four drugs are preferred. Unless there is reason to suspect drug resistance or non-tuberculous mycobacterium, treatment should be commenced immediately in any patient who is smear-positive, and in those who are smear-negative but with typical chest X-ray changes and no response to standard antibiotics. Where drug resistance is not anticipated, patients can be assumed to be non-infectious after 2 weeks of appropriate therapy.

17.50 Diagnosis of tuberculosis	
<b>Specimens required</b>	
<b>Pulmonary</b>	
<ul style="list-style-type: none"> <li>• Sputum* (induced with nebulised hypertonic saline if patient not expectorating)</li> <li>• Bronchoscopy with washings or BAL</li> <li>• Gastric washing* (mainly used for children)</li> </ul>	
<b>Extrapulmonary</b>	
<ul style="list-style-type: none"> <li>• Fluid examination (cerebrospinal, ascitic, pleural, pericardial, joint): yield classically very low</li> <li>• Tissue biopsy (from affected site or enlarged lymph node): bone marrow/liver may be diagnostic in disseminated disease</li> </ul>	
<b>Diagnostic tests</b>	
<ul style="list-style-type: none"> <li>• Stain               <ul style="list-style-type: none"> <li>• Auramine fluorescence</li> <li>• Ziehl–Neelsen</li> </ul> </li> <li>• Nucleic acid amplification</li> <li>• Culture               <ul style="list-style-type: none"> <li>• Solid media (Löwenstein–Jensen, Middlebrook)</li> <li>• Liquid media (e.g. MGIT)</li> </ul> </li> <li>• Pleural fluid: adenosine deaminase</li> <li>• Response to empirical antituberculous drugs</li> </ul>	
<b>Baseline blood tests</b>	
<ul style="list-style-type: none"> <li>• Full blood count, C-reactive protein, urea and electrolytes, liver function tests</li> </ul>	
<p>*Preferably three early morning samples. (BAL = bronchoalveolar lavage; MGIT = mycobacteria growth indicator tube)</p>

17.51 Treatment of new tuberculosis (TB) patients (World Health Organization recommendations)		
Intensive phase	Continuation phase	Comments
<b>Standard regimen</b>		
2 months of HRZE	4 months of HR	
2 months of HRZE	4 months of HRE	Applies only in countries with high levels of isoniazid resistance in new TB patients, and where isoniazid drug susceptibility testing in new patients is not done (or results are unavailable) before the continuation phase begins
<b>Dosing frequency</b>		
Daily*	Daily	Optimal
Daily*	3 times/week	No longer recommended but sometimes used in practice for patients receiving directly observed therapy
3 times/week	3 times/week	No longer recommended but sometimes used in practice for patients receiving directly observed therapy, provided the patient is <i>not</i> living with HIV or living in an HIV-prevalent setting
<p>*Daily (rather than 3 times weekly) intensive-phase dosing may help to prevent acquired drug resistance in TB patients starting treatment with isoniazid resistance. (H = isoniazid; R = rifampicin; Z = pyrazinamide; E = ethambutol; HIV = human immunodeficiency virus) Adapted from World Health Organization. <i>Guidelines for treatment of drug-susceptible tuberculosis and patient care, 2017 update.</i></p>		

### 17.52 Main adverse reactions of first-line antituberculous drugs

	Isoniazid	Rifampicin	Pyrazinamide	Ethambutol
<b>Mode of action</b>	Cell wall synthesis	DNA transcription	Unknown	Cell wall synthesis
<b>Major adverse reaction</b>	Peripheral neuropathy <sup>1</sup> Hepatitis <sup>2</sup> Rash	Febrile reactions Hepatitis Rash Gastrointestinal disturbance	Hepatitis Gastrointestinal disturbance Hyperuricaemia	Retrobulbar neuritis <sup>3</sup> Arthralgia
<b>Less common adverse reaction</b>	Lupoid reactions Seizures Psychoses	Interstitial nephritis Thrombocytopenia Haemolytic anaemia	Rash Photosensitisation Gout	Peripheral neuropathy Rash

<sup>1</sup>The risk may be reduced by prescribing pyridoxine. <sup>2</sup>More common in patients with a slow acetylator status and in alcoholics. <sup>3</sup>Reduced visual acuity and colour vision may be reported with higher doses and are usually reversible.

Six months of therapy is appropriate for all patients with pulmonary TB and most cases of extrapulmonary TB. However, 12 months of therapy is recommended for CNS TB. Most patients can be treated at home. Admission to a hospital unit with appropriate isolation facilities should be considered where there is uncertainty about the diagnosis, intolerance of medication, questionable treatment adherence, adverse social conditions or a significant risk of multidrug-resistant TB.

Adverse drug reactions occur in about 10% of patients (Box 17.52). Patients treated with rifampicin should be advised that their urine, tears and other secretions will develop a bright, orange/red coloration. Rifampicin is a cytochrome P450 inducer, it accelerates the metabolism of several drugs, thereby reducing their effective dose. These medications include steroids, oral hypoglycaemics, antiretrovirals, warfarin, opiates (including methadone) and contraceptives. Women taking oral or depot hormonal contraceptives must be warned that their efficacy, and that of emergency hormonal contraception, will be reduced and alternative contraception may be necessary. Standard TB medication is safe during pregnancy, however pregnant women experience an increased rate of side-effects, so conception is not advised. Pyridoxine should be prescribed in pregnant women and malnourished patients to reduce the risk of peripheral neuropathy with isoniazid. Ethambutol should be used with caution in severe renal impairment, with appropriate dose reduction and monitoring of drug levels. Visual acuity and colour vision should be assessed before commencing ethambutol.

Baseline liver function and regular monitoring are important for patients treated with standard therapy. Rifampicin may cause asymptomatic hyperbilirubinaemia but, along with isoniazid and pyrazinamide, may also cause hepatitis. Mild asymptomatic increases in transaminases are common but significant hepatotoxicity occurs in only 2%–5%. It is important to stop treatment and allow any symptoms to subside and the liver function tests to recover before commencing a stepwise re-introduction of the individual drugs. Less hepatotoxic regimens may be considered, including streptomycin, ethambutol and fluoroquinolones.

Glucocorticoids reduce inflammation and limit tissue damage; they are currently recommended when treating constrictive pericarditis or CNS disease, and in children with endobronchial disease. They may confer benefit in TB of the ureter, pleural effusions and extensive pulmonary disease, and can suppress hypersensitivity drug reactions. Embolization should be considered for treatment of massive haemoptysis. Surgery is required for patients with spinal TB causing spinal cord compression.

The effectiveness of therapy for pulmonary TB is assessed by further sputum analysis at 2 months to ensure sputum culture conversion, if the patient is still producing sputum. If sputum is culture-positive at 2 months, repeat sputum should be obtained at month 3. If this sample is culture-positive then DST should be repeated. Treatment failure is defined as a positive sputum culture at 5 months or any patient with a

newly converted multidrug-resistant strain, regardless of whether they are smear-positive or negative. Extrapulmonary TB must be assessed clinically or radiographically, as appropriate.

### Control and prevention

Active TB is preventable, particularly so in those with latent TB. Supporting the development of laboratory and health-care services to improve detection and treatment of active and latent TB is an important component of this goal.

### Latent TB infection (LTBI)

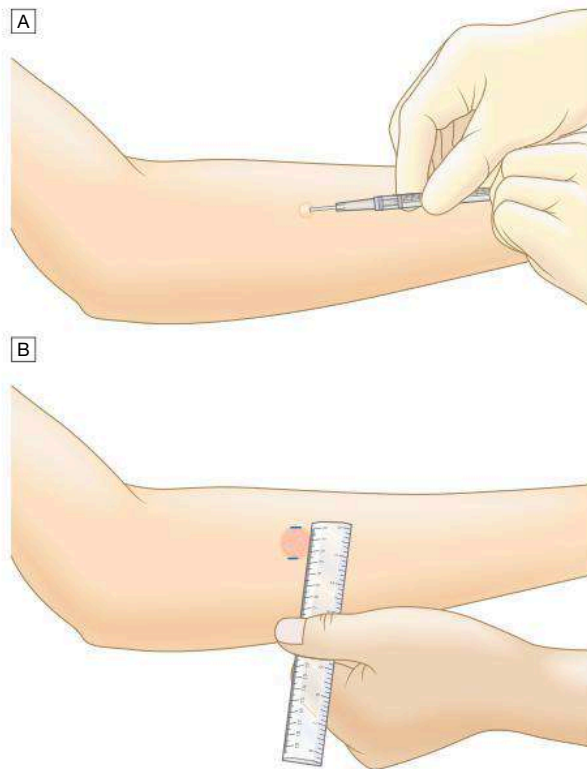

The majority of individuals exposed to MTB harbour the bacteria, which remain dormant. They do not develop any signs of active disease and are non-infectious. They are, however, at risk of developing active TB disease and becoming infectious. The lifetime risk of TB disease for a person with documented LTBI is estimated at 5%–15%, with the majority of cases occurring within the first 5 years after initial infection.

LTBI may be identified by the presence of immune responses to *M. tuberculosis* antigens. Contact tracing is a legal requirement in many countries. It has the potential to identify the probable index case, other cases infected by the same index patient (with or without evidence of disease), and close contacts who should receive BCG vaccination (see below) or chemotherapy. Approximately 10%–20% of close contacts of patients with smear-positive pulmonary TB and 2%–5% of those with smear-negative, culture-positive disease have evidence of TB infection.

Cases are commonly identified using the tuberculin skin test (TST; Fig. 17.41) or an IGRA (Fig. 17.42). An otherwise asymptomatic contact who tests positive but has a normal chest X-ray may be treated with chemoprophylaxis to prevent infection from progressing to clinical disease. Chemoprophylaxis should be offered to adults up to the age of 65 (although age-specific cut-off varies by country). It should also be considered for HIV-infected close contacts of a patient with smear-positive disease. A course of rifampicin and isoniazid for 3 months or isoniazid for 6 months is effective.

Tuberculin skin testing may be associated with false-positive reactions in those who have had a BCG vaccination and in areas where exposure to non-tuberculous mycobacteria is high. The skin tests may also be falsely negative in the setting of immunosuppression or overwhelming TB infection.

IGRAs detect the release of interferon-gamma (IFN- $\gamma$ ) from sensitised T cells in response to antigens, such as early secretory antigenic target (ESAT)-6 or culture filtrate protein (CFP)-10, which are encoded by genes specific to *M. tuberculosis* and are not shared with BCG or opportunistic mycobacteria (see Fig. 17.42). IGRAs are more specific than skin testing and logistically more convenient, as they require a single blood test rather than two clinic visits. In the UK, IGRA represents the first choice investigation, except in children, for whom TST is recommended.

**Fig. 17.41** The tuberculin skin test. **A** The reaction to the intradermal injection of tuberculin purified protein derivative (PPD) on the inner surface of the forearm is read between 48 and 72 hours. **B** The diameter of the indurated area should be measured across the forearm and is positive when  $\geq 5$  mm.

**Fig. 17.42** The principles of interferon-gamma release assays (IGRAs). A sample of either **A** purified T cells (T-SPOT.TB test) or **B** whole blood (QuantIFERON–TB Gold test) is incubated in the presence of antigens specific to *Mycobacterium tuberculosis* (MTB). The release of interferon-gamma (IFN- $\gamma$ ) by the cells is measured by enzyme-linked immunosorbent assay (ELISA). (ELISPOT = enzyme-linked immunosorbent spot assay)

### Directly observed therapy

Poor adherence to therapy is a major factor in prolonged illness, risk of relapse and the emergence of drug resistance. Directly observed therapy (DOT) involves the supervised administration of therapy three times weekly to improve adherence. DOT has become an important control strategy in resource-poor nations. In the UK, it is currently recommended for patients with previous TB, multidrug-resistant TB, poor adherence to treatment, denial of the diagnosis, those with a history of homelessness, alcohol or drug misuse, those currently or recently in prison, and those with major psychiatric, memory or cognitive disorders. DOT can be replaced by video-observed consultation (VOT) if appropriate facilities are available.

### TB and HIV/AIDS

The close links between HIV and TB, particularly in sub-Saharan Africa, and the potential for both diseases to overwhelm health-care funding in resource-poor nations, have been recognised, with the promotion of programmes that link detection and treatment of TB with detection and treatment of HIV. It is recommended that all patients with TB should be tested for HIV infection, in addition to hepatitis B and C. Mortality is high and TB is a leading cause of death in HIV-positive patients. Full discussion of its presentation and management with antiretroviral therapy (ART) is given in Chapter 14.

ART should be initiated for all HIV-positive patients with TB. ART is usually initiated after 2 weeks of tuberculous therapy, but in patients with a CD4 count under 50 cells/ $\mu$ L or CNS TB is often delayed until 8 weeks of TB therapy has been completed to reduced the risk of IRIS/paradoxical reaction. TB-associated immune reconstitution inflammatory syndrome (TB-IRIS) is a paradoxical increase in pre-existing, or development of new, TB signs or symptoms, due to ART reviving the immune system. TB-IRIS may be self-limiting, but in severe cases steroids are used to reduce symptoms, and patients are advised to continue TB chemotherapy and ART. Choice of initial ART or change in ART should reflect the need to avoid drug interactions.

### Drug-resistant TB

Drug-resistant TB is defined by the presence of resistance to any first-line agent. Multidrug-resistant tuberculosis (MDR-TB) is defined by resistance to at least rifampicin and isoniazid, with or without other drug resistance. Globally, an estimated 3.5% of new TB cases and 18% of previously treated cases have MDR-TB. In 2017, an estimated 230 000 people died of MDR-TB. Extensively drug-resistant tuberculosis (XDR-TB) is defined as resistance to at least rifampicin and isoniazid, in addition to any quinolone and at least one injectable second-line agent. An estimated 8.5% of people with MDR-TB have XDR-TB. The prevalence of MDR-TB is rising, particularly in post-Soviet states, Central Asia and South Africa. It is more common in individuals with a prior history of TB, particularly if treatment has been inadequate. [Box 17.53](#) lists the factors contributing to the emergence of drug-resistant TB. Diagnosis is challenging, especially in resource-poor settings, and although cure is possible, it requires prolonged treatment with less effective, more toxic and more expensive second-line therapies. These include injectable drugs (aminoglycosides), fluoroquinolones and various other antibiotics and TB-specific agents (see p. 315). The mortality rate from tuberculosis increases with the level of drug resistance.

### Vaccines

BCG (bacille Calmette–Guérin), a live attenuated vaccine derived from *M. bovis*, is the most established TB vaccine. It is administered by intradermal injection and is highly immunogenic. BCG appears to be effective in preventing disseminated disease, including tuberculous meningitis, in children, but its efficacy in adults is inconsistent and new vaccines are urgently needed. Current vaccination policies vary worldwide according to incidence and health-care resources, but usually target children and other high-risk individuals. BCG is very safe, with the occasional

complication of local abscess formation. It should not be administered to those who are immunocompromised (e.g. by HIV) or pregnant.

### Prognosis

Following successful completion of chemotherapy, cure should be anticipated in the majority of patients, though complications such as lung scarring and bronchiectasis are not uncommon (Box 17.54). There is a small (<5%) and unavoidable risk of relapse. Most relapses occur within 5 months and usually have the same drug susceptibility. In the absence of treatment, a patient with smear-positive TB will remain infectious for an average of 2 years; in 1 year, 25% of untreated cases will die. Death is more likely in those who are smear-positive and those who smoke. A few patients die unexpectedly soon after commencing therapy and it is possible that some have subclinical hypoadrenalism that is unmasked by a rifampicin-induced increase in glucocorticoid metabolism. HIV-positive patients have higher mortality rates and a modestly increased risk of relapse.

### Non-tuberculous mycobacterial infection

Other species of environmental mycobacteria (termed 'non-tuberculous') may cause human disease (Box 17.55). The sites commonly involved are the lungs, lymph nodes, skin and soft tissues. The most widely recognised of these mycobacteria, *M. avium* complex (MAC), is well described in severe HIV disease (CD4 count <50 cells/ $\mu$ L). However, several others (including MAC) colonise and/or infect apparently immunocompetent patients with chronic lung diseases such as COPD, bronchiectasis, pneumoconiosis, old TB, or cystic fibrosis. The clinical presentation varies from a relatively indolent course in some to an aggressive course characterised by cavitary or nodular disease in others. Radiological appearances may be similar to classical TB, but in patients with bronchiectasis, opportunistic infection may present with lower-zone nodules. The most commonly reported organisms include *M. kansasii*, *M. malmoense*, *M. xenopi* and *M. abscessus* but geographical variation is marked. *M. abscessus* and *M. fortuitum* grow rapidly but the majority of others grow slowly. More rapid diagnostic systems are under development, including DNA probes, high-performance liquid chromatography (HPLC), PCR restriction enzyme analysis (PRA) and 16S rRNA gene sequence analysis. Drug sensitivity testing is often unhelpful in predicting treatment response, with the exception of macrolide susceptibility for MAC and rifampicin sensitivity for *M. kansasii*. In the UK, these organisms are not

notifiable to local public health departments as they are not normally communicable; patient-to-patient transmission of *M. abscessus* in cystic fibrosis is a key exception.

### Respiratory diseases caused by fungi

The majority of fungi encountered by humans are harmless saprophytes but in certain circumstances (Box 17.56) some species may cause disease by infecting human tissue, promoting damaging allergic reactions or producing toxins. 'Mycosis' is the term applied to disease caused by fungal infection. The conditions associated with *Aspergillus* species are listed in Box 17.57.

### Allergic bronchopulmonary aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) occurs as a result of a hypersensitivity reaction to germinating fungal spores in the airway wall. The condition may complicate the course of asthma and cystic fibrosis, and is a recognised cause of pulmonary eosinophilia. The prevalence of ABPA is approximately 1%–2% in asthma and 5%–10% in patients with CF. A variety of human leucocyte antigens (HLAs) convey both an increased and a decreased risk of developing the condition, suggesting that genetic susceptibility is important.

### Clinical features

Clinical features depend on the stage of the disease. Common manifestations in the early phases include fever, breathlessness, cough

#### 17.53 Factors contributing to the emergence of drug-resistant tuberculosis

- Drug shortages
- Poor-quality drugs
- Poor concordance with drugs
- Lack of appropriate supervision
- Transmission of drug-resistant strains
- Prior antituberculosis treatment
- Treatment failure (culture-positive at 5 months)

#### 17.54 Complications of pulmonary tuberculosis

- Bronchiectasis
- Massive haemoptysis
- Cor pulmonale
- Fibrosis/emphysema
- Atypical mycobacterial infection
- Aspergilloma/chronic pulmonary aspergillosis
- Obstructive airways disease
- Bronchopleural fistula
- Lung/pleural calcification and pleural thickening

#### Non-pulmonary complications

- Empyema necessitans
- Laryngitis
- Enteritis\*
- Anorectal disease\*
- Amyloidosis
- Poncet's polyarthritis

\*From swallowed sputum.

#### 17.55 Site-specific opportunistic mycobacterial disease

##### Pulmonary

- *M. xenopi*
- *M. kansasii*
- *M. malmoense*
- MAC
- *M. abscessus* (in cystic fibrosis)

##### Lymph node

- MAC
- *M. malmoense*
- *M. fortuitum*
- *M. chelonae*

##### Soft tissue/skin

- *M. leprae*
- *M. ulcerans* (prevalent in Africa, northern Australia and South-east Asia)
- *M. marinum*
- *M. fortuitum*
- *M. chelonae*

##### Disseminated

- MAC (HIV-associated)
- *M. haemophilum*
- *M. genavense*
- *M. chimera* (cardiopulmonary bypass-associated)
- *M. fortuitum*
- *M. chelonae*
- BCG

(BCG = bacille Calmette–Guérin; MAC = *Mycobacterium avium* complex – *M. scrofulaceum*, *M. intracellulare* and *M. avium*)

#### 17.56 Factors predisposing to pulmonary fungal disease

##### Systemic factors

- Haematological malignancy
- HIV
- Diabetes mellitus
- Chronic alcoholism
- Radiotherapy
- Glucocorticoids, cytotoxic chemotherapy, biologic therapies and other immunosuppressant medication

##### Local factors

- Tissue damage by suppuration or necrosis
- Alteration of normal bacterial flora by antibiotic therapy

productive of bronchial casts and worsening of asthmatic symptoms. The appearance of radiographic infiltrates may cause ABPA to be mistaken for pneumonia but the diagnosis may also be suggested by segmental or lobar collapse on chest X-rays of patients whose asthma symptoms are stable. Diagnostic features are shown in [Box 17.58](#). If bronchiectasis develops, the symptoms and complications of that disease often overshadow those of asthma.

### Management

ABPA is generally considered an indication for regular therapy with low-dose oral glucocorticoids (prednisolone 7.5–10 mg/day) with the aim of suppressing the immunopathological responses and preventing progressive tissue damage. In some patients, itraconazole (400 mg/day) facilitates a reduction in oral glucocorticoids; a 4-month trial is usually recommended to assess its efficacy, but there needs to be consideration for the interactions with inhaled glucocorticoids. The use of specific anti-IgE monoclonal antibodies is under consideration. Exacerbations, particularly when associated with new chest X-ray changes, should be treated promptly with prednisolone (40–60 mg/day) and physiotherapy. If persistent lobar collapse occurs, bronchoscopy (usually under general anaesthetic) should be performed to remove impacted mucus and ensure prompt re-inflation.

## Chronic pulmonary aspergillosis

The term chronic pulmonary aspergillosis (CPA) encompasses simple aspergilloma, chronic cavitary pulmonary aspergillosis, chronic fibrosing pulmonary aspergillosis, *Aspergillus* nodule and semi-invasive aspergillosis. They are uncommon conditions and challenging to diagnose and treat.

### Simple aspergilloma

Cavities left by diseases such as TB or by damaged bronchi provide favourable conditions in which inhaled *Aspergillus* may lodge and germinate. At the earliest stage, CT scanning may identify an irregular mucosal wall and, as fungal growth progresses, this finally collapses into the cavity, forming a fungal ball that may be identified on imaging ([Fig. 17.43](#)).

Simple aspergillomas are often asymptomatic. They can, however, give rise to a variety of non-specific symptoms, such as lethargy and weight loss, and may cause recurrent haemoptysis, which may be life-threatening.

The typical radiological picture is invariably accompanied by elevated serum IgG/precipitins to *A. fumigatus*. Sputum microscopy typically demonstrates scanty hyphal fragments and is usually positive on culture. Less than half exhibit skin hypersensitivity to extracts of *A. fumigatus*.

### 17.57 Classification of bronchopulmonary aspergillosis

- Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)
- Hypersensitivity pneumonitis (*Aspergillus clavatus*)
- Intracavitary aspergilloma
- Invasive pulmonary aspergillosis
- Chronic and subacute pulmonary aspergillosis

### 17.58 Features of allergic bronchopulmonary aspergillosis

- Asthma (in the majority of cases)
- Proximal bronchiectasis (inner two-thirds of chest CT field)
- Positive skin test to an extract of *Aspergillus fumigatus*
- Elevated total serum IgE >417 kU/L (1000 ng/mL)
- Elevated *A. fumigatus*-specific IgE or IgG
- Peripheral blood eosinophilia >0.5 × 10<sup>9</sup>/L
- Presence or history of chest X-ray abnormalities
- Recovery of *A. fumigatus* from sputum

(CT = computed tomography; Ig = immunoglobulin)

Rarely, other filamentous fungi can cause intracavity mycetoma and are identified by culture.

Asymptomatic cases do not require treatment but haemoptysis should be controlled by surgery. Tranexamic acid or bronchial artery embolisation may provide a bridge to surgery or palliate haemoptysis when surgery is not possible. Antifungal agents are usually not beneficial due to poor penetration into the mycetoma, and generally surgical resection is the treatment of choice. Antifungals can be trialled in those patients with multiple mycetomas or who are not fit enough for surgical resection. Instillation of antifungal agents, such as amphotericin B, via a catheter placed into the cavity has been reported but is rarely used in the UK.

## Chronic cavitary pulmonary aspergillosis and chronic fibrosing pulmonary aspergillosis

The features of chronic cavitary pulmonary aspergillosis (CCPA) include cough (with or without haemoptysis), weight loss, anorexia and fatigue over months or years, with associated fever, night sweats and elevated inflammatory markers. Radiological features include thick-walled cavities (predominantly apical), pulmonary infiltrates and pleural thickening ([Fig. 17.44](#)). Once again, diagnosis rests on a combination of radiological examination, histopathology, isolation of fungus from the respiratory tract and detection of *Aspergillus* IgG in serum. Treatment usually involves prolonged courses of itraconazole or voriconazole. Cure is unusual and the most frequent pattern is chronic relapse/remission with gradual deterioration. Surgical intervention is fraught with complications and should be avoided. Many patients are malnourished and require nutritional support. Glucocorticoids should be avoided. As CCPA progresses, fibrotic destruction of the lung results and the condition may then be referred to as chronic fibrosing pulmonary aspergillosis (CFPA).

### Aspergillus nodule

The formation of one or more nodules is a less common manifestation of *Aspergillus* infection. In addition to lung cancer, the *Aspergillus* nodule may mimic TB but cavitation is unusual. Cryptococcosis or coccidioidomycosis should be considered in areas where these conditions are endemic.

### Subacute invasive aspergillosis

Subacute invasive aspergillosis (SIA) was previously referred to as chronic necrotising or semi-invasive pulmonary aspergillosis. The clinical and radiological picture is similar to CCPA but lung biopsy demonstrates invasion of lung tissue by hyphae. The development of SIA is favoured by mild immunocompromise and should be suspected in patients with diabetes mellitus, malnutrition or alcoholism, or with advanced age and in prolonged glucocorticoid use. It is also seen in the presence of COPD, non-tuberculous mycobacteria or HIV infection. SIA should be treated in a similar manner to invasive pulmonary aspergillosis.

**Fig. 17.43** Computed tomogram of aspergilloma in the left upper lobe. The rounded fungal ball is separated from the wall of the cavity by an 'air crescent' (arrow).

## Invasive pulmonary aspergillosis

Invasive pulmonary aspergillosis (IPA) is most commonly a complication of profound neutropenia caused by drugs (especially immunosuppressive agents) and/or disease (Box 17.59).

### Clinical features

Acute IPA causes a severe necrotising pneumonia and must be considered in any immunocompromised patient who develops fever, new respiratory symptoms (particularly pleural pain or haemoptysis) or a pleural rub. Invasion of pulmonary vessels causes thrombosis and infarction, and systemic spread may occur to the brain, heart, kidneys and other organs. Tracheobronchial aspergillosis involvement is characterised by the formation of fungal plaques and ulceration.

HRCT characteristically shows macronodules (usually  $\geq 1$  cm), which may be surrounded by a 'halo' of intermediate attenuation if captured early (<5 days). Culture or histopathological evidence of *Aspergillus* in diseased tissues provides a definitive diagnosis but the majority of patients are too ill for invasive tests, such as bronchoscopy or lung biopsy. Other investigations include detection of *Aspergillus* galactomannan in blood or BAL fluid,  $\beta$ -1,3-D-glucan in blood and (where available) *Aspergillus* DNA in blood. Diagnosis is often inferred from a combination of features (Box 17.60).

**Fig. 17.44** Chronic pulmonary aspergillosis. **A** The chest X-ray shows pleural thickening with loss of lung volume at the left apex (arrow). **B** High-resolution computed tomography reveals multiple small cavities and pleural thickening with an aspergilloma and surrounding air crescent (arrow) in one of the cavities. Courtesy of Professor David Denning, National Aspergillosis Centre, Manchester, UK.

### Management and prevention

IPA carries a high mortality rate, especially if treatment is delayed. The drug of choice is voriconazole. Second-line agents include liposomal amphotericin, caspofungin, posaconazole and isavuconazole. Response may be assessed clinically, radiologically and serologically (by estimation of the circulating galactomannan level). Recovery is dependent on immune reconstitution, which may be accompanied by enlargement and/or cavitation of pulmonary nodules.

Patients at risk of *Aspergillus* (and other fungal infections) should be managed in rooms with high-efficiency particulate air (HEPA) filters and laminar airflow. In areas with high spore counts, patients are advised to wear a mask if venturing outside their hospital room. Posaconazole (200mg 3 times daily) or itraconazole (200mg/day) may be prescribed for primary prophylaxis, and patients with a history of definite or probable IPA should be considered for secondary prophylaxis before further immunosuppression.

#### 17.59 Risk factors for invasive aspergillosis

- Neutropenia: risk related to duration and degree
- Solid organ or allogeneic stem cell transplantation
- Prolonged high-dose glucocorticoid therapy
- Leukaemia and other haematological malignancies
- Cytotoxic chemotherapy
- Advanced HIV disease
- Severe chronic obstructive pulmonary disease
- Critically ill patients on intensive care units
- Chronic granulomatous disease

#### 17.60 Criteria for the diagnosis of probable invasive pulmonary aspergillosis

##### Host factors

- Recent history of neutropenia ( $<0.5 \times 10^9/L$  for  $\geq 10$  days) temporally related to the onset of fungal disease
- Recipient of allogeneic stem cell transplant
- Prolonged use of glucocorticoids (average minimum 0.3 mg/kg daily prednisolone or equivalent) for  $>3$  weeks (excludes allergic bronchopulmonary aspergillosis)
- Treatment with other recognised T-cell immune suppressants, such as ciclosporin, tumour necrosis factor alpha-blockers, specific monoclonal antibodies (e.g. alemtuzumab) or nucleoside analogues during the last 90 days
- Inherited severe immune deficiency, e.g. chronic granulomatous disease or severe combined immune deficiency

##### Clinical criteria<sup>1</sup>

- The presence of one of the following on CT:  
Dense, well-circumscribed lesion(s) with or without a halo sign  
Air crescent sign  
Cavity

##### Tracheobronchitis

- Tracheobronchial ulceration, nodule, pseudomembrane, plaque or eschar seen on bronchoscopy

##### Mycological criteria

- Mould in sputum, BAL fluid or bronchial brush, indicated by one of the following:  
Recovery of fungal elements indicating a mould of *Aspergillus*  
Recovery by culture of a mould of *Aspergillus*
- Indirect tests (detection of antigen or cell wall constituents)  
Galactomannan antigen in plasma, serum or BAL fluid  
 $\beta$ -1,3-glucan detected in serum (detects other species of fungi, as well as *Aspergillus*)<sup>2</sup>

<sup>1</sup>Must be consistent with the mycological findings and temporally related to current episode. <sup>2</sup>May be useful as a preliminary screening tool for invasive aspergillosis. (BAL = bronchoalveolar lavage)

Adapted from De Pauw B, Walsh TJ, Donnelly JP, et al. Revised definitions of invasive fungal disease from the European Organisation for Research and Treatment of Cancer/Mycoses Study Group. *Clin Infect Dis* 2008; 46:1813–1821.

## Other fungal infections

Mucormycosis may present with a pulmonary syndrome that is clinically indistinguishable from acute IPA. Diagnosis relies on histopathology (where available) and/or culture of the organism from diseased tissue. The principles of treatment are as for other forms of mucormycosis: correction of predisposing factors, antifungal therapy with high-dose lipid amphotericin B or posaconazole (second line), and surgical débridement.

The endemic mycoses (histoplasmosis, coccidioidomycosis, blastomycosis and emeryngomycosis) and cryptococcosis are discussed on pages 345–347. *Pneumocystis jirovecii* pneumonia is described on page 361.

## Tumours of the bronchus and lung

Lung cancer is the most common cause of death from cancer worldwide, causing 2 million deaths per year (Box 17.61). Tobacco use is the major preventable cause. Just as tobacco use and cancer rates are falling in some high-income countries, both smoking and lung cancer are rising in many low- and middle-income countries. The great majority of tumours in the lung are primary lung cancers and, in contrast to many other tumours, the prognosis remains poor, with approximately 40% and 16% of patients surviving at 1 and 5 years respectively.

### Primary tumours of the lung

#### Aetiology

Cigarette smoking is by far the most important cause of lung cancer. It is thought to be directly responsible for at least 85% of cases in the UK, the risk being proportional to the amount smoked and the tar content of cigarettes, but the proportion of cases not related to tobacco exposure is rising. The death rate from the disease in heavy smokers is 40 times that in non-smokers. Risk falls slowly after smoking cessation but remains above that in non-smokers for many years. It is estimated that 1 in 2 smokers dies from a smoking-related disease, about half in middle age. The effect of 'passive' smoking is more difficult to quantify but is currently thought to be a factor in 5% of all lung cancer deaths. Exposure to naturally occurring radon is another risk. The incidence of lung cancer is slightly higher in urban than in rural dwellers, which may reflect differences in atmospheric pollution (including tobacco smoke) or occupation, since a number of industrial materials are associated with lung cancer, such as asbestos, arsenicals and beryllium-containing compounds. In recent years, the strong link between smoking and ill health has led many governments to legislate against smoking in public places, and smoking prevalence and some smoking-related diseases are already declining in these countries.

## Lung cancer

The incidence of lung cancer increased dramatically during the 20th century as a direct result of the tobacco epidemic (Fig. 17.45). In women, smoking prevalence and deaths from lung cancer continue to increase, and more women now die of lung cancer than breast cancer in the United States and the UK.

### 17.61 The burden of lung cancer

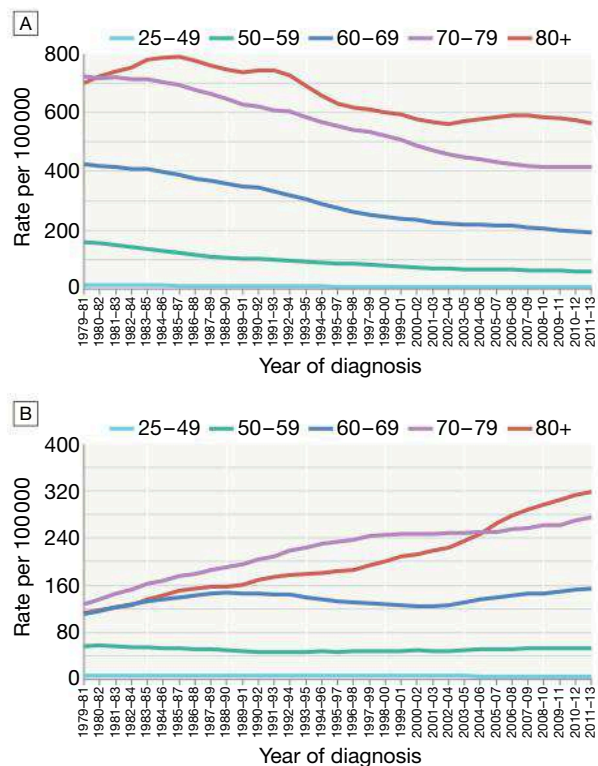

- 1.8 million new cases worldwide each year
- Most common cancer in men
- Rates rising in women:
  - Female lung cancer deaths outnumber male in some Nordic countries
  - Has overtaken breast cancer in several countries
- More than a threefold increase in deaths since 1950
- More than 50% of cases have metastatic disease at diagnosis

## Pathology

Lung cancers arise from the bronchial epithelium or mucous glands. The common cell types are listed in Box 17.62. When the tumour occurs in a large bronchus, symptoms arise early but tumours originating in a peripheral bronchus can grow very large without producing symptoms, resulting in delayed diagnosis. Peripheral squamous tumours may undergo central necrosis and cavitation and may resemble a lung abscess on X-ray (Fig. 17.46). Lung cancer may involve the pleura directly or by lymphatic spread and may extend into the chest wall, invading the intercostal nerves or the brachial plexus and causing pain. Lymphatic spread to mediastinal and supraclavicular lymph nodes often occurs before diagnosis. Blood-borne metastases occur most commonly in liver, bone, brain, adrenals and skin. Even a small primary tumour may cause widespread metastatic deposits and this is a particular characteristic of small-cell lung cancers.

## Clinical features

Lung cancer presents in many different ways, reflecting local, metastatic or paraneoplastic tumour effects.

**Fig. 17.45** Mortality trends from lung cancer in UK, 1979–2013, by age and year of death. **A** Males. **B** Females. Note the decline in mortality from lung cancer in men and increase in mortality in older women towards the end of this period, reflecting changes in smoking habits. ### 17.62 Common cell types in lung cancer

Cell type	%
Adenocarcinoma	35–40
Squamous	25–30
Small-cell	15
Large-cell	10–15

**Fig. 17.46** Large cavitated lung cancer in left lower lobe.

**Cough** This is the most common early symptom. It is often dry, but secondary infection may cause purulent sputum. A change in the character of a smoker's cough, particularly if associated with other new symptoms, should always raise suspicion of lung cancer.

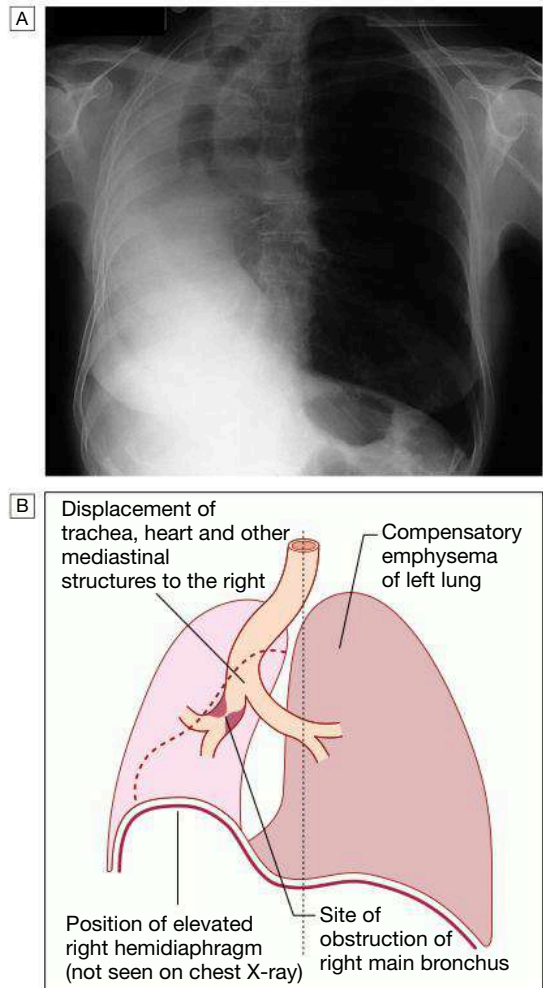

**Haemoptysis** Haemoptysis is common, especially with central bronchial tumours. Although it may be caused by bronchitic infection, haemoptysis in a smoker should always be investigated to exclude a lung cancer. Occasionally, central tumours invade large vessels, causing sudden massive haemoptysis which is invariably a terminal event.

**Bronchial obstruction** This is another common presentation. The clinical and radiological manifestations (Fig. 17.47 and see Fig. 17.5, and Box 17.63) depend on the site and extent of the obstruction, any secondary infection and the extent of coexisting lung disease. Complete obstruction causes collapse of a lobe or lung, with breathlessness, mediastinal displacement and dullness to percussion with reduced breath sounds. Partial bronchial obstruction may cause a monophonic, unilateral wheeze that fails to clear with coughing, and may also impair the drainage of secretions to cause pneumonia or lung abscess as a presenting problem. Pneumonia that recurs at the same site or responds slowly to treatment, particularly in a smoker, should always suggest an underlying lung cancer. Stridor (a harsh inspiratory noise) occurs when the larynx, trachea or a main bronchus is narrowed by the primary tumour or by compression from malignant enlargement of the subcarinal and paratracheal lymph nodes.

**Breathlessness** Breathlessness may be caused by collapse or pneumonia, or by tumour causing a large pleural effusion or compressing a phrenic nerve and leading to diaphragmatic paralysis.

**Pain and nerve entrapment** Pleural pain may indicate malignant pleural invasion, although it can occur with distal infection. Intercostal nerve involvement causes pain in the distribution of a thoracic dermatome. Cancer in the lung apex may cause Horner syndrome (ipsilateral partial ptosis, enophthalmos, miosis and hypohidrosis of the face) due to involvement of the sympathetic nerves to the eye at or above the stellate ganglion. Pancoast syndrome (pain in the inner aspect of the arm, sometimes with small muscle wasting in the hand) indicates malignant destruction of the T1 and C8 roots in the lower part of the brachial plexus by an apical lung tumour.

**Mediastinal spread** Involvement of the oesophagus may cause dysphagia. If the pericardium is invaded, arrhythmia or pericardial effusion may occur. Superior vena cava obstruction by malignant nodes causes

**Fig. 17.47** Collapse of the right lung: effects on neighbouring structures. **A** Chest X-ray. **B** The typical abnormalities are highlighted.

suffusion and swelling of the neck and face, conjunctival oedema, headache and dilated veins on the chest wall and is most commonly due to lung cancer. Involvement of the left recurrent laryngeal nerve by tumours at the left hilum causes vocal cord paralysis, voice alteration and a 'bovine' cough (lacking the normal explosive character). Supraclavicular lymph nodes may be palpably enlarged or identified using ultrasound; if so, a needle aspirate may provide a simple means of cytological diagnosis.

**Metastatic spread** This may lead to focal neurological defects, epileptic seizures, personality change, jaundice, bone pain or skin nodules. Lassitude, anorexia and weight loss usually indicate metastatic spread.

**Finger clubbing** Overgrowth of the soft tissue of the terminal phalanx, leading to increased nail curvature and nail bed fluctuation, is often seen.

**Hypertrophic pulmonary osteoarthropathy (HPOA)** This is a painful periostitis of the distal tibia, fibula, radius and ulna, with local tenderness and sometimes pitting oedema over the anterior shin. X-rays reveal subperiosteal new bone formation. While most frequently associated with lung cancer, HPOA can occur with other tumours.

**Non-metastatic extrapulmonary effects (Box 17.64)** The syndrome of inappropriate antidiuretic hormone secretion (SIADH, p. 624) and ectopic adrenocorticotrophic hormone secretion (p. 684) are usually associated with small-cell lung cancer. Hypercalcaemia may indicate malignant

## i

## 17.63 Causes of large bronchus obstruction

## Common

- Lung cancer or adenoma
- Enlarged tracheobronchial lymph nodes (malignant or tuberculous)
- Inhaled foreign bodies (especially right lung)
- Bronchial casts or plugs consisting of inspissated mucus or blood clot (especially asthma, cystic fibrosis, haemoptysis, debility)
- Collections of mucus or mucopus retained in the bronchi as a result of ineffective expectoration (especially post-operative following abdominal surgery)

## Rare

- Aortic aneurysm
- Giant left atrium
- Pericardial effusion
- Congenital bronchial atresia
- Fibrous bronchial stricture (e.g. following tuberculosis or bronchial surgery/lung transplant)

## i

## 17.64 Non-metastatic extrapulmonary manifestations of lung cancer

## Endocrine (Ch. 20)

- Inappropriate antidiuretic hormone (ADH, vasopressin) secretion, causing hyponatraemia
- Ectopic adrenocorticotrophic hormone secretion
- Hypercalcaemia due to secretion of parathyroid hormone-related peptides
- Carcinoid syndrome
- Gynaecomastia

## Neurological (Ch. 28)

- Polyneuropathy
- Myelopathy
- Cerebellar degeneration
- Myasthenia (Lambert–Eaton syndrome)

## Other

- Digital clubbing
- Hypertrophic pulmonary osteoarthropathy
- Nephrotic syndrome
- Polymyositis and dermatomyositis
- Eosinophilia

bone destruction or production of hormone-like peptides by a tumour. Associated neurological syndromes may occur with any type of lung cancer.

**Investigations**

The main aims of investigation are to confirm the diagnosis, establish the histological cell type and define the extent of the disease.

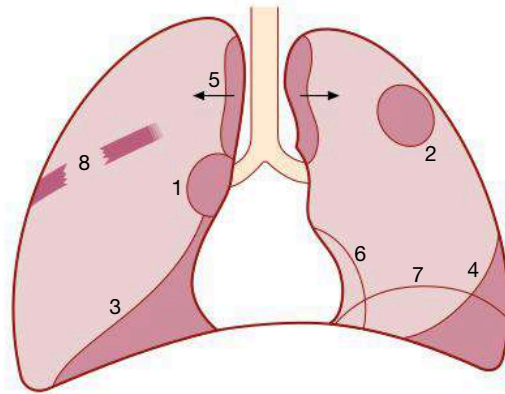

**Imaging**

Lung cancer produces a range of appearances on chest X-ray, from lobar collapse (see Fig. 17.5) to mass lesions, effusion or malignant rib destruction (Fig. 17.48). CT should be performed early, as it may reveal mediastinal or metastatic spread and is helpful for planning biopsy procedures, e.g. in establishing whether a tumour is accessible by bronchoscopy or percutaneous CT-guided biopsy.

**Biopsy and histopathology**

Over half of primary lung tumours can be visualised and sampled directly by biopsy and brushing using a flexible bronchoscope. Bronchoscopy also allows an assessment of operability, from the proximity of central tumours to the main carina (Fig. 17.49).

For tumours that are too peripheral to be accessible by bronchoscope, the yield of 'blind' bronchoscopic washings and brushings from the radiologically affected area is low and percutaneous needle biopsy under CT

**Fig. 17.48 Common radiological presentations of lung cancer.** (1) Unilateral hilar enlargement suggests a central tumour or hilar glandular involvement. However, a peripheral tumour in the apex of a lower lobe can look like an enlarged hilar shadow on the posteroanterior X-ray. (2) Peripheral pulmonary opacity is usually irregular but well circumscribed, and may contain irregular cavitation. It can be very large. (3) Lung lobe or segmental collapse is usually caused by tumour occluding a proximal bronchus. Collapse may also be due to compression of a bronchus by enlarged lymph glands. (4) Pleural effusion usually indicates tumour invasion of the pleural space or, very rarely, infection in collapsed lung tissue distal to a lung cancer. (5) Paratracheal lymphadenopathy may cause widening of the upper mediastinum. (6) A malignant pericardial effusion may cause enlargement of the cardiac shadow. (7) A raised hemidiaphragm may be caused by phrenic nerve palsy. Screening will show paradoxical upward movement when the patient sniffs. (8) Osteolytic rib destruction indicates direct invasion of the chest wall or metastatic spread.

**Fig. 17.49 Bronchoscopic view of a lung cancer.** There is distortion of mucosal folds, partial occlusion of the airway lumen and abnormal tumour tissue.

(or less commonly ultrasound) guidance is a more reliable way to obtain a histological diagnosis. There is a risk of iatrogenic pneumothorax, which may preclude the procedure if there is extensive coexisting emphysema. In patients with a peripheral tumour and enlarged hilar or paratracheal lymph nodes on CT, bronchoscopy with EBUS-guided node sampling may allow both diagnosis and staging.

In patients with pleural effusions, pleural aspiration and biopsy is the preferred investigation. Where facilities exist, thoracoscopy increases yield by allowing targeted biopsies under direct vision. In patients with metastatic disease, the diagnosis can often be confirmed by needle aspiration or biopsy of affected lymph nodes, skin lesions, liver or bone marrow.

**Staging to guide treatment**

The propensity of small-cell lung cancer to metastasise early means these patients are usually not suitable for surgical intervention. In non-small-cell

lung cancer (NSCLC), treatment and prognosis are determined by disease extent, so careful staging is required. CT is used early to detect obvious local or distant spread. Enlarged upper mediastinal nodes may be sampled using an EBUS-equipped bronchoscope or by mediastinoscopy. Nodes in the lower mediastinum can be sampled through the oesophageal wall using endoscopic ultrasound. Combined CT and whole-body FDG-PET (see Fig. 17.6) is commonly used to detect occult but metabolically active metastases. Head CT, radionuclide bone scanning, liver ultrasound and bone marrow biopsy are generally reserved for patients with clinical, haematological or biochemical evidence of tumour spread to these sites. Information on tumour size and nodal and metastatic spread is then collated to assign the patient to one of nine staging groups that determine optimal management and prognosis (Fig. 17.50). Detailed physiological testing is required to assess whether respiratory and cardiac function is sufficient to allow aggressive treatment.

**Management**

Surgical resection carries the best hope of long-term survival but some patients treated with radical radiotherapy and chemotherapy also achieve prolonged remission or cure. In over 75% of cases, treatment with the aim of cure is not possible or is inappropriate due to extensive spread or comorbidity. Such patients are offered palliative therapy and best supportive care. Radiotherapy and, in some cases, chemotherapy can relieve symptoms.

**Surgical treatment**

Accurate preoperative staging, coupled with improvements in surgical and postoperative care, now offers 5-year survival rates of over 80% in stage I disease (N0, tumour confined within visceral pleura) and over 70% in stage II disease, which includes resection in patients with ipsilateral peribronchial or hilar node involvement.

**Radiotherapy**

While much less effective than surgery, radical radiotherapy can offer long-term survival in selected patients with localised disease in whom comorbidity precludes surgery. Radical radiotherapy is usually combined with chemotherapy when lymph nodes are involved (stage III). Highly targeted (stereotactic) radiotherapy may be given in 3–5 treatments for small lesions.

The greatest value of radiotherapy, however, is in the palliation of distressing complications, such as superior vena cava obstruction, recurrent haemoptysis and pain caused by chest wall invasion or by skeletal metastatic deposits. Obstruction of the trachea and main bronchi can also be relieved temporarily. Radiotherapy can be used in conjunction with chemotherapy in the treatment of small-cell carcinoma and is particularly efficient at preventing the development of brain metastases in patients who have had a complete response to chemotherapy.

**Chemotherapy**

The treatment of small-cell carcinoma with combinations of cytotoxic drugs, sometimes with radiotherapy, can increase median survival from 3 months to well over a year. The use of combinations of chemotherapeutic drugs requires considerable skill and should be overseen by multidisciplinary teams of clinical oncologists and specialist nurses. Combination chemotherapy leads to better outcomes than single-agent treatment. Regular cycles of therapy, including combinations of intravenous cyclophosphamide, doxorubicin and vincristine or intravenous cisplatin and etoposide, are commonly used.

In NSCLC chemotherapy is less effective, though platinum-based chemotherapy regimens offer 30% response rates and a modest increase in survival, and are widely used. Some non-small-cell lung tumours, particularly adenocarcinomas in non-smokers, carry detectable pathogenic variants, e.g. in the epidermal growth factor receptor (*EGFR*) gene. Tyrosine kinase inhibitors, such as erlotinib and monoclonal antibodies to *EGFR* (e.g. bevacizumab), show improved treatment responses in metastatic NSCLC and *EGFR* variants, and similar approaches are being developed to target other known genetic abnormalities.

In NSCLC there is some evidence that chemotherapy given before surgery may increase survival and can effectively ‘down-stage’ disease with limited nodal spread. Post-operative chemotherapy is now proven to enhance survival rates when operative samples show nodal involvement by tumour.

Nausea and vomiting are common side-effects of chemotherapy and are best treated with 5-HT<sub>3</sub> receptor antagonists.

**Laser therapy and stenting**

Palliation of symptoms caused by major airway obstruction can be achieved in selected patients using bronchoscopic laser treatment to

	Tumour stage			
	N0 (None)	N1 (Ipsilateral hilar)	N2 (Ipsilateral mediastinal or subcarinal)	N3 (Contralateral or supraclavicular)
T1a (≤1 cm)	IA1 (92%)	IIB (53%)	IIIA (36%)	IIIB (26%)
T1b (>1 to ≤2 cm)	IA2 (83%)			
T1c (>2 to ≤3 cm)	IA3 (77%)			
T2a (>3 to ≤4 cm)	IB (68%)			
T2b (>4 cm to ≤5 cm)	IIA (60%)			
T3 (>5 cm)	IIB (53%)	IIIA (36%)	IIIB (26%)	IIIC (13%)
T4 (>7 cm or invading heart, vessels, oesophagus, carina etc.)				
M1a Lung metastasis/effusion	IVA (10%)			
M1b Single extrathoracic metastasis				
M1c Multiple extrathoracic metastases	IVB (0%)			

Lymph node spread

**Fig. 17.50 Tumour stage and 5-year survival in non-small-cell lung cancer.** The figure shows the relationship between tumour extent (size, lymph node status and metastases) and prognosis (% survival at 5 years for each clinical stage). Based on data from Detterbeck FC, Boffa DJ, Kim AW, Tanoue T. *The eighth edition lung cancer stage classification.* *Chest* 2017; 151:193–203.

clear tumour tissue and allow re-aeration of collapsed lung. The best results are achieved in tumours of the main bronchi. Endobronchial stents can be used to maintain airway patency in the face of extrinsic compression by malignant nodes.

### General aspects of management

The best outcomes are obtained when lung cancer is managed in specialist centres by multidisciplinary teams, including oncologists, thoracic surgeons, respiratory physicians and specialist nurses. Effective communication, pain relief and attention to diet are important. Lung tumours can cause clinically significant depression and anxiety, and these may need specific therapy. The management of non-metastatic endocrine manifestations is described in [Chapter 20](#). When a malignant pleural effusion is present, an attempt should be made to drain the pleural cavity using an intercostal drain; depending upon response to initial drainage, subsequent fluid accumulations can be managed with long-term indwelling pleural catheters or pleurodesis with sclerosing agents such as talc.

### Prognosis

The overall prognosis in lung cancer is very poor, approximately 60% and over 80% of patients dying within 1 and 5 years respectively of diagnosis. The best prognosis is with well-differentiated squamous cell tumours that have not metastasised and are amenable to surgical resection. The clinical features and prognosis of some less common tumours are given in [Box 17.65](#).

## Secondary tumours of the lung

Blood-borne metastatic deposits in the lungs may be derived from many primary carcinomas, in particular breast, kidney, uterus, ovary, testes and thyroid, and also from osteogenic and other sarcomas. These secondary deposits are usually multiple and bilateral. Often there are no respiratory symptoms and the diagnosis is incidental on X-ray. Breathlessness may occur if a considerable amount of lung tissue has been replaced by metastatic tumour. Endobronchial deposits are uncommon but can cause haemoptysis and lobar collapse.

Lymphatic infiltration may develop in carcinoma of the breast, stomach, bowel, pancreas or bronchus. 'Lymphangitic carcinomatosis' causes severe, rapidly progressive breathlessness with marked hypoxaemia. The chest X-ray shows diffuse pulmonary shadowing radiating from the hilar regions, often with septal lines, and CT shows characteristic polygonal thickened interlobular septa. Palliation of breathlessness with opiates may help.

## Tumours of the mediastinum

[Figure 17.51](#) shows the major compartments of the mediastinum and [Box 17.66](#) lists likely causes of a mediastinal mass.

Benign tumours and cysts in the mediastinum are often diagnosed when a chest X-ray is undertaken for some other reason. In general, they do not invade vital structures but may cause symptoms by compressing

17.65 Rare types of lung tumour				
Tumour	Status	Histology	Typical presentation	Prognosis
Adenosquamous carcinoma	Malignant	Tumours with areas of unequivocal squamous and adeno-differentiation	Peripheral or central lung mass	Stage-dependent
Neuro-endocrine (carcinoid) tumour	Low-grade malignant	Neuro-endocrine differentiation	Bronchial obstruction, cough	95% 5-year survival with resection
Bronchial gland adenoma	Benign	Salivary gland differentiation	Tracheobronchial irritation/obstruction	Local resection curative
Bronchial gland carcinoma	Low-grade malignant	Salivary gland differentiation	Tracheobronchial irritation/obstruction	Local recurrence
Hamartoma	Benign	Mesenchymal cells, cartilage	Peripheral lung nodule	Local resection curative
Bronchoalveolar carcinoma	Malignant	Tumour cells line alveolar spaces	Alveolar shadowing, productive cough	Variable, worse if multifocal

**Fig. 17.51** The divisions of the mediastinum. (1) Superior mediastinum. (2) Anterior mediastinum. (3) Middle mediastinum. (4) Posterior mediastinum. Sites of the more common mediastinal tumours are also illustrated. *From Johnson N McL. Respiratory medicine. Oxford: Blackwell Science; 1986.*

the trachea or the superior vena cava. A dermoid cyst may very occasionally rupture into a bronchus.

Malignant mediastinal tumours are distinguished by their power to invade, as well as compress, surrounding structures. As a result, even a small malignant tumour can produce symptoms, although, more commonly, the tumour has attained a considerable size before this happens (Box 17.67). The most common cause is mediastinal lymph node metastasis from lung cancer but lymphomas, leukaemia, malignant thymic tumours and germ-cell tumours can cause similar features. Aortic and innominate aneurysms have destructive features resembling those of malignant mediastinal tumours.

**Investigations**

A benign mediastinal tumour generally appears on chest X-ray as a sharply circumscribed mediastinal opacity encroaching on one or both lung fields (as shown in Fig. 17.52). CT (or MRI) is the investigation of choice for mediastinal tumours (e.g. see Fig. 20.12). A malignant mediastinal tumour seldom has a clearly defined margin and often presents as a general broadening of the mediastinum.

Bronchoscopy may reveal a primary lung cancer causing mediastinal lymphadenopathy. EBUS may be used to guide sampling of peribronchial masses. The posterior mediastinum can be imaged and biopsied via the oesophagus using endoscopic ultrasound.

Mediastinoscopy under general anaesthetic can be used to visualise and biopsy masses in the superior and anterior mediastinum but surgical exploration of the chest, with removal of part or all of the tumour, is often required to obtain a histological diagnosis.

**Management**

Benign mediastinal tumours should be removed surgically because most produce symptoms sooner or later. Cysts may become infected, while neural tumours have the potential to undergo malignant transformation. The operative mortality is low in the absence of coexisting cardiovascular disease, COPD or extreme age.

**Interstitial and infiltrative pulmonary diseases**

**Diffuse parenchymal lung disease**

The diffuse parenchymal lung diseases (DPLDs) are a heterogeneous group of conditions affecting the pulmonary parenchyma (interstitium)

and/or alveolar lumen, which are frequently considered collectively as they share a sufficient number of clinical physiological and radiographic similarities (Box 17.68). They often present with cough, which is typically dry and distressing, and breathlessness, which is often insidious in onset but thereafter relentlessly progressive. Physical examination reveals the presence of inspiratory crackles and in many cases digital clubbing develops. Pulmonary function tests typically show a restrictive ventilatory defect in the presence of small lung volumes and reduced gas transfer. The typical radiographic findings include, in the earliest stages, ground glass and reticulonodular shadowing, with progression to honeycomb cysts and traction bronchiectasis. While these appearances may be seen on a 'plain' chest X-ray, they are most easily appreciated on HRCT, which has assumed a central role in the evaluation of DPLD (Fig. 17.53). The current classification is shown in Figure 17.54 and the potential differential diagnoses in Box 17.69. Common features of interstitial lung disease in old age are shown in Box 17.70.

## Idiopathic interstitial pneumonias

The idiopathic interstitial pneumonias represent a major subgroup of DPLD that are grouped together as a result of their unknown aetiology (Box 17.71). They are often distinguished by the predominant histological pattern on tissue biopsy; hence they are frequently referred to by their pathological description, e.g. usual interstitial pneumonia (UIP) or non-specific interstitial pneumonia (NSIP). The most important of these is idiopathic pulmonary fibrosis.

### Idiopathic pulmonary fibrosis

Idiopathic pulmonary fibrosis (IPF) is defined as a progressive fibrosing interstitial pneumonia of unknown cause, occurring in adults and associated with the histological or radiological pattern of UIP. Important differentials include fibrosing diseases caused by occupational exposure, medication or connective tissue diseases, which must be excluded by careful history, examination and investigation.

The histological features of the condition are suggestive of repeated episodes of focal damage to the alveolar epithelium consistent with an autoimmune process but the aetiology remains elusive: speculation has included exposure to viruses (e.g. Epstein–Barr virus), occupational dusts (metal or wood), drugs (antidepressants) or chronic gastro-oesophageal

Fig. 17.53 Algorithm for the investigation of patients with interstitial lung disease following initial clinical and chest X-ray examination.

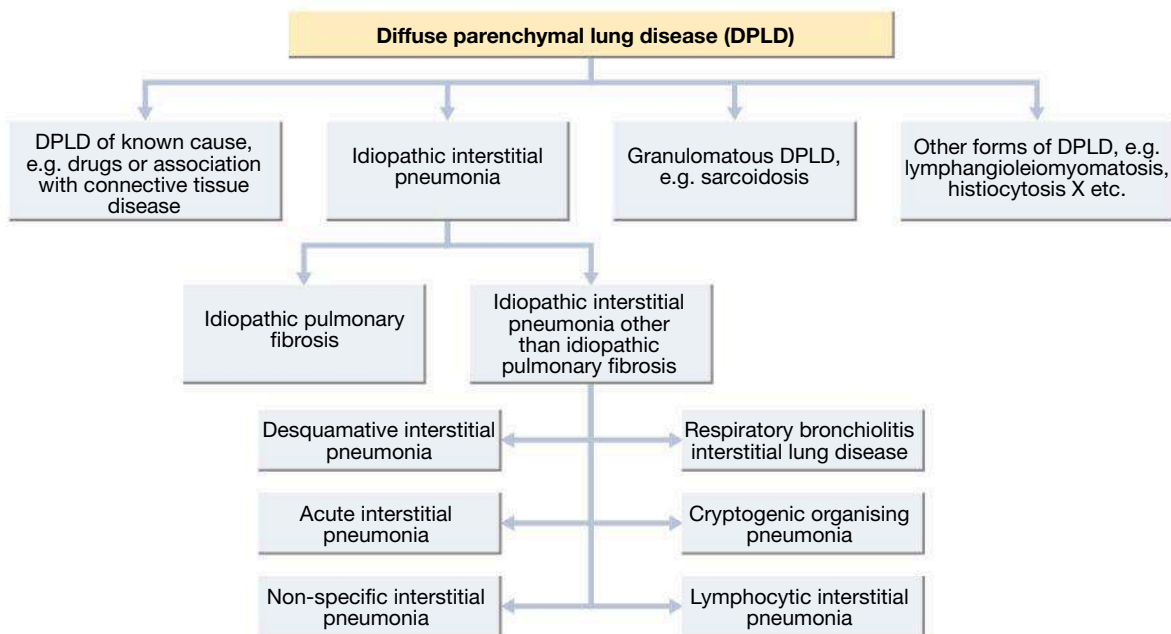

Fig. 17.54 Classification of diffuse parenchymal lung disease.

**17.69 Conditions that mimic diffuse parenchymal lung disease**
**Infection**

- Viral pneumonia
- *Pneumocystis jirovecii*
- *Mycoplasma pneumoniae*
- Tuberculosis
- Parasite, e.g. filariasis
- Fungal infection

**Malignancy**

- Leukaemia and lymphoma
- Lymphangitic carcinomatosis
- Multiple metastases
- Bronchoalveolar carcinoma

**Pulmonary oedema**
**Aspiration pneumonitis**

**17.70 Interstitial lung disease in old age**

- **Idiopathic pulmonary fibrosis:** the most common interstitial lung disease, with a poor prognosis.
- **Chronic aspiration pneumonitis:** must always be considered in older patients presenting with bilateral basal shadowing on a chest X-ray.
- **Granulomatosis with polyangiitis (GPA):** a rare condition but more common in old age. Renal involvement is more common at presentation and upper respiratory problems are fewer.
- **Asbestosis:** symptoms may appear only in old age because of the prolonged latent period between exposure and disease.
- **Drug-induced interstitial lung disease:** more common, presumably because of the increased chance of exposure to multiple drugs.
- **Rarer interstitial disease:** sarcoidosis, idiopathic pulmonary haemosiderosis, alveolar proteinosis and eosinophilic pneumonia rarely present.
- **Increased dyspnoea:** coexistent muscle weakness, chest wall deformity (e.g. thoracic kyphosis) and deconditioning may all exacerbate dyspnoea associated with interstitial lung disease.
- **Surgical lung biopsy:** often inappropriate in the very frail. A diagnosis therefore frequently depends on clinical and high-resolution computed tomography findings alone.

reflux. Familial cases are rare but genetic factors that control the inflammatory and fibrotic response are likely to be important. There is a strong association with cigarette smoking.

**Clinical features**

IPF usually presents in the older adult and is uncommon before the age of 50 years. With the advent of widespread CT scanning it may present as an incidental finding in an otherwise asymptomatic individual but more typically presents with progressive breathlessness (which may have been insidious) and a non-productive cough. Constitutional symptoms are unusual. Clinical findings include finger clubbing and the presence of bi-basal fine late inspiratory crackles likened to the unfastening of Velcro.

**Investigations**

These are summarised in [Box 17.72](#). Established IPF will be apparent on chest X-ray as a bilateral lower lobe and subpleural reticular shadowing. The chest X-ray may be normal in individuals with early or limited disease, however. HRCT typically demonstrates a patchy, predominantly peripheral, subpleural and basal reticular pattern and, in more advanced disease, the presence of honeycombing cysts and traction bronchiectasis ([Fig. 17.55](#)). When these features are present, HRCT has a high positive predictive value for the diagnosis of IPF and recourse to biopsy is seldom necessary. HRCT appearances may also be sufficiently characteristic to suggest an alternative diagnosis such as hypersensitivity pneumonitis or sarcoidosis. The presence of pleural plaques may suggest asbestosis.

Pulmonary function tests classically show a restrictive defect with reduced lung volumes and gas transfer. However, lung volumes may be preserved in patients with concomitant emphysema. Dynamic tests are useful to document exercise tolerance and demonstrate exercise-induced arterial hypoxaemia, but as IPF advances, arterial hypoxaemia and hypocapnia are present at rest.

**17.71 Idiopathic interstitial pneumonias**

Clinical diagnosis	Notes
<b>Usual interstitial pneumonia (UIP)</b>	Idiopathic pulmonary fibrosis – see text
<b>Non-specific interstitial pneumonia (NSIP)</b>	See page 537
<b>Respiratory bronchiolitis–interstitial lung disease</b>	More common in men and smokers. Usually presents at age 40–60 years. Smoking cessation may lead to improvement. Natural history unclear
<b>Acute interstitial pneumonia</b>	Often preceded by viral upper respiratory tract infection. Severe exertional dyspnoea, widespread pneumonic consolidation and diffuse alveolar damage on biopsy. Prognosis often poor
<b>Desquamative interstitial pneumonia (DIP)</b>	More common in men and smokers. Presents at age 40–60 years. Insidious onset of dyspnoea. Clubbing in 50%. Biopsy shows increased macrophages in alveolar space, septal thickening and type II pneumocyte hyperplasia. Prognosis generally good
<b>Cryptogenic organising pneumonia ('bronchiolitis obliterans organising pneumonia' – BOOP)</b>	Presents as clinical and radiological pneumonia. Systemic features and markedly raised erythrocyte sedimentation rate common. Finger clubbing absent. Biopsy shows florid proliferation of immature collagen (Masson bodies) and fibrous tissue. Response to glucocorticoids classically excellent
<b>Lymphocytic interstitial pneumonia (LIP)</b>	More common in women, slow onset over years. Investigate for associations with connective tissue disease or HIV. Unclear whether glucocorticoids are helpful

Bronchoscopy is seldom indicated unless there is serious consideration of differential diagnoses of infection or a malignant process; lymphocytosis may suggest chronic hypersensitivity pneumonitis. The tissue samples obtained by transbronchial lung biopsy are invariably insufficient to be of value, and if tissue is required, a surgical lung biopsy should be sought. Lung biopsy should be considered in cases of diagnostic uncertainty or with atypical features. UIP is the histological pattern predominantly encountered in IPF ([Fig. 17.56](#)); however, it is also found in asbestosis, hypersensitivity pneumonitis, connective tissue diseases and drug reactions.

It is not uncommon to identify a mildly positive antinuclear antibody (ANA) or anti-cyclic citrullinated peptide 2 (anti-CCP2) and repeat serological testing may be performed, as lung disease may precede the appearance of connective tissue disease.

**Management**

The management options for IPF are improving. If the vital capacity is between 50% and 80% predicted, patients may be offered either pirfenidone (an antifibrotic agent) or nintedanib (a tyrosine kinase inhibitor). Both of these agents have been shown to reduce the rate of decline in lung function. Patients taking pirfenidone should be advised to avoid direct exposure to sunlight and use photoprotective clothing and high-protection sunscreens. Nintedanib may be accompanied by diarrhoea. Neither drug improves cough or breathlessness and treatment should be discontinued if lung function declines by more than 10% over the first year of treatment. Medication to control gastro-oesophageal reflux may improve

the cough. Current smokers should be apprised of the increased risk of lung cancer and advised to stop. Influenza and pneumococcal vaccination should be recommended. Patients should be encouraged to exercise and participate in pulmonary rehabilitation using ambulatory oxygen if appropriate. Domiciliary oxygen should be considered for palliation of breathlessness in severe cases. Where appropriate, lung transplantation should be considered. The optimum treatment for acute exacerbations is unknown. Treatment is largely supportive. Broad-spectrum antibiotics may be combined with glucocorticoids and sometimes additional immunosuppression but there are few data to support this approach.

### Prognosis

The natural history is usually one of steady decline; however, some patients are prone to exacerbations accompanied by an acute deterioration in

breathlessness, disturbed gas exchange, and new ground glass changes or consolidation on HRCT. In advanced disease, central cyanosis is detectable and patients may develop pulmonary hypertension and features of right heart failure. A median survival of 3 years is widely quoted; the rate of disease progression varies considerably, however, from death

within a few months to survival with minimal symptoms for many years. Serial lung function testing may provide useful prognostic information, relative preservation of lung function suggesting longer survival and significantly impaired gas transfer and/or desaturation on exercise heralding a poorer prognosis. The finding of high numbers of fibroblastic foci on biopsy suggests a more rapid deterioration.

**Non-specific interstitial pneumonia**

The clinical picture of fibrotic NSIP is similar to that of IPF, although patients tend to be women and younger in age. As with UIP, the condition may present as an isolated idiopathic pulmonary condition, but an NSIP pattern is often associated with connective tissue disease, certain drugs, chronic hypersensitivity pneumonitis or HIV infection and care must be taken to exclude these possibilities. As with UIP, the pulmonary condition may precede the appearance of connective tissue disease. HRCT findings are less specific than with IPF and lung biopsy may be required. The prognosis is significantly better than that of IPF, particularly in the cellular form of the condition, and the 5-year mortality rate is typically less than 15%.

**Sarcoidosis**

Sarcoidosis is a multisystem granulomatous disorder of unknown aetiology that is characterised by the presence of non-caseating granulomas (Fig. 17.57). The condition is more frequently described in colder parts of northern Europe. It also appears to be more common and more severe in those from an African Caribbean background. The tendency for sarcoidosis to present in the spring and summer has led to speculation about the role of infective agents, including mycobacteria, propionibacteria and viruses, but the cause remains elusive. Genetic susceptibility is supported by familial clustering; a range of class II HLA alleles confer protection from,

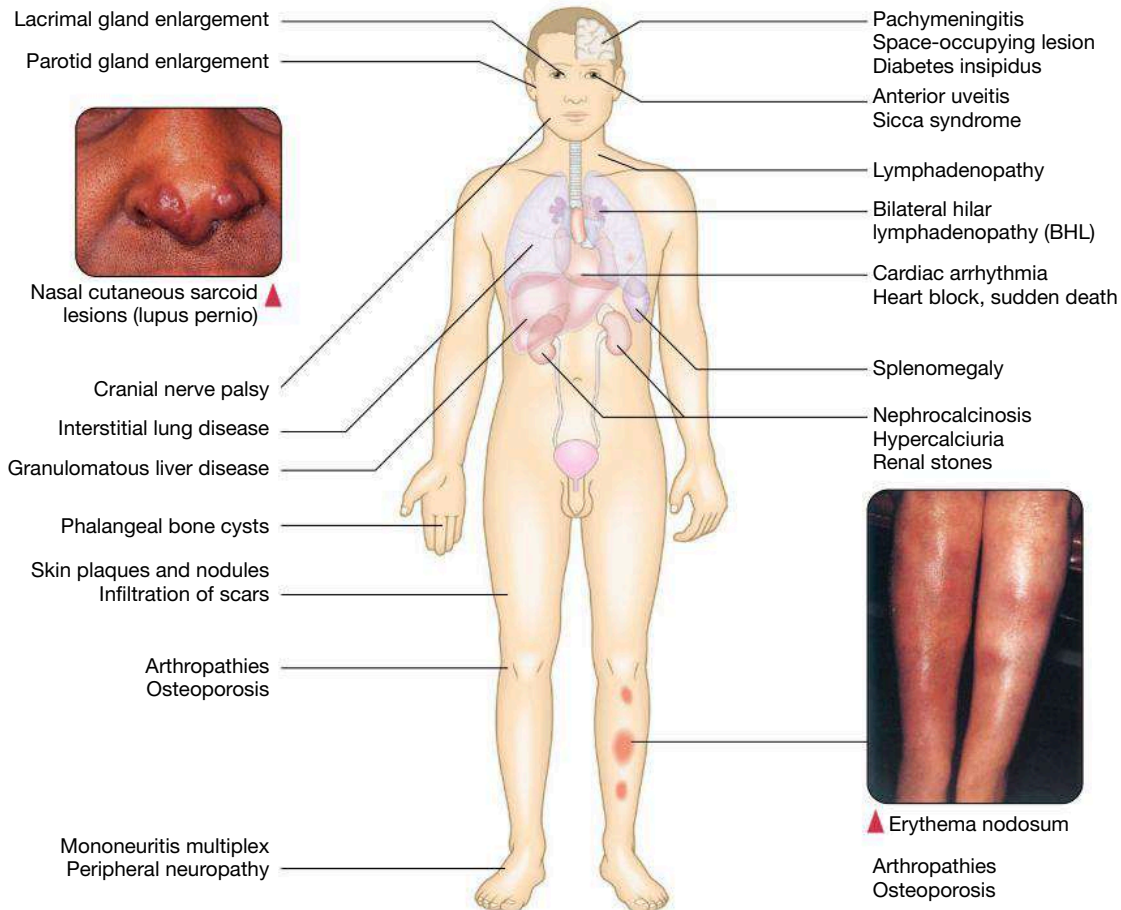

or susceptibility to, the condition. Sarcoidosis occurs less frequently in smokers. It may be associated with common variable immunodeficiency.

**Clinical features**

Sarcoidosis is considered with other DPLDs, as over 90% of cases affect the lungs, but the condition can involve almost any organ (Fig. 17.58 and Box 17.73). Löfgren syndrome – an acute illness characterised by

**Fig. 17.57 Sarcoidosis of the lung.** Histology showing non-caseating granulomas (arrows). Courtesy of Dr William Wallace, Department of Pathology, Royal Infirmary of Edinburgh.

**Fig. 17.58 Possible systemic involvement in sarcoidosis.** Inset (Erythema nodosum): From Savin JA, Hunter JAA, Hepburn NC. *Skin signs in clinical medicine*. London: Mosby-Wolfe; 1997.

### 17.73 Presentation of sarcoidosis

- Asymptomatic: abnormal routine chest X-ray (~30%) or abnormal liver function tests
- Respiratory and constitutional symptoms (20%–30%)
- Erythema nodosum and arthralgia (20%–30%)
- Ocular symptoms (5%–10%)
- Skin sarcoidosis (including lupus pernio) (5%)
- Superficial lymphadenopathy (5%)
- Other (1%), e.g. hypercalcaemia, diabetes insipidus, cranial nerve palsies, cardiac arrhythmias, nephrocalcinosis

erythema nodosum, peripheral arthropathy, uveitis, bilateral hilar lymphadenopathy (BHL), lethargy and occasionally fever – is often seen in young women. Alternatively, BHL may be detected in an otherwise asymptomatic individual undergoing a chest X-ray for other purposes. Pulmonary disease may also present in a more insidious manner with cough, exertional breathlessness and radiographic infiltrates; chest auscultation is often surprisingly unremarkable. Fibrosis occurs in around 20% of cases of pulmonary sarcoidosis and may cause a silent loss of lung function. Pleural disease is uncommon and finger clubbing is not a feature. Complications such as bronchiectasis, aspergilloma, pneumothorax, pulmonary hypertension and cor pulmonale have been reported but are rare.

#### Investigations

Lymphopenia is characteristic and liver function tests may be mildly deranged. Hypercalcaemia may be present (reflecting increased formation of calcitriol – 1,25-dihydroxyvitamin D – by alveolar macrophages), particularly if the patient has been exposed to strong sunlight. Hypercalciuria may also be seen and may lead to nephrocalcinosis. Serum angiotensin-converting enzyme (ACE) may provide a non-specific marker of disease activity and can assist in monitoring the clinical course. Chest radiography has been used to stage sarcoidosis (Box 17.74). In patients with pulmonary infiltrates, pulmonary function testing may show a restrictive defect accompanied by impaired gas exchange. Exercise tests may reveal oxygen desaturation. Bronchoscopy may demonstrate a ‘cobblestone’ appearance of the mucosa, and bronchial and transbronchial biopsies usually show non-caseating granulomas, as may samples from the mediastinal nodes obtained by EBUS. Bronchoalveolar lavage fluid typically contains an increased CD4:CD8 T-cell ratio. Characteristic HRCT appearances include reticulonodular opacities that follow a perilymphatic distribution centred on bronchovascular bundles and the subpleural areas. FDG-PET scanning can detect extrapulmonary disease.

The occurrence of erythema nodosum with BHL on chest X-ray is often sufficient for a confident diagnosis, without recourse to a tissue biopsy. Similarly, a typical presentation with classical HRCT features may also be accepted. In other instances, however, the diagnosis should be confirmed by histological examination of the involved organ. The presence of anergy (e.g. to tuberculin skin tests) may support the diagnosis.

#### Management

Patients who present with acute illness and erythema nodosum should receive NSAIDs and, on occasion, a short course of glucocorticoids. The majority of patients enjoy spontaneous remission and so, if there is no evidence of organ damage, systemic glucocorticoid therapy can be withheld for 6 months. However, prednisolone (at a starting dose of 20–40mg/day) should be commenced immediately in the presence of hypercalcaemia, pulmonary impairment, renal impairment and uveitis. Topical glucocorticoids may be useful in cases of mild uveitis, and inhaled glucocorticoids have been used to shorten the duration of systemic glucocorticoid use in asymptomatic parenchymal sarcoidosis. Patients should be warned that strong sunlight may precipitate hypercalcaemia and endanger renal function.

### 17.74 Chest X-ray changes in sarcoidosis

#### Stage I: BHL (usually symmetrical); paratracheal nodes often enlarged

- Often asymptomatic but may be associated with erythema nodosum and arthralgia. The majority of cases resolve spontaneously within 1 year

#### Stage II: BHL and parenchymal infiltrates

- Patients may present with breathlessness or cough. The majority of cases resolve spontaneously

#### Stage III: parenchymal infiltrates without BHL

- Disease less likely to resolve spontaneously

#### Stage IV: pulmonary fibrosis

- Can cause progression to ventilatory failure, pulmonary hypertension and cor pulmonale

(BHL = bilateral hilar lymphadenopathy)

Features suggesting a less favourable outlook include age over 40, African Caribbean ancestry, persistent symptoms for more than 6 months, the involvement of more than three organs, lupus pernio (see Fig. 17.58) and a stage III/IV chest X-ray. In patients with severe disease, methotrexate (10–20mg/week), azathioprine (50–150mg/day) and specific tumour necrosis factor alpha (TNF- $\alpha$ ) inhibitors have been effective. Chloroquine, hydroxychloroquine and low-dose thalidomide may be useful in cutaneous sarcoidosis with limited pulmonary involvement. Selected patients may be referred for consideration of single lung transplantation. The overall mortality is low (1%–5%) and usually reflects cardiac involvement or pulmonary fibrosis.

## Lung diseases due to systemic inflammatory disease

### The acute respiratory distress syndrome

See page 201.

### Respiratory involvement in connective tissue disorders

Pulmonary complications of connective tissue disease are common, affecting the airways, alveoli, pulmonary vasculature, diaphragm and chest wall muscles, and the chest wall itself. In some instances, pulmonary disease may precede the appearance of the connective tissue disorder (Box 17.75). Indirect associations between connective tissue disorders and respiratory complications include those due to disease in other organs, e.g. thrombocytopenia causing haemoptysis; pulmonary toxic effects of drugs used to treat the connective tissue disorder (e.g. gold and methotrexate); and secondary infection due to the disease itself, neutropenia or immunosuppressive drug regimens.

#### Rheumatoid disease

Pulmonary involvement in rheumatoid disease is important, accounting for around 10%–20% of the mortality associated with the condition. The majority of cases occur within 5 years of the rheumatological diagnosis but pulmonary manifestations may precede joint involvement in 10%–20%. Pulmonary fibrosis is the most common pulmonary manifestation. All forms of interstitial disease have been described but NSIP is probably the most common. A rare variant of localised upper lobe fibrosis and cavitation is occasionally seen.

Pleural effusion is common, especially in men with seropositive disease. Effusions are usually small and unilateral, but can be large and bilateral. Most resolve spontaneously. Biochemical testing shows an exudate with markedly reduced glucose levels and raised lactate dehydrogenase (LDH). Effusions that fail to resolve spontaneously may respond to a short course of oral prednisolone (30–40mg/day) but some become chronic.

### 17.75 Respiratory complications of connective tissue disorders

Disorder	Airways	Parenchyma	Pleura	Diaphragm and chest wall
<b>Rheumatoid arthritis</b>	Bronchitis, obliterative bronchiolitis, bronchiectasis, crico-arytenoid arthritis, stridor	Pulmonary fibrosis, nodules, upper lobe fibrosis, infections	Pleurisy, effusion, pneumothorax	Poor healing of intercostal drain sites
<b>Systemic lupus erythematosus</b>	–	Pulmonary fibrosis, 'vasculitic' infarcts	Pleurisy, effusion	Diaphragmatic weakness (shrinking lungs)
<b>Systemic sclerosis</b>	Bronchiectasis	Pulmonary fibrosis, aspiration pneumonia	–	Cutaneous thoracic restriction (hidebound chest)
<b>Dermatomyositis/polymyositis</b>	Lung cancer	Pulmonary fibrosis	–	Intercostal and diaphragmatic myopathy
<b>Granulomatosis with polyangiitis (GPA)</b>	Epistaxis, nasal discharge crusting, subglottic stenosis	Pulmonary nodules that may cavitate	Pleurisy, effusion	–

**Fig. 17.59 Rheumatoid (necrobiotic) nodules.** Thoracic CT just below the level of the main carina, showing the typical appearance of peripheral pleural-based nodules (arrows). The nodule in the left lower lobe shows characteristic cavitation.

Rheumatoid pulmonary nodules are usually asymptomatic and detected incidentally on imaging. They are most often multiple and subpleural in site (Fig. 17.59). Solitary nodules can mimic primary lung cancer; when multiple, the differential diagnoses include pulmonary metastatic disease. Cavitation raises the possibility of TB and predisposes to pneumothorax. The combination of rheumatoid nodules and pneumococcosis is known as Caplan syndrome.

Bronchitis and bronchiectasis are both more common in rheumatoid patients. Rarely, the potentially fatal condition called obliterative bronchiolitis may develop. Bacterial lower respiratory tract infections are frequent. Treatments given for rheumatoid arthritis may also be relevant: glucocorticoid therapy predisposes to infections, methotrexate may cause pulmonary fibrosis, and anti-TNF therapy has been associated with the reactivation of TB.

#### Systemic lupus erythematosus

Pleuropulmonary involvement is more common in lupus than in any other connective tissue disorder and may be a presenting problem, when it is sometimes attributed incorrectly to infection or pulmonary embolism. Up to two-thirds of patients have repeated episodes of pleurisy, with or without effusions. Effusions may be bilateral and may also involve the pericardium.

The most serious manifestation of lupus is an acute pneumonitis that may be associated with diffuse alveolar haemorrhage. This condition is life-threatening and requires either immediate immunosuppression with glucocorticoids or a step-up in immunosuppressive treatment, if already started.

Pulmonary fibrosis is a relatively uncommon manifestation of systemic lupus erythematosus (SLE). Some patients with SLE present with exertional dyspnoea and orthopnoea but without overt signs of pulmonary fibrosis. The chest X-ray reveals elevated diaphragms and pulmonary function testing shows reduced lung volumes. This condition has been described as 'shrinking lungs' and has been attributed to diaphragmatic myopathy.

SLE patients with antiphospholipid antibodies are at increased risk of venous and pulmonary thromboembolism and require life-long anticoagulation.

#### Systemic sclerosis

Most patients with systemic sclerosis eventually develop diffuse pulmonary fibrosis; at necropsy more than 90% have evidence of lung fibrosis. In some patients it is indolent, but when progressive, as in IPF, the median survival time is around 4 years. Pulmonary fibrosis is rare in CREST syndrome but isolated pulmonary hypertension may develop.

Other pulmonary complications include recurrent aspiration pneumonias secondary to oesophageal disease. Rarely, sclerosis of the skin of the chest wall may be so extensive and cicatrising as to restrict chest wall movement – the so-called 'hidebound chest'.

#### Pulmonary eosinophilia and vasculitides

Pulmonary eosinophilia refers to the association of radiographic (usually pneumonic) abnormalities and peripheral blood eosinophilia. The term encompasses a group of disorders of different aetiology (Box 17.76). Eosinophils are the predominant cell recovered in sputum or BAL, and eosinophil products are likely to be the prime mediators of tissue damage.

#### Acute eosinophilic pneumonia

Acute eosinophilic pneumonia is an acute febrile illness (of less than 5 days' duration), characterised by diffuse pulmonary infiltrates and hypoxic respiratory failure. The pathology is usually that of diffuse alveolar damage. Diagnosis is confirmed by BAL, which characteristically demonstrates >25% eosinophils. The condition is usually idiopathic but drug reactions should be considered. Glucocorticoids invariably induce prompt and complete resolution.

#### Chronic eosinophilic pneumonia

Chronic eosinophilic pneumonia typically presents in an insidious manner with malaise, fever, weight loss, breathlessness and unproductive cough. It is more common in middle-aged females. The classical chest X-ray appearance has been likened to the photographic negative of pulmonary oedema with bilateral, peripheral and predominantly upper lobe

parenchymal shadowing. The peripheral blood eosinophil count is almost always very high, and the erythrocyte sedimentation rate (ESR) and total serum IgE are elevated. BAL reveals a high proportion of eosinophils in the lavage fluid. Response to prednisolone (20–40 mg/day) is usually dramatic. Prednisolone can usually be withdrawn after a few weeks without relapse but long-term, low-dose therapy is occasionally necessary.

### Tropical pulmonary eosinophilia

Tropical pulmonary eosinophilia occurs as a result of a mosquito-borne filarial infection with *Wuchereria bancrofti* or *Brugia malayi* (p. 335). The condition presents with fever, weight loss, dyspnoea and asthma-like symptoms. The peripheral blood eosinophilia is marked, as is the elevation of total IgE. High antifilarial antibody titres are seen. The diagnosis may be confirmed by a response to treatment with diethylcarbamazine (6 mg/kg daily for 3 weeks). Tropical pulmonary eosinophilia must be distinguished from infection with *Strongyloides stercoralis*, in which glucocorticoids may cause a life-threatening hyperinfection syndrome. Ascariasis ('larva migrans') and other hookworm infestations are covered in Chapter 13.

### Granulomatosis with polyangiitis

Granulomatosis with polyangiitis (GPA, formerly referred to as Wegener's granulomatosis) is a rare vasculitic and granulomatous condition described in Chapter 26). The lung is commonly involved in systemic forms of the disease but a limited pulmonary form may also occur. Respiratory symptoms include cough, haemoptysis and chest pain. Associated upper respiratory tract manifestations include nasal discharge and crusting, and otitis media. Fever, weight loss and anaemia are common. Radiological features include multiple nodules and cavitation that may resemble primary or metastatic carcinoma, or a pulmonary abscess. Tissue biopsy confirms the distinctive pattern of necrotising granulomas and necrotising vasculitis. Other respiratory complications include tracheal subglottic stenosis and saddle nose deformity. The differential diagnoses include mycobacterial and fungal infection and other forms of pulmonary vasculitis, including polyarteritis nodosa (pulmonary infarction), microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis (EGPA: marked tissue eosinophilia and association with asthma), necrotising sarcoidosis, bronchocentric granulomatosis and lymphomatoid granulomatosis.

### Goodpasture's disease

This describes the association of pulmonary haemorrhage and glomerulonephritis, in which IgG antibodies bind to the glomerular or

alveolar basement membranes. Pulmonary disease usually precedes renal involvement and includes radiographic infiltrates and hypoxia with or without haemoptysis. It occurs more commonly in men and almost exclusively in smokers.

## Lung diseases due to irradiation and drugs

### Radiotherapy

Targeting radiotherapy to certain tumours is inevitably accompanied by irradiation of normal lung tissue. Although delivered in divided doses, the effects are cumulative. Acute radiation pneumonitis is typically seen within 6–12 weeks and presents with cough and dyspnoea. This may resolve spontaneously but responds to glucocorticoid treatment. Chronic interstitial fibrosis may present several months later with symptoms of exertional dyspnoea and cough. Changes are often confined to the area irradiated but may be bilateral. Established post-irradiation fibrosis does not usually respond to glucocorticoid treatment. The pulmonary effects of radiation are exacerbated by treatment with cytotoxic drugs, and the phenomenon of 'recall pneumonitis' describes the appearance of radiation injury in a previously irradiated area when chemotherapy follows radiotherapy. If the patient survives, there are long-term risks of lung cancer.

### Drugs

Drugs may cause a variety of pulmonary conditions (Box 17.77). Pulmonary fibrosis may occur in response to a variety of drugs but is seen most frequently with bleomycin, methotrexate, amiodarone and nitrofurantoin. Eosinophilic pulmonary reactions can also be caused by drugs. The pathogenesis may be an immune reaction similar to that in hypersensitivity pneumonitis, which specifically attracts large numbers of eosinophils into the lungs. This type of reaction is well described as a rare reaction to a variety of antineoplastic agents (e.g. bleomycin), antibiotics (e.g. sulphonamides), sulfasalazine and the anticonvulsants phenytoin and carbamazepine. Patients usually present with breathlessness, cough and fever. The chest X-ray characteristically shows

17.76 Pulmonary eosinophilia	
<b>Extrinsic (cause known)</b>	
<ul style="list-style-type: none"> <li>• Helminths: e.g. <i>Ascaris</i>, <i>Toxocara</i>, <i>Filaria</i></li> <li>• Drugs: nitrofurantoin, para-aminosalicylic acid (PAS), sulfasalazine, imipramine, chlorpropamide, phenylbutazone</li> <li>• Fungi: e.g. <i>Aspergillus fumigatus</i> causing allergic bronchopulmonary aspergillosis</li> </ul>

(ARDS = acute respiratory distress syndrome; NSAIDs = non-steroidal anti-inflammatory drugs)	

patchy shadowing. Most cases resolve completely on withdrawal of the drug, but if the reaction is severe, rapid resolution can be obtained with glucocorticoids.

Drugs may also cause other lung diseases, such as asthma, pulmonary haemorrhage, pleural effusion and, rarely, pleural thickening. An ARDS-like syndrome of acute non-cardiogenic pulmonary oedema may present with dramatic onset of breathlessness, severe hypoxaemia and signs of alveolar oedema on the chest X-ray. This syndrome has been reported most frequently in cases of opiate overdose in injection drug users but also after salicylate overdose, and there are occasional reports of its occurrence after therapeutic doses of drugs, including hydrochlorothiazides and some cytotoxic agents.

## Rare interstitial lung diseases

See [Box 17.78](#).

## Occupational and environmental lung disease

The role of occupation and environmental exposure in lung disease is a particularly important area of respiratory medicine. Occupational lung disease is common and, in addition to the challenges of its diagnosis and management, often involves discussions about the workplace and, in some circumstances, litigation. Many countries encourage the registration of cases of occupational lung disease.

## Occupational airway disease

### Occupational asthma

Occupational asthma is asthma that results from specific workplace sensitizers and not asthma exacerbated by occupational irritants. It is

responsible for 10% of adult-onset asthma and should be considered in any individual of working age who develops new-onset asthma, particularly if the individual reports improvement in asthma symptoms during periods away from work, e.g. at weekends and on holidays. Workers in certain occupations appear to be at particularly high risk ([Box 17.79](#)) and the condition is more common in smokers and atopic individuals. Depending on the intensity of exposure, asthmatic symptoms usually develop within the first few years of employment but are classically preceded by a latent period. Symptoms of rhinoconjunctivitis often precede the development of asthma. When occupational asthma follows exposure to high-molecular-weight proteins, sensitisation may be demonstrated by skin testing or measurement of specific IgE to the agent in question. Confirmation of occupational asthma should be sought from lung function tests. This usually involves serial recording of peak flow at work and home at least four times per day for a minimum of 3 weeks and, if possible, including a holiday period away from work ([Fig. 17.60](#)). In certain circumstances, specific challenge tests are required to confirm the diagnosis.

It may be possible to remove the worker from the implicated agent, but when this cannot be done, consideration of personal protective equipment and workplace hygiene may allow the worker to retain their job

### 17.79 Occupational asthma

#### Most frequently reported causative agents

- Isocyanates
- Flour and grain dust
- Colophony and fluxes
- Latex
- Animals
- Aldehydes
- Wood dust

#### Workers most commonly reported to occupational asthma schemes

- Paint sprayers
- Bakers and pastry-makers
- Nurses
- Chemical workers

### 17.78 Rare interstitial lung diseases

Disease	Presentation	Chest X-ray	Course
<b>Idiopathic pulmonary haemosiderosis</b>	Haemoptysis, breathlessness, anaemia	Bilateral infiltrates, often perihilar Diffuse pulmonary fibrosis	Rapidly progressive in children Slow progression or remission in adults Death from massive pulmonary haemorrhage or cor pulmonale and respiratory failure
<b>Alveolar proteinosis</b>	Breathlessness and cough Occasionally fever, chest pain and haemoptysis	Diffuse bilateral shadowing, often more pronounced in the hilar regions Air bronchogram	Spontaneous remission in one-third Whole-lung lavage or granulocyte-macrophage colony-stimulating factor (GM-CSF) therapy may be effective
<b>Langerhans cell histiocytosis (histiocytosis X)</b>	Breathlessness, cough, pneumothorax	Diffuse interstitial shadowing progressing to honeycombing	Course unpredictable but may progress to respiratory failure Smoking cessation may be followed by significant improvement Poor response to immunosuppressive treatment
<b>Neurofibromatosis</b>	Breathlessness and cough in a patient with multiple organ involvement with neurofibromas, including skin	Bilateral reticulonodular shadowing of diffuse interstitial fibrosis	Slow progression to death from respiratory failure Poor response to glucocorticoid therapy
<b>Alveolar microlithiasis</b>	May be asymptomatic Breathlessness and cough	Diffuse calcified micronodular shadowing more pronounced in the lower zones	Slowly progressive to cor pulmonale and respiratory failure May stabilise in some
<b>Lymphangioleiomyomatosis (LAM)</b>	Haemoptysis, breathlessness, pneumothorax and chylous effusion in females	Diffuse bilateral shadowing CT shows characteristic thin-walled cysts with well-defined walls throughout both lungs	Progressive to death within 10 years Oestrogen ablation and progesterone therapy of doubtful value Consider lung transplantation
<b>Pulmonary tuberous sclerosis</b>	Very similar to lymphangioleiomyomatosis, except occasionally occurs in men		

and livelihood. Specialist follow-up in such situations is highly advisable. Where reduction or avoidance of exposure fails to bring about resolution, the management is identical to that of any patient with asthma.

### Irritant-induced asthma

Irritant-induced asthma (previously called reactive airways dysfunction syndrome) refers to the development of a persistent asthma-like syndrome following the inhalation of an airway irritant: typically, a single, specific exposure to a gas, smoke, fume or vapour in very high concentrations. Pulmonary function tests show airflow obstruction and airway hyper-reactivity, and the management is similar to that of asthma. Once developed, the condition often persists but it is common for symptoms to improve over years.

### Chronic obstructive pulmonary disease

While tobacco smoking remains the most important preventable cause of COPD, there is increasing recognition that other noxious particles and gases can cause, or aggravate, the condition. Occupational COPD is recognised in workers exposed to coal dust, crystalline silica and cadmium. In many low-income countries, indoor air pollution from the burning of biomass fuels in confined spaces used for cooking contributes to the development of COPD.

### Byssinosis

Byssinosis occurs in workers of cotton and flax mills exposed to cotton brack (dried leaf and plant debris). An acute form of the disease may occur, but more typically, byssinosis develops after 20–30 years' exposure. Typical symptoms include chest tightness or breathlessness accompanied by a drop in lung function; classically, these are most severe on the first day of the working week ('Monday fever') or on return to work following a period away. As the week progresses, symptoms improve and the fall in lung function becomes less dramatic. Continued exposure leads to the development of persistent symptoms and a progressive decline in FEV<sub>1</sub>, similar to that observed in COPD.

### Pneumoconiosis

Pneumoconiosis may be defined as a permanent alteration of lung structure due to the inhalation of mineral dust and the tissue reactions of the lung to its presence, excluding bronchitis and emphysema (Box 17.80).

Not all dusts are pathogenic. For example, silica is highly fibrogenic, whereas iron (siderosis), tin (stannosis) and barium (baritosis) are almost inert. Beryllium causes an interstitial granulomatous disease similar to sarcoidosis. In many types of pneumoconiosis, a long period of dust exposure is required before radiological changes appear and these may precede clinical symptoms. The most important pneumoconioses include coal worker's pneumoconiosis, silicosis and asbestosis.

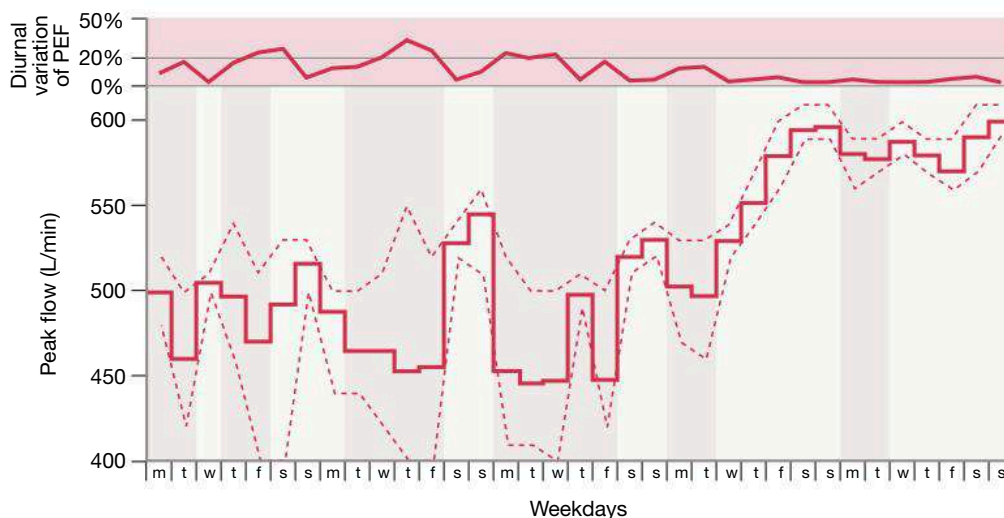

### Coal worker's pneumoconiosis

Coal worker's pneumoconiosis (CWP) follows prolonged inhalation of coal dust. Dust-laden alveolar macrophages aggregate to form macules in or near the centre of the secondary pulmonary lobule and a fibrotic reaction ensues, resulting in the appearance of scattered discrete fibrotic lesions. Classification is based on the size and extent of radiographic nodularity. Simple coal worker's pneumoconiosis (SCWP) refers to the appearance of small radiographic nodules in an otherwise asymptomatic individual. SCWP does not impair lung function and, once exposure ceases, will seldom progress. Progressive massive fibrosis (PMF) refers to the formation of one or more conglomerate masses more than 1 cm in diameter (mainly in the upper lobes), which may calcify, cavitate, or undergo necrosis. The development of PMF is usually associated with cough, sputum that may be black (melanoptysis) and breathlessness. Despite the term fibrosis, examination is unremarkable, and the identification of clubbing or crepitations suggests an alternative diagnosis. The chest X-ray appearances may be confused with lung cancer, TB and granulomatosis with polyangiitis (GPA). Management involves removing or reducing coal dust exposure, and is otherwise supportive treatment. PMF may progress, even after coal dust exposure ceases, and in extreme cases leads to respiratory failure and right ventricular failure. CWP is not associated with increased risk of lung cancer.

Caplan syndrome describes the coexistence of rheumatoid arthritis and rounded fibrotic nodules 0.5–5 cm in diameter. They show pathological features similar to a rheumatoid nodule, including central necrosis, palisading histiocytes, and a peripheral rim of lymphocytes and plasma cells. This syndrome may also occur in other types of pneumoconiosis.

### Silicosis

Silicosis results from the inhalation of crystalline silica, usually in the form of quartz, by workers cutting, grinding and polishing stone. Patients experience dry cough and breathlessness, with the sensation of chest restriction

**Fig. 17.60 Peak flow readings in occupational asthma.** In this example, an individual with suspected occupational asthma has performed serial peak flow recording both at and away from work. The maximum, mean and minimum values are plotted daily. Days at work are indicated by the shaded areas. The diurnal variation is displayed at the top. Here, a period away from work is followed by a marked improvement in peak flow readings and a reduction in diurnal variation. (PEF = peak expiratory flow)

## 17.80 Lung diseases caused by exposure to inorganic dusts

Cause	Occupation	Description	Characteristic pathological features
Coal dust	Coal mining	Coal worker's pneumoconiosis	Focal and interstitial fibrosis, centrilobular emphysema, progressive massive fibrosis
Silica	Mining, quarrying, stone dressing, metal grinding, pottery, boiler scaling	Silicosis	
Asbestos	Demolition, ship breaking, manufacture of fireproof insulating materials, pipe and boiler lagging	Asbestos-related disease	Pleural plaques, diffuse pleural thickening, acute benign pleurisy, carcinoma of lung, interstitial fibrosis, mesothelioma
Iron oxide	Arc welding	Siderosis	Mineral deposition only
Tin oxide	Tin mining	Stannosis	Tin-laden macrophages
Beryllium	Aircraft, atomic energy and electronics industries	Berylliosis	Granulomas, interstitial fibrosis

replicated on spirometry. Classic or sub-acute silicosis is most common and usually manifests after 10–20 years of continuous silica exposure, during which time the patient remains asymptomatic. Accelerated silicosis is associated with a much shorter duration of dust exposure (typically 5–10 years), may present as early as after 1 year of exposure and, as the name suggests, follows a more aggressive course. Intense exposure to very fine crystalline silica dust can cause a more acute disease: silicoproteinosis, similar to alveolar proteinosis (see Box 17.78). Chronic silicosis can develop after 10–30 years of continuous exposure to lower concentrations of silica dust.

Radiological features are similar to those of CWP, with multiple well-circumscribed 3–5 mm nodular opacities predominantly in the mid- and upper zones. As the disease progresses, PMF may develop (Fig. 17.61), and often does so more rapidly than in CWP and with larger opacities. Enlargement of the hilar glands with an 'egg-shell' pattern of calcification is said to be characteristic but is non-specific. Silica is highly fibrogenic and the disease is usually progressive, even when exposure ceases; hence the affected worker should invariably be removed from further exposure. Individuals with silicosis are at increased risk of TB (silicotuberculosis), non-tuberculous mycobacterial infection, lung cancer and COPD; associations with renal and connective tissue disease have also been described. Treatment, aside from stopping exposure, is mainly supportive, though some individuals benefit from inhaled bronchodilators, and transplant is occasionally appropriate.

### Berylliosis

Exposure to beryllium is encountered in the aerospace, engineering, telecommunications and biomedical industries. The presence of cough, progressive breathlessness, night sweats and arthralgia in a worker exposed to dusts, fumes or vapours containing beryllium should raise suspicion of berylliosis. Berylliosis is a delayed hypersensitivity-type reaction with a symptom latency ranging from months to more than 10 years. The radiographic appearances are similar in type and distribution to those of sarcoidosis, with nodules and then progression to interstitial fibrosis predominantly in the upper lobes. Bronchoalveolar lavage reveals lymphocytes, biopsy shows sarcoid-like granulomas, and spirometry is restrictive. The diagnosis may be confirmed by the beryllium lymphocyte proliferation test, which indicates sensitization to beryllium. Treatment is with long-term steroids to delay or prevent progression to fibrosis. As with sarcoidosis, complications can occur as a result of hypercalcaemia.

### Less common pneumoconioses

Siderosis refers to the development of a benign iron oxide pneumoconiosis in welders and other iron foundry workers. Baritosis may be seen

**Fig. 17.61 Silicosis.** **A** A chest X-ray from a patient with silicosis, showing the presence of small rounded nodules, predominantly seen in the upper zones. **B** High-resolution computed tomogram from the same patient, demonstrating conglomeration of nodules with posterior bias.

in barium process workers and stannosis in tin refining. Haematite lung occurs in iron ore miners and resembles silicosis but stains the lung red. Diamond polishers may develop hard metal disease, which is similar to UIP but the pathology shows a giant-cell interstitial pneumonia. Workers exposed to aluminium oxide develop bauxite pneumoconiosis, sometimes referred to as Shaver disease. Popcorn worker's lung is a form

of obliterative bronchiolitis following ingestion of diacetyl, used in butter flavouring.

## Lung diseases due to organic dusts

A wide range of organic agents may cause respiratory disorders (Box 17.81). Disease results from a local immune response to animal proteins or fungal antigens in mouldy vegetable matter. Hypersensitivity pneumonitis is the most common of these conditions.

### Hypersensitivity pneumonitis

Hypersensitivity pneumonitis (HP; previously called extrinsic allergic alveolitis) results from the inhalation of a wide variety of organic antigens that give rise to a diffuse immune complex reaction in the walls of alveoli and bronchioles. Common causes include farmer's lung and bird fancier's lung. Other examples are shown in Box 17.81. HP is not exclusively occupational or environmental and other important causes include medications (see Box 17.77).

The pathology of HP is consistent with both type III and type IV immunological mechanisms. Precipitating IgG antibodies may be detected in the serum and a type III Arthus reaction is believed to occur in the lung, where the precipitation of immune complexes results in activation of complement and an inflammatory response in the alveolar walls, characterised by the influx of mononuclear cells and foamy histiocytes. The presence of poorly formed non-caseating granulomas in the alveolar walls suggests that type IV responses are also important. The distribution of the inflammatory infiltrate is predominantly peribronchiolar. Chronic forms of the disease may be accompanied by fibrosis. For reasons that remain uncertain, there is a lower incidence of HP in smokers compared to non-smokers.

#### Clinical features

The presentation of HP varies from an acute form to a more indolent pattern in accordance with the antigen load. For example, the farmer exposed to mouldy hay, as occurs when the hay is gathered and stored damp during a wet summer, or the pigeon fancier cleaning a large pigeon loft, will, within a few hours, report influenza-like symptoms accompanied by cough, breathlessness and wheeze. The individual with low-level antigen exposure, however, such as the owner of an indoor pet bird, will typically present in a more indolent fashion with slowly progressive

breathlessness; in some cases, established fibrosis may be present by the time the disease is recognised. Chest auscultation typically reveals widespread end-inspiratory crackles and squeaks.

#### Investigations

In cases of acute HP, the chest X-ray typically shows ill-defined patchy airspace shadowing, which, given the systemic features, may be confused with pneumonia. HRCT is more likely to show bilateral ground-glass shadowing and areas of consolidation superimposed on small centrilobar nodular opacities with an upper and middle lobe predominance and mosaicism (areas of increased lucency due to air-trapping) (Fig. 17.62). In more chronic disease, features of fibrosis, such as volume loss, traction bronchiectasis and honeycombing, appear. In common with other fibrotic diseases, pulmonary function tests show a restrictive ventilatory defect with reduced lung volumes and impaired gas transfer, dynamic tests may detect oxygen desaturation and, in more advanced disease, type I respiratory failure is present at rest.

#### Diagnosis

The diagnosis of HP is usually based on the characteristic clinical and radiological features, together with the identification of a potential source of antigen at the patient's home or place of work (Box 17.82). It may be supported by a positive serum antibody (IgG) or precipitin test or by more sensitive serological investigations. It is important, however, to be aware that the presence of antibodies in the absence of other features does not make the diagnosis; the great majority of farmers with positive precipitins do not have farmer's lung, and up to 15% of pigeon breeders may have positive serum precipitins yet remain healthy.

Where HP is suspected but the cause is not readily apparent, a visit to the patient's home or workplace should be arranged. Occasionally,

17.81 Examples of lung diseases caused by organic dusts		
Disorder	Source	Antigen/agent
Farmer's lung*	Mouldy hay, straw, grain	<i>Saccharopolyspora rectivirgula</i> (formerly <i>Micropolyspora faeni</i> ) <i>Aspergillus fumigatus</i>
Bird fancier's lung*	Avian excreta, proteins and feathers	Avian serum proteins
Malt worker's lung*	Mouldy maltings	<i>Aspergillus clavatus</i>
Cheese worker's lung*	Mouldy cheese	<i>Aspergillus clavatus</i> <i>Penicillium casei</i>
Maple bark stripper's lung*	Bark from stored maple	<i>Cryptosporium corticale</i>
Saxophone player's lung*	Reed of any wind instrument	<i>Fusarium</i> spp. <i>Penicillium</i> spp. <i>Cladosporium</i> spp.
Byssinosis	Textile industries	Cotton, flax, hemp dust
Inhalation ('humidifier') fever	Contamination of air conditioning	Thermophilic actinomycetes

\*Presents as hypersensitivity pneumonitis.

**Fig. 17.62 Hypersensitivity pneumonitis.** **A** High-resolution computed tomogram showing typical patchy ground-glass opacification. **B** Histology shows evidence of an interstitial inflammatory infiltrate in the lung, and expanding alveolar walls, with a peribronchial distribution. Within the infiltrate, there are foci of small, poorly defined non-caseating granulomas (inset), which often lie adjacent to the airways. In this case, there is little in the way of established lung fibrosis but this can be marked. (A) Courtesy of Dr S. Jackson, Western General Hospital, Edinburgh. (B) Courtesy of Dr William Wallace, Department of Pathology, Royal Infirmary of Edinburgh.

### **i** 17.82 Predictive factors in the identification of hypersensitivity pneumonitis

- Exposure to a known offending antigen
- Positive precipitating antibodies to offending antigen
- Recurrent episodes of symptoms
- Inspiratory crackles on examination
- Symptoms occurring 4–8 hours after exposure
- Weight loss

such as when an agent previously unrecognised as causing HP is suspected, provocation testing may be necessary to prove the diagnosis; if positive, inhalation of the relevant antigen is followed after 3–6 hours by pyrexia and a reduction in vital capacity and gas transfer factor. BAL fluid usually shows an increase in the number of CD8<sup>+</sup> T lymphocytes and transbronchial biopsy can occasionally provide sufficient tissue for a confident diagnosis; however, open lung biopsy may be necessary. In up to 40% of patients with HP, the causative antigen remains unknown despite extensive investigation.

#### **Management**

If it is practical, the patient should cease exposure to the inciting agent. In some cases this may be difficult, however, because of either implications for livelihood (e.g. farmers) or addiction to hobbies (e.g. pigeon breeders). Dust masks with appropriate filters may minimise exposure and may be combined with methods of reducing levels of antigen (e.g. drying hay before storage). In acute cases, prednisolone 0.5 mg/kg is given daily until clinical and radiological resolution, before slowly weaning over several months down to 10 mg/day for a further few months. Severely hypoxaemic patients may require high-concentration oxygen therapy initially. Most patients recover completely, but if unchecked, fibrosis may progress to cause severe respiratory disability, hypoxaemia, pulmonary hypertension, cor pulmonale and eventually death.

#### **Inhalation ('humidifier') fever**

Inhalation fever shares similarities with HP. It occurs as a result of contaminated humidifiers or air-conditioning units that release a fine spray of microorganisms into the atmosphere. The illness is characterised by self-limiting fever and breathlessness; permanent sequelae are unusual. An identical syndrome can also develop after disturbing an accumulation of mouldy hay, compost or mulch. So-called 'hot tub lung' appears to be attributable to *Mycobacterium avium*. Outbreaks of HP in workers using metalworking fluids appear to be linked to *Acinetobacter* or *Ochrobactrum*.

#### **Asbestos-related lung and pleural diseases**

Asbestos is a naturally occurring silicate. Asbestos fibres may be classified as either serpentine (chrysotile or white asbestos), which accounts for 95% of the world's production, or amphibole serpentine (crocidolite or blue asbestos, and amosite or brown asbestos). The favourable thermal and chemical insulation properties led to its extensive use by the shipbuilding and construction industries throughout the latter part of the 20th century. Exposure to asbestos may be followed, after a lengthy latent period, by the development of both pleural and pulmonary disease. With the exception of an increased risk of lung cancer in asbestosis, benign asbestos-related diseases do not increase the risk of malignancy beyond that already resulting from exposure to asbestos.

#### **Pleural plaques**

Pleural plaques are the most common manifestation of previous asbestos exposure, being discrete circumscribed areas of hyaline fibrosis situated on the parietal pleura of the chest wall, diaphragm, pericardium or mediastinum. They are virtually always asymptomatic, usually being identified as an incidental finding on a chest X-ray (Fig. 17.63) or thoracic

**Fig. 17.63** Asbestos-related benign pleural plaques. Chest X-ray showing extensive calcified pleural plaques ('candle wax' appearance – arrows), particularly marked on the diaphragm and lateral pleural surfaces.

CT scan, particularly when partially calcified. They do not cause impairment of lung function and are benign.

#### **Acute benign asbestos pleurisy**

Benign asbestos pleurisy is estimated to occur in around 20% of asbestos workers but many episodes are subclinical and pass unreported. When symptomatic, patients present with features of pleurisy, including mild fever and systemic disturbance. The diagnosis requires the exclusion of other causes of pleurisy, and treatment is with NSAIDs. Repeated episodes may be followed by the development of diffuse (visceral) pleural thickening.

#### **Benign asbestos-related pleural effusion**

Benign asbestos-related pleural effusions are usually small and unilateral. The patient is commonly asymptomatic, though some have symptoms of pleurisy or breathlessness, especially if the effusion is moderate to large. Diagnosis requires the exclusion of mesothelioma, usually by thoracoscopy. Pleural fluid analysis demonstrates an exudate that is often haemorrhagic. Treatment is with drainage if symptomatic.

#### **Diffuse pleural thickening**

Diffuse pleural thickening (DPT) refers to thickening of the visceral pleura. In contrast to pleural plaques, if this is sufficiently extensive, it may cause restrictive lung function impairment, exertional breathlessness and, occasionally, persistent chest pain. The typical appearances of DPT on chest X-ray include thickening of the pleura along the chest wall and obliteration of the costophrenic angles. Earlier manifestations detected by CT scanning include parenchymal bands (Fig. 17.64) and 'rounded atelectasis'. There is no treatment and the condition may be progressive in around one-third of individuals. A pleural biopsy may be required to exclude mesothelioma.

#### **Asbestosis**

Fibrosis of the lung following asbestos exposure generally requires substantial exposure over several years and is rarely associated with low-level or bystander exposure (unlike other asbestos-related diseases). In common with other fibrosing lung diseases, asbestosis usually presents with exertional breathlessness and fine, late inspiratory crackles over the lower zones. Finger clubbing may be present. Pulmonary function tests and HRCT appearances are similar to those of UIP. These features,

**Fig. 17.64** Thoracic CT scan showing right-sided pleural thickening and an associated parenchymal band.

accompanied by a history of substantial asbestos exposure, are generally sufficient to establish the diagnosis. In some cases, asbestos fibre counts may be performed on lung biopsy material to establish the diagnosis, but this is rarely appropriate pre-mortem.

Asbestosis is usually slowly progressive and has a better prognosis than untreated IPF. In advanced cases respiratory failure, pulmonary hypertension and cor pulmonale may still develop, and treatment is supportive. Those with asbestosis have a 10-fold increased risk of developing lung cancer, with rates even higher amongst those with additional smoking history.

## Mesothelioma

Mesothelioma is a malignant tumour affecting the pleura or, less commonly, the peritoneum. Its occurrence almost invariably suggests past asbestos exposure, which may be low-level. There is typically a long latent interval between first exposure and the onset of clinical manifestations, and this accounts for the continued increasing incidence many years after control measures have been implemented. Despite regulations, 125 million people are exposed to asbestos in the workplace. Around 1 in 170 of all British men born in the 1940s will die of mesothelioma.

Pleural mesothelioma typically presents with increasing breathlessness resulting from pleural effusion or unremitting chest pain, reflecting involvement of the chest wall. As the tumour progresses, it encases the underlying lung and may invade the parenchyma, the mediastinum and the pericardium. Metastatic disease, although not often clinically detectable in life, is a common finding on postmortem examination.

Mesothelioma is almost invariably fatal. The use of chemotherapy may improve quality of life and is accompanied by a small survival benefit, typically regarded as being around 3 months. Radiotherapy can be used to control pain. A variety of surgical techniques have been trialled, but to date these have shown no benefit and even possible harm to patients. Pleural effusions are managed with drainage (preferably with indwelling pleural catheters) with or without pleurodesis. Typical figures for survival from onset of symptoms are around 16 months for epithelioid tumours, 10 months for sarcomatoid tumours and 15 months for biphasic tumours, with only a minority of patients surviving for longer periods.

## Occupational lung cancer

Individuals exposed to substantial quantities of asbestos are at increased risk of lung cancer, particularly if they smoke tobacco. Increased risks of lung cancer have also been reported in workers who develop silicosis and those exposed to radon gas, beryllium, diesel exhaust fumes, cadmium, chromium, and dust and fumes from coke plants.

## Occupational pneumonia

Occupational and environmental exposures may be linked to the development of pneumonia. Pneumococcal vaccine is recommended for welders and metal workers. Farm workers, abattoir workers and hide factory workers may be exposed to *Coxiella burnetii*, the causative agent of Q fever. The organisms are excreted from milk, urine, faeces and amniotic fluid; they may be transmitted by cattle ticks or contaminated dust from the milking floor, or by drinking milk that is inadequately pasteurised. Birds (often parrots) or budgerigars infected with *Chlamydothrips psittaci* can cause psittacosis. Sewage workers, farmers, animal handlers and vets run an increased risk of leptospirosis and leptospiral pneumonia, due to their exposure to *Leptospira interrogans* in rodent urine. Contact with rabbits, hares, muskrats and ground squirrels is associated with tularaemic pneumonia, caused by *Francisella tularensis*. Anthrax (wool-sorter's disease) may occur in workers exposed to hides, hair, bristle, bonemeal and animal carcasses that are contaminated with *Bacillus anthracis* spores. In some countries, COVID-19 is classified as an occupational disease of people whose occupations cause them to come into close contact with other people (e.g. medical staff, taxi drivers, retail workers etc.). This is potentially a contentious issue, however, as the high prevalence of the disease in the community makes it difficult to establish the specific source of a COVID-19 infection.

## Pulmonary vascular disease

### Pulmonary embolism

The majority of pulmonary emboli arise from the propagation of lower limb deep vein thrombosis (venous thromboembolism, VTE). Rare causes include septic emboli (from endocarditis affecting the tricuspid or pulmonary valves), tumour (especially choriocarcinoma), fat following fracture of long bones (such as the femur), air, and amniotic fluid (which may enter the mother's circulation following delivery).

#### Clinical features

The diagnosis of pulmonary embolism (PE) may be aided by asking three questions:

- Is the clinical presentation consistent with PE?
- Does the patient have risk factors for PE?
- Are there any alternative diagnoses that can explain the patient's presentation?

Clinical presentation varies, depending on number, size and distribution of emboli and on underlying cardiorespiratory reserve (Box 17.83). A recognised risk factor for VTE is present in 80%–90% (see Box 25.67). The presence of one or more risk factors increases the risk further still.

#### Investigations

A variety of non-specific radiographic appearances have been described (Fig. 17.65) but the chest X-ray is most useful in excluding key differential diagnoses, e.g. pneumonia or pneumothorax. Normal appearances in an acutely breathless and hypoxaemic patient should raise the suspicion of PE, as should bilateral changes in anyone presenting with unilateral pleuritic chest pain.

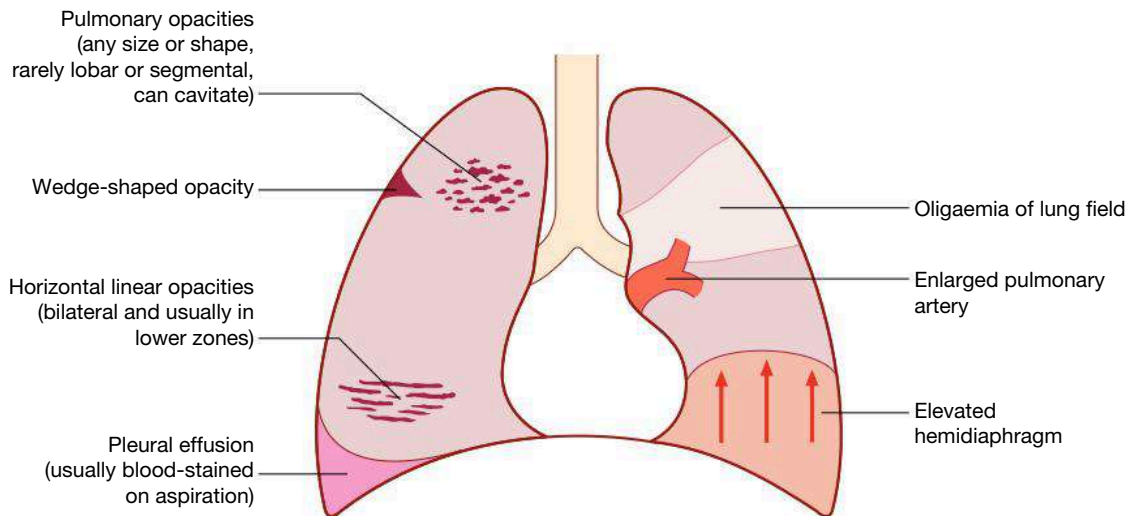

The ECG is often normal but is useful in excluding other important differential diagnoses, such as acute myocardial infarction and pericarditis. The most common findings in PE include sinus tachycardia and anterior T-wave inversion but these are non-specific; larger emboli may cause right heart strain revealed by an S<sub>1</sub>Q<sub>3</sub>T<sub>3</sub> pattern, ST-segment and T-wave changes, or the appearance of right bundle branch block.

Arterial blood gases typically show a reduced PaO<sub>2</sub> and a normal or low PaCO<sub>2</sub>, and an increased alveolar–arterial oxygen gradient, but may

17.83 Features of pulmonary thromboemboli			
	Acute massive PE	Acute small/medium PE	Chronic PE
<b>Pathophysiology</b>	Major haemodynamic effects: ↓cardiac output; acute right heart failure	Occlusion of segmental pulmonary artery → infarction ± effusion	Chronic occlusion of pulmonary microvasculature, right heart failure
<b>Symptoms</b>	Faintness or collapse, crushing central chest pain, apprehension, severe dyspnoea	Pleuritic chest pain, restricted breathing, haemoptysis	Exertional dyspnoea Late: symptoms of pulmonary hypertension or right heart failure
<b>Signs</b>	Major circulatory collapse: tachycardia, hypotension, ↑JVP, RV gallop rhythm, loud P <sub>2</sub> , severe cyanosis, ↓urinary output	Tachycardia, pleural rub, raised hemidiaphragm, crackles, effusion (often blood-stained), low-grade fever	Early: may be minimal Later: RV heave, loud P <sub>2</sub> Terminal: signs of right heart failure
<b>Chest X-ray</b>	Usually normal; may be subtle oligoemia	Pleuropulmonary opacities, pleural effusion, linear shadows, raised hemidiaphragm	Enlarged pulmonary artery trunk, enlarged heart, prominent right ventricle
<b>Electrocardiogram</b>	S <sub>1</sub> Q <sub>3</sub> T <sub>3</sub> anterior T-wave inversion, RBBB	Sinus tachycardia	RV hypertrophy and strain
<b>Arterial blood gases</b>	Markedly abnormal with ↓PaO <sub>2</sub> and ↓PaCO <sub>2</sub> , metabolic acidosis	May be normal or ↓PaO <sub>2</sub> or ↓PaCO <sub>2</sub>	Exertional ↓PaO <sub>2</sub> or desaturation on formal exercise testing
<b>Alternative diagnoses</b>	Myocardial infarction, pericardial tamponade, aortic dissection	Pneumonia, pneumothorax, musculoskeletal chest pain	Other causes of pulmonary hypertension

(JVP = jugular venous pressure; PE = pulmonary embolism; RBBB = right bundle branch block; RV = right ventricular)

**Fig. 17.65** Features of pulmonary thromboembolism/infarction on chest X-ray.

be normal in a significant minority. A metabolic acidosis may be seen in acute massive PE with cardiovascular collapse.

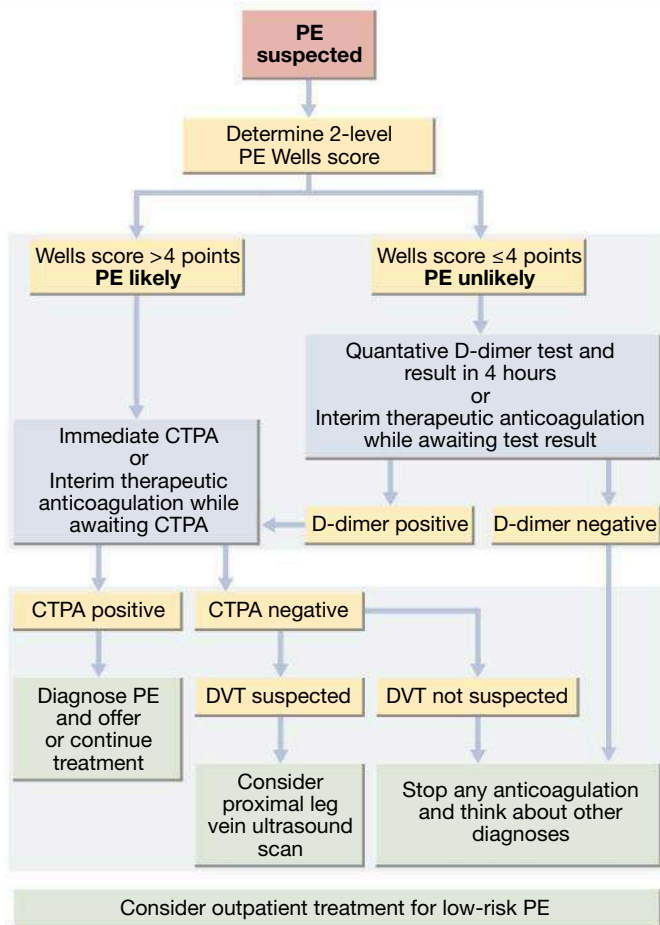

The 2-level PE Wells score is used to estimate the likelihood of PE (Fig. 17.66). If a PE is likely, the patient should have definitive imaging (as below). If a PE is unlikely, a D-dimer test is performed. An elevated D-dimer (see Fig. 9.6) is of limited value, as it may be raised in a variety of other conditions, including myocardial infarction, pneumonia and sepsis. However, low levels, particularly in the context of a low clinical risk, have a high negative predictive value and further investigation is usually unnecessary (Fig. 17.66). The serum troponin I (see Box 9.3) may be elevated, reflecting right heart strain.

CTPA is the first-line diagnostic test (Fig. 17.67). It has the advantage of visualising the distribution and extent of the emboli or highlighting an alternative diagnosis, such as consolidation, pneumothorax or aortic dissection. The sensitivity of CT scanning may be increased by simultaneous visualisation of the femoral and popliteal veins, although this is not

widely practised. As the contrast media may be nephrotoxic, care should be taken in patients with renal impairment, and CTPA avoided in those with a history of allergy to iodinated contrast media. In these cases, either V/Q scanning or ventilation/perfusion single photon emission computed tomography (V/Q SPECT) may be considered. V/Q scanning is of little benefit in patients with an abnormal chest X-ray, as perfusion abnormalities are likely due to underlying lung disease rather than PE. Specific diagnostic and management considerations for PE in pregnancy are shown in Box 17.84.

Colour Doppler ultrasound of the leg veins may be used in patients with suspected PE, particularly if there are clinical signs in a limb, as many will have identifiable proximal thrombus in the leg veins.

Beside echocardiography is extremely helpful in the differential diagnosis and assessment of acute circulatory collapse. Acute dilatation of the right heart is usually present in massive PE, and thrombus (embolism in transit) may be visible. Important differential diagnoses, including left

**Fig. 17.66** Algorithm for the investigation of patients with suspected pulmonary thromboembolism. Clinical risk is based on the presence of risk factors for venous thromboembolism and the probability of another diagnosis. (CTPA = computed tomography pulmonary angiography; DVT = deep vein thrombosis; PE = pulmonary embolism)

ventricular failure, aortic dissection and pericardial tamponade, can also be identified.

In the absence of haemodynamic instability and hypoxia, most patients can have outpatient investigations for PE, providing they receive anticoagulation. The Pulmonary Embolism Severity Index (PESI) predicts 30-day outcome, and those with a low risk of morbidity and mortality can be considered for outpatient management.

## Management

### General measures

Prompt recognition and treatment are potentially life-saving. Sufficient oxygen should be given to hypoxaemic patients to maintain the target oxygen saturations specified on p. 195. Opiates may be necessary to relieve pain and distress but should be used with caution in the hypotensive patient.

### Anticoagulation

The main principle of treatment for PE is anticoagulation, which is discussed for PE and other forms of venous thromboembolism (VTE) on page 985.

### Thrombolytic and surgical therapy

Thrombolysis is indicated in any patient presenting with acute massive PE accompanied by haemodynamic instability. Patients must be screened carefully for haemorrhage risk, as there is a high risk of intracranial haemorrhage. Surgical or percutaneous pulmonary embolectomy may be

**Fig. 17.67** CT pulmonary angiogram. The arrow points to a saddle embolism in the bifurcation of the pulmonary artery.

## 17.84 Pulmonary embolism in pregnancy

- **Maternal mortality:** venous thromboembolism is the leading direct cause in the UK.
- **CT pulmonary angiography:** may be performed safely (0.01–0.06 mGy). It is important to consider the risk of radiation to breast tissue (particularly if there is a family history of breast carcinoma).
- **VQscanning:** greater radiation dose to fetus (0.11–0.22 mGy) but significantly less to maternal breast tissue.
- **In utero radiation exposure:** estimated incidence of childhood malignancy is about 1 in 16 000 per mGy.
- **Warfarin:** teratogenic, so pulmonary embolism should be treated with low-molecular-weight heparin during pregnancy.

considered in patients with an absolute contraindication to thrombolysis, but carries a high mortality.

### Caval filters

An inferior vena cava filter should be considered in any patient in whom anticoagulation is contraindicated or who has had recurrent VTE despite anticoagulation. Retrievable caval filters are particularly useful in individuals with temporary risk factors. The caval filter should be used only until anticoagulation can be safely initiated, at which time the filter should be removed if possible.

### Further investigations

All patients with an unprovoked PE (those with no risk factors) should be assessed for underlying malignancy. A detailed history, examination (including breast and rectal examination) and review of baseline bloods, should elicit any red-flag symptoms, signs or results. Further focused investigation is required only if there are any positive findings.

Thrombophilia screening is only considered for patients with an unprovoked PE and a plan to stop anticoagulation. Specialist advice is recommended as test results can be affected by anticoagulation.

### Prognosis

Immediate mortality is greatest in those with echocardiographic evidence of right ventricular dysfunction or cardiogenic shock. Once anticoagulation is commenced, however, the risk of mortality falls rapidly. The risk of recurrence is highest in the first 6–12 months after the initial event, and at 10 years around one-third of individuals will have suffered a further event. Patients with right ventricular dysfunction at presentation should have a

repeat echocardiogram at 3 months to assess for evidence of chronic thromboembolic pulmonary hypertension (CTEPH).

## Pulmonary hypertension

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure (PAP) of at least 25 mmHg at rest, as measured by right heart catheterisation. The definition may be further refined by consideration of the pulmonary wedge pressure (PWP), the cardiac output and the transpulmonary pressure gradient (mean PAP – mean PWP). The clinical classification of PH is shown in [Box 17.85](#). Further classification is based on the degree of functional disturbance, assessed using the New York Heart Association (NYHA) grades I–IV. Although respiratory failure due to intrinsic pulmonary disease is the most common cause of PH, severe PH may occur as a primary disorder, as a complication of connective tissue disease (e.g. systemic sclerosis), left heart disease, or as a result of CTEPH.

Primary pulmonary hypertension (PPH) is a rare but important disease that predominantly affects women aged between 20 and 30 years. Familial disease is rarer still but is known to be associated with pathogenic variants in the gene encoding type II bone morphogenetic protein receptor (*BMPR2*), a member of the transforming growth factor beta (TGF- $\beta$ ) superfamily. Variants in this gene have been identified in some patients with sporadic PH. Pathological features include hypertrophy of both the media and the intima of the vessel wall and a clonal expansion of endothelial cells, which take on the appearance of plexiform lesions. There is marked narrowing of the vessel lumen and this, together with the frequently observed in situ thrombosis, leads to an increase in pulmonary vascular resistance and PH.

### Clinical features

PH presents insidiously and is often diagnosed late. Typical symptoms include breathlessness, chest pain, fatigue, palpitations, exertional dizziness and syncope. Important signs include elevation of the JVP (with a prominent 'a' wave if in sinus rhythm), a parasternal heave (right ventricular hypertrophy), accentuation of the pulmonary component of the second heart sound, a right ventricular third heart sound, peripheral oedema and ascites. Signs of interstitial lung disease or cardiac, liver or connective tissue disease may suggest the underlying cause.

### Investigations

PH is suspected if an ECG shows a right ventricular 'strain' pattern or a chest X-ray shows enlarged pulmonary arteries, peripheral pruning and right ventricle enlargement ([Fig. 17.68](#)). Doppler assessment of the tricuspid regurgitant jet by transthoracic echocardiography provides a non-invasive estimate of the PAP, which is equal to  $4 \times (\text{tricuspid regurgitation velocity})^2$ . Further assessment should be by right heart catheterisation to assess pulmonary haemodynamics, measure vasodilator responsiveness and thus guide further therapy. Additional investigations are performed to identify the cause of PH, including pulmonary function tests,  $\dot{V}/\dot{Q}$ scan, CT thorax, CTPA, MRI, overnight oximetry and exercise testing.

### Management

Specialist centres should direct the management of PH. Diuretic therapy should be prescribed for patients with right heart failure. Supplemental oxygen should be given to maintain resting  $PaO_2$  above 8 kPa (60 mmHg). Anticoagulation should be considered unless there is an increased risk of bleeding. Digoxin may be useful in patients who develop atrial tachyarrhythmias. Pregnancy carries a very high risk of death and women of child-bearing age should be counselled appropriately. Excessive physical activity that leads to distressing symptoms should be avoided but otherwise patients should be encouraged to remain active. Pneumococcal and influenza vaccination should be offered. Nitrates should be avoided owing to the risk of hypotension, and  $\beta$ -blockers are poorly tolerated. Cyclizine can aggravate PH and should also be avoided.

Disease-targeted strategies have focused on replacing endogenous prostacyclins with epoprostenol, treprostinil or iloprost; blocking endothelin-mediated vasoconstriction with agents such as bosentan,

## 17.85 Classification of pulmonary hypertension

### Pulmonary arterial hypertension

- Idiopathic
- Heritable
- Drugs
- Connective tissue disease
- HIV
- Portal hypertension
- Congenital heart disease
- Schistosomiasis
- Pulmonary veno-occlusive disease
- Pulmonary capillary haemangiomatosis

### Pulmonary hypertension owing to left heart disease

- Systolic dysfunction
- Diastolic dysfunction
- Valvular disease

### Pulmonary hypertension owing to lung disease/hypoxia

- Chronic obstructive pulmonary disease
- Interstitial lung disease
- Sleep-disordered breathing

### Pulmonary hypertension caused by chronic thromboembolic disease

- Chronic thromboembolic pulmonary hypertension (CTEPH)

### Miscellaneous

- Haematological – chronic haematolytic anaemia, myeloproliferative disease, splenectomy
- Systemic disorders – sarcoidosis, Langerhans cells histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
- Metabolic disorders – glycogen storage disease, Gaucher's disease, thyroid disorder
- Others – extrinsic tumour obstruction, fibrosing mediastinitis, chronic kidney disease

Adapted from Kiely DG, Elliot CA, Sabroe I, Condliffe R. Pulmonary hypertension: diagnosis and management. *BMJ* 2013;346:f2028.

**Fig. 17.68** Chest X-ray showing the typical appearance in pulmonary hypertension.

ambrisentan or macitentan; or enhancing endogenous nitric oxide-mediated vasodilatation with phosphodiesterase V inhibitors such as sildenafil or tadalafil, or the guanylate cyclase stimulator riociguat. High-dose calcium channel blockers may be appropriate in those with an acute vasodilator response.

Selected patients are referred for double-lung transplantation, and pulmonary thrombo-endarterectomy may be contemplated in those with CTEPH. Atrial septostomy (the creation of a right-to-left shunt) decompresses the right ventricle and improves haemodynamic performance; it may be used as a bridge to transplantation.

## Diseases of the upper airway

### Diseases of the nasopharynx

#### Allergic rhinitis

This is a disorder in which there are episodes of nasal congestion, watery nasal discharge and sneezing. It may be seasonal or perennial, and is due to an immediate hypersensitivity reaction in the nasal mucosa. Seasonal antigens include pollens from grasses, flowers, weeds or trees. Grass pollen is responsible for hay fever, the most common type of seasonal allergic rhinitis in northern Europe, which is at its peak between May and July. This is a worldwide problem, however, which may be aggravated during harvest seasons.

Perennial allergic rhinitis may be a specific reaction to antigens derived from house dust, fungal spores or animal dander, but similar symptoms can be caused by physical or chemical irritants, e.g. pungent odours or fumes, including strong perfumes, cold air and dry atmospheres. The phrase 'vasomotor rhinitis' is often used in this context, as the term 'allergic' is a misnomer.

#### Clinical features

In the seasonal type, there are frequent sudden attacks of sneezing, with profuse watery nasal discharge and nasal obstruction. These attacks last for a few hours and are often accompanied by pruritus, watering of the eyes and conjunctival irritation. In perennial rhinitis, the symptoms are similar but more continuous and usually less severe. Skin hypersensitivity tests with the relevant antigen are usually positive in seasonal allergic rhinitis but are less useful in perennial rhinitis.

#### Management

In those sensitised to house dust, simple measures, such as thorough dust removal from the bed area, leaving a window open and washing all bedding once weekly, are often helpful. Avoidance of pollen and antigens from domestic pets, however desirable and beneficial, is usually impractical.

The following medications, singly or in combination, are usually effective in both seasonal and perennial allergic rhinitis:

- an antihistamine (such as loratadine or cetirizine)
- sodium cromoglicate nasal spray
- glucocorticoid nasal spray, e.g. beclomethasone dipropionate, fluticasone, mometasone or budesonide.

When symptoms are very severe, resistant to usual treatments and seriously interfering with school, business or social activities, immunotherapy (desensitisation) is also used but carries the risk of serious reactions and must be managed in specialist centres. Vasomotor rhinitis is often difficult to treat but may respond to ipratropium bromide, administered into each nostril 3 times daily.

### Sleep-disordered breathing

A variety of respiratory disorders affect sleep or are affected by sleep. Cough and wheeze disturbing sleep are characteristic of asthma, while the hypoventilation that accompanies normal sleep can precipitate respiratory failure in patients with disordered ventilation due to chest wall restrictive diseases, neuromuscular diseases, or diaphragmatic paralysis.

In contrast, a small but important group of disorders cause problems only during sleep. Patients may have normal lungs and daytime respiratory function, but during sleep have either abnormalities of ventilatory drive (central sleep apnoea) or upper airway obstruction (obstructive sleep apnoea). Of these, the obstructive sleep apnoea/hypopnoea syndrome is by far the most common and important. When this coexists with COPD (overlap syndrome), severe respiratory failure can result, even if the COPD is mild.

### The obstructive sleep apnoea/hypopnoea syndrome

Recurrent upper airway obstruction during sleep, sufficient to cause sleep fragmentation and daytime sleepiness, is thought to affect 2% of women and 4% of men aged 30–60 in populations of predominantly European descent. Daytime sleepiness, especially in monotonous situations, results in a threefold increased risk of road traffic accidents and a ninefold increased risk of single-vehicle accidents.

#### Aetiology

Sleep apnoea results from recurrent occlusion of the pharynx during sleep, usually at the level of the soft palate. Inspiration results in negative pressure within the pharynx. During wakefulness, upper airway dilating muscles, including palatoglossus and genioglossus, contract actively during inspiration to preserve airway patency. During sleep, muscle tone declines, impairing the ability of these muscles to maintain pharyngeal patency. In a minority of people, a combination of an anatomically narrow palatopharynx and under-activity of the dilating muscles during sleep results in inspiratory airway obstruction. Incomplete obstruction causes turbulent flow, resulting in snoring (44% of men and 28% of women aged 30–60 snore). More severe obstruction triggers increased inspiratory effort and transiently wakes the patient, allowing the dilating muscles to re-open the airway. These awakenings are so brief that patients have no recollection of them. After a series of loud deep breaths that may wake their bed partner, the patient rapidly returns to sleep, snores and becomes apnoeic once more. This cycle of apnoea and awakening may repeat itself many hundreds of times per night and results in severe sleep fragmentation and secondary variations in blood pressure, which may predispose over time to cardiovascular disease.

Factors that predispose to the obstructive sleep apnoea/hypopnoea syndrome (OSAHS) include male gender, which doubles the risk, and obesity, which is found in about 70% because parapharyngeal fat deposits tend to narrow the pharynx. Nasal obstruction or a recessed mandible can further exacerbate the problem. Acromegaly and hypothyroidism also predispose by causing submucosal infiltration and narrowing of the upper airway. Sleep apnoea is often familial, where the maxilla and mandible are back-set, narrowing the upper airway. Alcohol and sedatives predispose to snoring and apnoea by relaxing the upper airway dilating muscles. As a result of marked sympathetic activation during apnoea, sleep-disordered breathing is associated over time with sustained hypertension and an increased risk of coronary events and stroke. Associations have also been described with insulin resistance, the metabolic syndrome and type 2 diabetes. In addition to improving symptoms and reducing vehicular risk, treatment of sleep apnoea reduces sympathetic drive and blood pressure and may also improve these associated metabolic disorders.

#### Clinical features

Excessive daytime sleepiness is the principal symptom and snoring is virtually universal. The patient usually feels that he or she has been asleep all night but wakes unrefreshed, though may recall waking with choking/gasping episodes. Bed partners report loud snoring in all body positions and often have noticed multiple breathing pauses (apnoeas). Difficulty with concentration, impaired cognitive function and work performance, depression, irritability and nocturia are other features. Early morning headaches may be a sign of more severe OSAHS.

#### Investigations

Provided that the sleepiness does not result from inadequate time in bed or from shift work, anyone who repeatedly falls asleep during the day when not in bed, who complains that their work is impaired by sleepiness, or who is a habitual snorer with multiple witnessed apnoeas should be referred for a sleep assessment. A more quantitative assessment of daytime tendency to fall asleep can be obtained by questionnaire (Box 17.86).

Overnight studies of breathing, oxygenation and sleep quality are diagnostic (Fig. 17.69) but the level of investigation depends on local resources and the probability of the diagnosis. The severity of OSAHS

### 17.86 Epworth sleepiness scale

How likely are you to doze off or fall asleep in the situations described below? Choose the most appropriate number for each situation from the following scale:

- 0 = would never doze
- 1 = slight chance of dozing
- 2 = moderate chance of dozing
- 3 = high chance of dozing

- Sitting and reading
- Watching TV
- Sitting inactive in a public place (e.g. a theatre or a meeting)
- As a passenger in a car for an hour without a break
- Lying down to rest in the afternoon when circumstances permit
- Sitting and talking to someone
- Sitting quietly after a lunch without alcohol
- In a car, while stopped for a few minutes in the traffic

Normal subjects average 5.9 (SD 2.2) and patients with severe obstructive sleep apnoea average 16.0 (SD 4.4).

**Fig. 17.69** Sleep apnoea/hypopnoea syndrome: overnight oxygen saturation trace. The left-hand panel shows the trace of a patient who had 53 apnoeas plus hypopnoeas/hour, 55 brief awakenings/hour and marked oxygen desaturation. The right-hand panel shows the effect of continuous positive airway pressure (CPAP) of 10 cm H<sub>2</sub>O delivered through a tight-fitting nasal mask: it abolished his breathing irregularity and awakenings, and improved oxygenation. *Courtesy of Professor N.J. Douglas.*

is determined by the number of apnoeas/hypopnoeas per hour of sleep (apnoea/hypopnoea index, AHI). An apnoea is defined as a 10-second or longer breathing pause and a hypopnoea is a 10-second or longer 50% reduction in ventilation that results in a 4% drop in arterial oxygen saturation. An AHI of 5–14 indicates mild OSAHS, 15–30 is moderate and more than 30 is severe.

Several other conditions can cause daytime sleepiness but can usually be excluded by a careful history (Box 17.87). Narcolepsy is a rare cause of sudden-onset sleepiness, occurring in 0.05% of the population. Idiopathic hypersomnolence occurs in younger individuals and is characterised by long nocturnal sleeps.

### Management

The major hazard to patients and those around them is traffic accidents. Drivers must be strongly advised not to drive until treatment has relieved their sleepiness, and have a responsibility to inform their driving licence authority if there is sleepiness sufficient to impair driving. Overweight or obese patients should be encouraged to lose weight, and be considered for bariatric surgery if appropriate. Though rarely resulting in complete remission of OSAHS, weight loss decreases the AHI and blood pressure, and improves overall health and quality of life. In a minority, relief of nasal obstruction or the avoidance of alcohol or sedating medication

### 17.87 Differential diagnosis of persistent sleepiness

#### Lack of sleep

- Inadequate time in bed
- Extraneous sleep disruption (e.g. babies/children)
- Shift work
- Excessive caffeine intake
- Physical illness (e.g. pain)

#### Sleep disruption

- Sleep apnoea/hypopnoea syndrome
- Periodic limb movement disorder (recurrent limb movements during non-REM sleep, frequent nocturnal awakenings)

#### Sleepiness with relatively normal sleep

- Narcolepsy
- Idiopathic hypersomnolence (rare)
- Neurological lesions (e.g. hypothalamic or upper brainstem infarcts or tumours)
- Drugs

#### Psychological/psychiatric

- Depression

may prevent obstruction. Mandibular advancement devices that fit over the teeth and hold the mandible forward, thus opening the pharynx, are an alternative that is effective in some patients. There is no evidence that palatal surgery is of benefit. The gold standard therapy for the majority of patients is continuous positive airway pressure (CPAP) delivered by a mask every night to splint the upper airway open. When CPAP is tolerated, the effect is often dramatic (see Fig. 17.69), with relief of somnolence and improved daytime performance, quality of life and survival. Unfortunately, 30%–50% of patients do not tolerate CPAP or have poor adherence. Increasing use of telemedicine to remotely monitor CPAP use and overnight oximetry will enable non-adherers to be identified and supported to improve adherence. Interventions to promote adherence include improving mask fit, pressure modification and humidification, education and behavioural therapy.

### Central sleep apnoea and nocturnal hypoventilation

Episodic reduced ventilation during sleep in the absence of upper airway obstruction is called central sleep apnoea (CSA) or nocturnal hypoventilation. CSA is much less prevalent than OSAHS.

#### Aetiology

CSA or nocturnal hypoventilation occur when there is an altered ventilatory drive and/or an inability to adequately expand the chest. Loss of drive can be a result of brainstem abnormality, such as in post-polio syndrome and brainstem stroke, or ventilatory suppression, such as by opiates and alcohol. Cheyne–Stokes breathing is a sinusoidal cycling between hypoventilation and compensatory hyperventilation, that occurs most often when left ventricular failure influences ventilatory drive. The normal ventilatory mechanism can be impaired by neurological conditions, including myopathies (e.g. Duchenne muscular dystrophy, myotonic dystrophy), neuropathies (e.g. motor neurone disease, Guillain–Barré syndrome), and neuromuscular junction abnormalities (e.g. myasthenia gravis). Chest wall expansion is reduced by conditions such as scoliosis and severe ankylosing spondylitis. Severe obstructive airways disease also impairs ventilation, and the effect is exacerbated by coexisting OSA, obesity and/or muscle weakness.

#### Clinical features

Patients may present with the same signs and symptoms as those with OSAHS, in addition to features of the condition that has caused their CSA or hypoventilation. Patients can also present in acute type II respiratory failure or with features of cor pulmonale (fluid retention due to chronic hypoxia). Early morning headaches are common.

## Investigations

Sleep studies are used to differentiate between OSAHS, CSA and nocturnal hypoventilation. Blood gases can demonstrate the presence of type II respiratory failure, and PFTs can assess ventilatory muscle strength. History and examination will often reveal the underlying cause for CSA or hypoventilation, but further targeted investigations may be necessary.

## Management

Overnight home NIV improves symptoms and, in many conditions, prognosis. Sedating medications (unless palliative) and excessive alcohol should be stopped. Optimizing heart failure treatment can reduce Cheyne–Stokes breathing, but patients who remain symptomatic may benefit from CPAP or nocturnal oxygen.

## Laryngeal disorders

The larynx is commonly affected by acute self-limiting infections. Other disorders include chronic laryngitis, laryngeal tuberculosis, laryngeal paralysis and laryngeal obstruction. Tumours of the larynx are relatively common, particularly in smokers. For further details, the reader should refer to an otolaryngology text.

### Chronic laryngitis

The common causes are listed in [Box 17.88](#). The chief symptoms are hoarseness or loss of voice (aphonia). There is irritation of the throat and a spasmodic cough. The disease pursues a chronic course, frequently uninfluenced by treatment, and the voice may become permanently impaired. Other causes of chronic hoarseness include use of inhaled glucocorticoid treatment, tuberculosis, laryngeal paralysis or tumour.

In some patients, a chest X-ray may reveal an unsuspected lung cancer or pulmonary tuberculosis. If these are not found, laryngoscopy should be performed to exclude a local structural cause.

When no specific treatable cause is found, the voice must be rested completely. This is particularly important for public speakers and singers. Smoking should be avoided. Some benefit may be obtained from frequent inhalations of steam.

### Laryngeal paralysis

Interruption of the motor nerve supply of the larynx is nearly always unilateral and, because of the intrathoracic course of the left recurrent laryngeal nerve, usually left-sided. One or both recurrent laryngeal nerves may be damaged by thyroidectomy, carcinoma of the thyroid or anterior neck injury. Rarely, the vagal trunk itself is involved by tumour, aneurysm or trauma.

### Clinical features and management

Hoarseness always accompanies laryngeal paralysis, whatever its cause. Paralysis of organic origin is seldom reversible, but when only one vocal cord is affected, hoarseness may improve or even disappear after a few weeks, as the normal cord compensates by crossing the midline to approximate with the paralysed cord on phonation.

#### 17.88 Causes of chronic laryngitis

- Excessive use of the voice
- Heavy tobacco smoking
- Heavy alcohol intake
- Gastroesophageal reflux disease
- Repeated attacks of acute laryngitis
- Chronic sinusitis with post-nasal drip
- Occupational exposure to irritating chemicals or dusts
- Sarcoidosis

'Bovine cough' is a characteristic feature of organic laryngeal paralysis, and lacks the explosive quality of normal coughing because the cords fail to close the glottis. Sputum clearance may also be impaired. A normal cough in patients with partial loss of voice or aphonia virtually excludes laryngeal paralysis. Stridor is occasionally present but seldom severe, except when laryngeal paralysis is bilateral.

Laryngoscopy is required to establish the diagnosis of laryngeal paralysis. The paralysed cord lies in a paramedian position, midway between abduction and adduction.

The cause of laryngeal paralysis should be treated, if possible, and speech and language therapy offered. In unilateral paralysis, persistent dysphonia may be improved by the injection of bulking agents into the affected vocal cord. In bilateral organic paralysis, tracheal intubation, tracheostomy or surgery to reposition and/or reshape the larynx may be necessary.

### Psychogenic hoarseness and aphonia

Psychogenic causes of hoarseness or aphonia may be suggested by associated symptoms in the history (p. 1242). Laryngoscopy may be necessary, however, to exclude a physical cause. In psychogenic aphonia, only the voluntary movement of adduction of the vocal cords is seen to be impaired. Speech therapy may be helpful.

### Laryngeal obstruction

Laryngeal obstruction is more liable to occur in children than in adults because of the smaller size of the glottis. Important causes are given in [Box 17.89](#). Sudden complete laryngeal obstruction by a foreign body produces the clinical picture of acute asphyxia: violent but ineffective inspiratory efforts with indrawing of the intercostal spaces and the unsupported lower ribs, accompanied by cyanosis. Unrelieved, the condition progresses to coma and death within a few minutes. When, as in most cases, the obstruction is incomplete at first, the main clinical features are progressive breathlessness accompanied by stridor and cyanosis. Urgent treatment to prevent complete obstruction is needed.

### Management

Laryngeal obstruction carries a high mortality and demands prompt treatment. When a foreign body causes laryngeal obstruction, give up to five sharp back blows using the heel of the hand between the scapulae. If this is ineffective use abdominal thrusts, or, in those aged under 12 months old or pregnant, give chest thrusts. Tracheostomy must be performed without delay if these procedures fail to relieve complete obstruction. If the adult patient is stable with only partial obstruction, direct laryngoscopy can be used to remove the foreign body or insert a tube past the obstruction into the trachea to maintain the airway.

In diphtheria, antitoxin should be administered, and for other infections the appropriate antibiotic should be given. In angioedema, complete laryngeal occlusion can usually be prevented by treatment with adrenaline (epinephrine; 0.5–1 mg (0.5–1 mL of 1 : 1000) IM), chlorphenamine (10 mg by slow intravenous injection) and intravenous hydrocortisone sodium succinate (200 mg).

#### 17.89 Causes of laryngeal obstruction

- Inflammatory or allergic oedema, or exudate
- Spasm of laryngeal muscles
- Inhaled foreign body
- Inhaled blood clot or vomitus in an unconscious patient
- Tumours of the larynx
- Bilateral vocal cord paralysis
- Fixation of both cords in rheumatoid disease

## Tracheal disorders

### Tracheal obstruction

External compression by lymph nodes containing metastases, usually due to lung cancer, is a more frequent cause of tracheal obstruction than primary benign or malignant tumours. The trachea may also be compressed by a retrosternal goitre (see Fig. 20.12). Rare causes include an aneurysm of the aortic arch and (in children) tuberculous mediastinal lymph nodes. Tracheal stenosis is an occasional complication of tracheostomy, prolonged intubation, granulomatosis with polyangiitis (GPA) or trauma.

### Clinical features and management

Stridor can be detected in every patient with severe tracheal narrowing. CT will usually enable the cause to be identified, and bronchoscopic examination (if safe) can determine the degree and nature of the obstruction and enable biopsy.

Localised tumours of the trachea can be resected but reconstruction after resection may be technically difficult. Endobronchial laser therapy, bronchoscopically placed tracheal stents, chemotherapy and radiotherapy are alternatives to surgery. The choice of treatment depends on the nature of the tumour and the general health of the patient. Benign tracheal strictures can sometimes be dilated but may require resection.

### Tracheo-oesophageal fistula

Tracheo-oesophageal fistula may be present in newborn infants as a congenital abnormality. In adults, it is usually due to malignant lesions in the mediastinum, such as carcinoma or lymphoma, eroding both the trachea and oesophagus to produce a communication between them. Swallowed liquids enter the trachea and bronchi through the fistula and provoke coughing.

Surgical closure of a congenital fistula, if undertaken promptly, is usually successful. There is usually no curative treatment for malignant fistulae, and death from overwhelming pulmonary infection rapidly supervenes.

## Pleural disease

Pleurisy, pleural effusion, empyema and asbestos-associated pleural disease have been described above. Specific features of pleural disease in old age are shown in Box 17.90.

### Pneumothorax

Pneumothorax is the presence of air in the pleural space, which can either occur spontaneously, or result from iatrogenic injury or trauma to the lung or chest wall (Box 17.91). Primary spontaneous pneumothorax occurs in patients with no history of lung disease. Smoking, tall stature and the presence of apical subpleural blebs are risk factors. Secondary

pneumothorax affects patients with pre-existing lung disease and is associated with higher mortality rates (Fig. 17.70).

Where the communication between the airway and the pleural space seals off as the lung deflates and does not re-open, the pneumothorax is referred to as 'closed' (Fig. 17.71A). The mean pleural pressure remains negative, spontaneous re-absorption of air and re-expansion of the lung occur over a few days or weeks, and infection is uncommon. This contrasts with an 'open' pneumothorax, where the communication fails to seal and air continues to pass freely between the bronchial tree and pleural space (Fig. 17.71B). An example of the latter is a bronchopleural fistula, which can facilitate the transmission of infection from the airways into the pleural space, leading to empyema. An open pneumothorax is commonly seen following rupture of an emphysematous bulla, tuberculous cavity or lung abscess into the pleural space.

Occasionally, the communication between the airway and the pleural space acts as a one-way valve, allowing air to enter the pleural space during inspiration but not to escape on expiration. This is a tension pneumothorax. Large amounts of trapped air accumulate progressively in the pleural space and the intrapleural pressure rises to well above atmospheric levels. This causes mediastinal displacement towards the opposite side, with compression of the opposite normal lung and impairment of systemic venous return, causing cardiovascular compromise (Fig. 17.71C).

### Clinical features

The most common symptoms are sudden-onset unilateral pleuritic chest pain and/or breathlessness. In those individuals with underlying lung disease, breathlessness can be severe and may not resolve spontaneously. In patients with a small pneumothorax, physical examination may be normal. A larger pneumothorax (>15% of the hemithorax) results in decreased or absent breath sounds. The combination of absent breath sounds and a resonant percussion note is diagnostic of pneumothorax.

#### 17.91 Classification of pneumothorax

##### Spontaneous

##### Primary

- No evidence of overt lung disease; air escapes from the lung into the pleural space through rupture of a small pleural bleb, or the pulmonary end of a pleural adhesion

##### Secondary

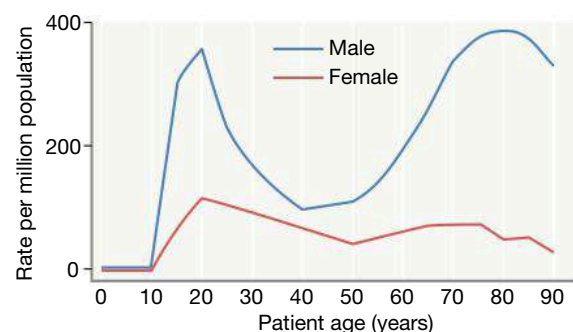

- Underlying lung disease, most commonly chronic obstructive pulmonary disease and tuberculosis; also seen in asthma, lung abscess, pulmonary infarcts, lung cancer and all forms of fibrotic and cystic lung disease

##### Traumatic

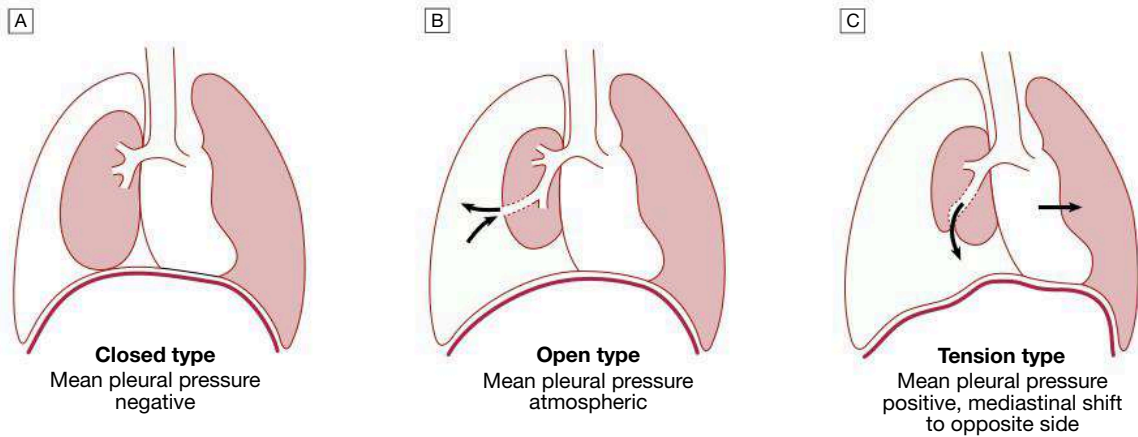

- Iatrogenic (e.g. following thoracic surgery or biopsy) or chest wall injury

#### 17.90 Pleural disease in old age

- **Spontaneous pneumothorax:** invariably associated with underlying lung disease in old age and has a significant mortality.
- **Rib fracture:** common cause of pleural-type pain; may be spontaneous (due to coughing), traumatic or pathological. Underlying osteomalacia may contribute to poor healing, especially in the housebound with no exposure to sunlight.
- **Tuberculosis:** should always be considered and actively excluded in older patients presenting with a unilateral pleural effusion.
- **Mesothelioma:** more common in older individuals than younger people due to a long latency period between asbestos exposure (often more than 20 years) and the development of disease.
- **Analgesia:** frail older people are particularly sensitive to the respiratory depressant effects of opiate-based analgesia and careful monitoring is required when using these agents for pleural pain.

**Fig. 17.70** Bimodal age distribution for hospital admissions for pneumothorax in England. The incidence of primary spontaneous pneumothorax peaks in males aged 15–30 years. Secondary spontaneous pneumothorax occurs mainly in males over 55 years.

**Fig. 17.71** Types of spontaneous pneumothorax. **A** Closed type. **B** Open type. **C** Tension (valvular) type.

By contrast, in tension pneumothorax there is rapidly progressive breathlessness, associated with a marked tachycardia, hypotension, cyanosis and tracheal displacement away from the side of the silent hemithorax. Occasionally, tension pneumothorax may occur without mediastinal shift, if malignant disease or scarring has splinted the mediastinum.

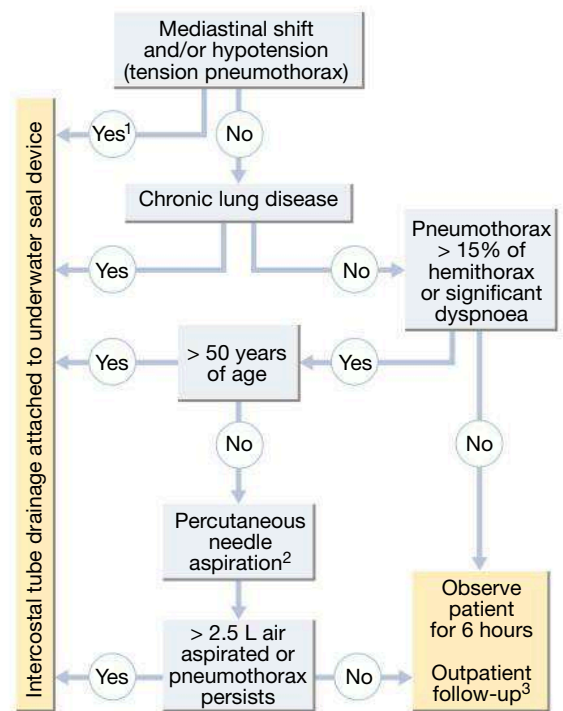

### Investigations

The chest X-ray shows the sharply defined edge of the deflated lung with complete translucency (no lung markings) between this and the chest wall. Care must be taken to differentiate between a large pre-existing emphysematous bulla and a pneumothorax. In general, the lung edge is convex in a pneumothorax, whereas the edge of a bulla is concave. X-ray findings should be correlated with the patient's clinical condition. CT is used in difficult cases to avoid iatrogenic bronchopleural fistula, caused by misdirected attempts at aspiration. X-rays may also show the extent of any mediastinal displacement and reveal any pleural fluid or underlying pulmonary disease.

### Management

Spontaneous pneumothoraces are classified as large or small on account of the distance between the lung edge and chest wall being greater or less than 2 cm (this equates to approximately half the volume of the hemithorax). Small primary pneumothoraces usually resolve spontaneously, and only require intervention if the patient is breathless. For these patients, and those with large primary pneumothoraces, percutaneous needle aspiration of air is a simple and well-tolerated alternative to intercostal tube drainage, with a 60%–80% chance of avoiding the need for a chest drain (Fig. 17.72). Patients who remain breathless or have a persistent large pneumothorax despite aspiration will require a chest drain. In patients with significant underlying chronic lung disease, however, secondary pneumothorax may cause respiratory distress. In these individuals, the success rate of aspiration is much lower, and this should therefore be attempted only for 1–2 cm pneumothoraces in patients who are not breathless. A chest drain is required if the pneumothorax remains greater than 1 cm, and in patients who are breathless or have a large pneumothorax. All patients with a secondary pneumothorax require admission for observation. If there is a tension pneumothorax, life-saving immediate release of the positive pressure by insertion of a cannula into the pleural space is performed, allowing time to prepare for chest drain insertion.

When needed, intercostal drains are inserted in the triangle of safety (Fig. 17.73), connected to an underwater seal or one-way Heimlich valve, and secured firmly to the chest wall with stitches. Clamping of an intercostal drain is potentially dangerous and rarely indicated. The drain should be removed the morning after the lung has fully re-inflated and bubbling has stopped. Continued bubbling after 5–7 days is an

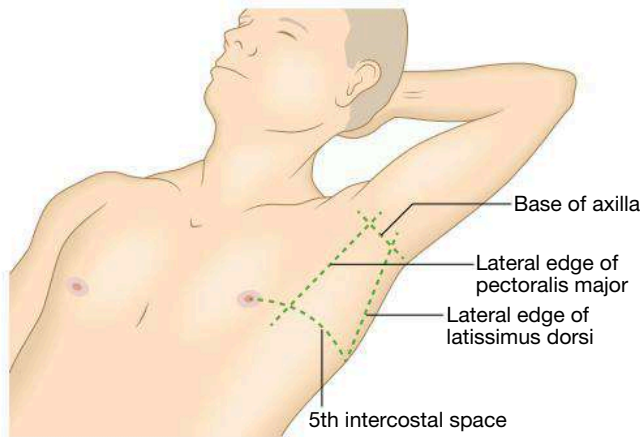

**Fig. 17.72** Management of spontaneous pneumothorax. (1) Immediate decompression prior to insertion of the intercostal drain. (2) Aspirate in the second intercostal space anteriorly in the mid-clavicular line using a 16 F cannula; discontinue if resistance is felt, the patient coughs excessively, or more than 2.5 L of air are removed. (3) The post-aspiration chest X-ray is not a reliable indicator of whether a pleural leak remains, and all patients should be told to attend again immediately in the event of deterioration.

indication for surgery, though in practice CT and surgical referral occurs after 48 hours. If bubbling in the drainage bottle stops before full re-inflation, the tube is either blocked or kinked or displaced. Supplemental oxygen may speed resolution, as it accelerates the rate at which nitrogen is reabsorbed by the pleura.

Patients with a closed pneumothorax should be advised not to fly, as the trapped gas expands at altitude. After complete resolution, there is no clear evidence to indicate how long patients should avoid flying. British Thoracic Society guidelines suggest that flying should be delayed until 7 days after X-ray confirmation of full inflation. Patients should also be advised to stop smoking and informed about the risks of a recurrent pneumothorax, which is significantly reduced by smoking cessation.

**Fig. 17.73 The triangle of safety.** The triangle of safety is the anatomical region that has the axilla as the apex, the lateral border of the pectoralis major anteriorly, the lateral border of the latissimus dorsi posteriorly and, inferiorly, the 5th intercostal space.

Diving is contraindicated following a pneumothorax, unless a surgical pleurodesis has sealed the lung to the chest wall.

#### Recurrent spontaneous pneumothorax

After primary spontaneous pneumothorax, recurrence occurs within a year of either aspiration or tube drainage in approximately 25% of patients and should prompt definitive treatment. Surgical pleurodesis is recommended in all patients following a second pneumothorax and should be considered following the first episode of secondary pneumothorax if low respiratory reserve makes recurrence hazardous. Pleurodesis can be achieved by pleural abrasion or parietal pleurectomy at thoracotomy or thoracoscopy.

## Diseases of the diaphragm and chest wall

### Disorders of the diaphragm

#### Congenital disorders

##### Diaphragmatic hernias

Congenital defects of the diaphragm can allow herniation of abdominal viscera. Posteriorly situated hernias through the foramen of Bochdalek are more common than anterior hernias through the foramen of Morgagni.

##### Eventration of the diaphragm

Abnormal elevation or bulging of one hemidiaphragm, more often the left, results from total or partial absence of muscular development of the septum transversum. Most eventrations are asymptomatic and are detected by chance on X-ray in adult life but severe respiratory distress can be caused in infancy if the diaphragmatic muscular defect is extensive.

#### Acquired disorders

Elevation of a hemidiaphragm may result from paralysis or other structural causes (Box 17.92). The phrenic nerve may be damaged by lung cancer, disease of cervical vertebrae, tumours of the cervical cord, shingles, trauma (including road traffic and birth injuries), surgery, and stretching of the nerve by mediastinal masses and aortic aneurysms. Idiopathic diaphragmatic paralysis occasionally occurs in otherwise fit patients. Paralysis of one hemidiaphragm results in loss of around 20% of ventilatory capacity but may not be noticed by otherwise healthy

#### 17.92 Causes of elevation of a hemidiaphragm

- Phrenic nerve paralysis
- Eventration of the diaphragm
- Decrease in volume of one lung (e.g. lobectomy, unilateral pulmonary fibrosis)
- Severe pleuritic pain
- Pulmonary infarction
- Subphrenic abscess
- Large volume of gas in the stomach or colon
- Large tumours or cysts of the liver

individuals. Supine vital capacity is significantly reduced compared to erect. Ultrasound screening can be used to demonstrate paradoxical upward movement of the paralysed hemidiaphragm on sniffing. CT of the chest and neck is the best way to exclude occult disease affecting the phrenic nerve.

Bilateral diaphragmatic weakness occurs in peripheral neuropathies of any type, including Guillain–Barré syndrome; in disorders affecting the anterior horn cells, e.g. poliomyelitis; in muscular dystrophies; and in connective tissue disorders, such as SLE and polymyositis.

Hiatus hernia is common. Diaphragmatic rupture is usually caused by a crush injury and may not be detected until years later. Respiratory disorders that cause pulmonary hyperinflation (e.g. emphysema), and those that result in small stiff lungs (e.g. diffuse pulmonary fibrosis), compromise diaphragmatic function and predispose to fatigue.

### Deformities of the chest wall

#### Thoracic kyphoscoliosis

Abnormalities of alignment of the dorsal spine and their consequent effects on thoracic shape may be caused by:

- congenital abnormality
- vertebral disease, including tuberculosis, osteoporosis and ankylosing spondylitis
- trauma
- neuromuscular disease, such as poliomyelitis.

Simple kyphosis (increased anterior curvature of the thoracic spine) causes less pulmonary embarrassment than kyphoscoliosis (antero-posterior and lateral curvature). Kyphoscoliosis, if severe, restricts and distorts expansion of the chest wall and impairs diaphragmatic function, causing ventilation–perfusion mismatch in the lungs. Patients with severe deformity may develop type II respiratory failure (initially manifest during sleep), pulmonary hypertension and right ventricular failure. They can often be successfully treated with non-invasive ventilatory support.

#### Pectus

Pectus is the result of abnormal costal cartilage growth, causing the sternum to protrude (carinatum), or more commonly, to be depressed (excavatum). In patients with pectus excavatum the heart is displaced to the left and may be compressed between the sternum and the vertebral column but only rarely is there associated disturbance of cardiac function. The deformity may restrict chest expansion and reduce vital capacity. Operative correction is rarely performed, and then only for cosmetic reasons. Although no associated gene has yet been identified, pectus is likely genetic, and a quarter of those affected have a family history of chest wall deformity. Pectus can be associated with kyphoscoliosis and is a feature of certain syndromes (including Marfan and Poland syndromes).

# FCPS Single Best Question

## Multiple Choice Questions

17.1 A 24-year-old woman presents to the Emergency Department with sudden onset of left-sided chest pain and breathlessness over the preceding 4 hours. The pain is worse on inspiration. She smokes 10 cigarettes per day. She has no significant past medical history, and her only regular medication is the oral contraceptive pill. She has a temperature of 37.4°C, BP of 95/60 mmHg and pulse rate 120 bpm. Her oxygen saturation is 89% breathing air and improves to 96% with oxygen at 40% FiO<sub>2</sub>. Chest examination is normal. Which is the most likely diagnosis?

- A. Left lower lobe pneumonia
- B. Myocardial infarction
- C. Pneumothorax
- D. Hyperventilation
- E. Pulmonary embolism

Answer: E.

Pulmonary embolism is the most likely diagnosis. She has two risk factors for pulmonary embolism – tobacco exposure and oral contraceptive pill use. Clinically, she has presented with an acute history that would be compatible with pulmonary embolism, but could also be compatible with other diagnoses such as pneumonia or pneumothorax. Normal examination findings would make the diagnosis of pulmonary embolism much more likely. It would be anticipated that there would be abnormal examination findings if she was presenting with pneumonia or pneumothorax. Patients with hyperventilation can have normal examination findings, but are not hypoxic on air and conversely have normal or potentially supra-normal oxygen saturations, which would again make this diagnosis unlikely. The clinical history is not suggestive of myocardial infarctions, and it would be very unusual for a patient of this age to present with a myocardial infarction.

17.2 A 76-year-old woman has presented to the Emergency Department with community-acquired pneumonia. She has a past medical history of hypertension and hypercholesterolaemia. She is disorientated, with an AMTS of 6/10. On examination, her temperature is 38.3°C, pulse rate 120 bpm, BP 90/61 mmHg, respiratory rate 28 breaths per minute and oxygen saturation of 94% on room air. She has bronchial breathing at the left base. She has a number of investigations:

Chest X-ray	right lower lobe consolidation
White cell count	13 × 10 <sup>9</sup> /L (3.8–10.0)
Urea	9.9 mmol/L (2.5–7.8)
Creatinine	170 μmol/L (60–120)
CRP	60 mg/L (<5)

What is her CURB-65 score?

- A. 1
- B. 2
- C. 3
- D. 4
- E. 5

Answer: C.

CURB-65, also known as the CURB criteria, is a validated clinical scoring tool that has been validated for predicting mortality in people with community-acquired pneumonia. The score is an acronym for the risk factors measured. Each risk factor scores one point, for a maximum score of 5:

- Confusion of new onset (defined as an AMTS of 8 or less)
- Blood Urea nitrogen greater than 7 mmol/L (19 mg/dL)
- Respiratory rate of 30 breaths per minute or greater
- Blood pressure less than 90 mmHg systolic or diastolic blood pressure 60 mmHg or less
- Age 65 or older

The scoring system is used to predict 30-day mortality (see below), and can be used to guide the need for inpatient or outpatient treatment of people with pneumonia as well the appropriate use of treatments such as broad-spectrum intravenous antibiotics.

CURB-65 score	30-day mortality	Treatment guidance
0	0.7%	Treat as outpatient
1	3.2%	
2	13.0%	Consider a short stay in hospital or watch very closely as an outpatient
3	17.0%	Requires hospitalisation with consideration for referral for critical care
4	41.5%	
5	57.0%	

17.3 A 78-year-old attends the respiratory outpatients clinic with 1 month of increasing shortness of breath, persistent chest wall pain and 5 kg weight loss. He has no past medical history and is not taking any regular medication. He has a 60 pack-year smoking history and is a retired dock worker. He is afebrile and haemodynamically stable. There are no clinical features to suggest cardiac failure. On examination of his thorax there is a stony dull percussion note at the left base, with absent breath sounds. Chest X-ray confirms the presence of a large left pleural effusion and numerous bilateral pleural plaques. Which is the most appropriate initial investigation?

- A. Bronchoscopy
- B. CT pulmonary angiography
- C. Sputum for microscopy and culture
- D. Ultrasound-guided pleural fluid aspiration
- E. Pulmonary function tests

Answer: D.

The clinical concern for this man would be the possibility of thoracic malignancy and specifically mesothelioma. He has a heavy smoking history, and the occupational history of dock working with the presence of pleural plaques on chest X-ray would raise a concern with regards to possible asbestos exposure.

Diagnostic pleural fluid aspiration would be recommended as the first investigation. This should be done under ultrasound guidance to confirm the presence of the effusion, and ensure minimisation of risk of complications of pleural aspiration such as pneumothorax or perforation of other organs. Analysis of the fluid using Light's criteria will provide guidance as to whether the fluid is a transudate or exudate. Samples should also be sent for cytological examination – the detection of malignant cells in the fluid may provide the diagnosis. Samples should also be sent for both standard and AAFB microscopy and culture.

Pulmonary function tests are not going to help in this situation as the chest X-ray has already identified that the cause of the breathlessness is due to the pleural effusion. As this is a pleural-based pathology, sputum analysis and bronchoscopy are not going to be helpful. CT scanning may need to be undertaken, particularly in view of the suspicion of malignancy, however this should not be a CT pulmonary angiogram. A staging CT with contrast would be the appropriate form of CT imaging in this clinical situation.

## Clinical examination of the kidney and urinary tract

Many diseases of the kidney and urinary tract are clinically silent, at least in the early stages. Accordingly, it is common for these conditions to be detected first by routine blood tests or on dipstick testing of the urine. Several important abnormalities can also be picked up on physical examination and these are summarised below.

### 5 Fundoscopy

▲ Hypertensive changes

### 4 Jugular venous pressure

Elevated in fluid overload

### 3 Blood pressure

Often elevated

### 2 Skin

Clinical examination techniques to evaluate urological and renal abnormalities. Inset (Dipstick): From Pitkin J, Peattie AB, Magowan BA. *Obstetrics and gynaecology: An illustrated colour text*. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2003.

Male lower urinary tract demonstrating the relationship of the bladder, urethra, vas deferens and testes.

This chapter describes the disorders of the kidneys and urinary tract that are commonly encountered in routine practice, as well as giving an overview of the highly specialised field of renal replacement therapy. Disorders of renal tubular function, which may cause alterations in electrolyte and acid–base balance, are described in [Chapter 19](#).

## Functional anatomy and physiology

### The kidneys

The kidneys play a central role in excretion of many metabolic breakdown products, including ammonia and urea from protein, creatinine from muscle, uric acid from nucleic acids, drugs and toxins. They achieve this by making large volumes of an ultrafiltrate of plasma (125 mL/min, 180 L/24 hrs) at the glomerulus, and selectively reabsorbing components of this ultrafiltrate at points along the nephron. The rates of filtration and reabsorption are controlled by many hormonal and haemodynamic signals to regulate fluid and electrolyte balance, blood pressure, and acid–base and calcium–phosphate homeostasis (all discussed in [Ch. 19](#)). In addition, the kidneys activate vitamin D and control the synthesis of red blood cells by producing erythropoietin. Strategies to replace each of these important functions are required when managing patients with kidney failure.

Each kidney is approximately 10–13 cm in length in healthy adults; they are located retroperitoneally on either side of the aorta and inferior vena cava between the 12th thoracic and 3rd lumbar vertebrae ([Fig. 18.1A](#)). The right kidney is usually a few centimetres lower because the liver lies above it. Both kidneys rise and descend several centimetres with respiration.

In keeping with their role as efficient blood filters, the kidneys have a rich blood supply and receive approximately 20%–25% of cardiac output through the renal arteries, which arise from the abdominal aorta. The renal arteries undergo various subdivisions within the kidney, eventually forming interlobular arteries that run through the renal cortex. These eventually give rise to afferent glomerular arterioles that supply the glomeruli. The efferent arteriole, leading from the glomerulus, supplies the distal nephron and medulla ([Fig. 18.1B](#)). This unique arrangement of two serial capillary beds reflects the role of the afferent and efferent arterioles in autoregulation of glomerular filtration.

### The nephron

Each kidney contains approximately 1 million individual functional units, called nephrons. Each nephron consists of a glomerulus, which is responsible for ultrafiltration of blood, a proximal renal tubule, a loop of Henle, a distal renal tubule and a collecting duct, which together are responsible for selective reabsorption of water and electrolytes that have been filtered at the glomerulus (see [Fig. 19.2](#) and [Fig. 18.1B](#)). Under normal circumstances, approximately 99% of the 180 L of glomerular filtrate that is produced each day is reabsorbed in the tubules. The remainder passes through the collecting ducts of each nephron and drains into the renal pelvis and ureters.

### The glomerulus

The glomerulus comprises a tightly packed loop of capillaries supplied by an afferent arteriole and drained by an efferent arteriole. It is surrounded by a cup-shaped extension of the proximal tubule termed Bowman's capsule, which is composed of epithelial cells. The glomerular capillary endothelial cells contain pores (fenestrae), through which circulating molecules can pass to reach the underlying glomerular basement membrane (GBM), which is formed by fusion of the basement membranes of tubular epithelial and vascular endothelial cells ([Fig. 18.1C and D](#)). Glomerular epithelial cells (podocytes) have multiple long foot processes that interdigitate with those of the adjacent epithelial cells, thereby maintaining a selective barrier to filtration ([Fig. 18.1E](#)). Mesangial cells lie in the central region of the glomerulus. They have contractile properties similar to those of vascular smooth muscle cells and play a role in regulating glomerular filtration rate.

Under normal circumstances, the glomerulus is impermeable to proteins the size of albumin (67 kDa) or larger, while proteins of 20 kDa or smaller are filtered freely. The ability of molecules between 20 and 67 kDa to pass through the GBM is variable and depends on the size (smaller molecules are filtered more easily) and charge (positively charged molecules are filtered more easily). Very little lipid is filtered by the glomerulus.

Filtration pressure in the glomerulus is normally maintained at a constant level in the face of wide variations in systemic blood pressure and cardiac output, by alterations in muscle tone within the afferent and efferent arterioles and mesangial cells. This is known as autoregulation. Reduced renal perfusion pressure increases local production of prostaglandins that mediate vasodilatation of the afferent arteriole, thereby increasing the intraglomerular pressure (see [Fig. 18.1D](#)). In addition, renin is released by specialised smooth muscle cells in the juxtaglomerular apparatus in response to reduced perfusion pressure, stimulation of sympathetic nerves or low sodium concentration of fluid in the distal convoluted tubule at the macula densa. Renin cleaves angiotensinogen to release angiotensin I, which is further cleaved by angiotensin-converting enzyme (ACE) to produce angiotensin II. This restores glomerular perfusion pressure in the short term by causing vasoconstriction of the efferent arterioles within the kidney to raise intraglomerular pressure selectively (see [Fig. 18.1D](#)), and by inducing systemic vasoconstriction to increase blood pressure and thus renal perfusion pressure. In the longer term, angiotensin II increases plasma volume by stimulating aldosterone release, which enhances sodium reabsorption by the renal tubules (see [Fig. 20.19](#)). Consumption of non-steroidal anti-inflammatory preparations and renin–angiotensin system inhibitors in the context of volume depletion may impair the ability of the kidney to maintain glomerular filtration and exacerbate pre-renal failure (see [Fig. 18.19](#)).

### Renal tubules, loop of Henle and collecting ducts

The proximal renal tubule, loop of Henle, distal renal tubule and collecting ducts are responsible for reabsorption of water, electrolytes and other solutes, as well as regulating acid–base balance, as described in detail on page 618 and in [Figure 19.2](#). They also play a key role in regulating calcium homeostasis by converting 25-hydroxyvitamin D to the active metabolite 1,25-dihydroxyvitamin D ([Fig. 26.62](#)). Failure of this process contributes to the pathogenesis of hypocalcaemia and hyperparathyroidism that occurs in chronic kidney disease (CKD). Fibroblast-like cells that lie in the interstitium of the renal cortex are responsible for production of erythropoietin, which is required for production of red blood cells. Erythropoietin synthesis is regulated by oxygen tension; anaemia and hypoxia increase production, whereas polycythaemia and hyperoxia inhibit it. Failure of erythropoietin production plays an important role in the pathogenesis of anaemia in CKD.

### The ureters and bladder

The ureters drain urine from the renal pelvis (see [Fig. 18.1A](#)) and deliver it to the bladder, a muscular organ that lies anteriorly in the lower part of the pelvis, just behind the pubic bone. The function of the bladder is to store and then release urine during micturition. The bladder is richly innervated. Sympathetic nerves arising from T10–L2 relay in the pelvic ganglia to cause relaxation of the detrusor muscle and contraction of the bladder neck (both via  $\alpha$ -adrenoceptors), thereby preventing release of urine from the bladder. The distal sphincter mechanism is innervated by somatic motor fibres from sacral segments S2–4, which reach the sphincter either by the pelvic plexus or via the pudendal nerves. Afferent sensory impulses pass to the cerebral cortex, from where reflex-increased sphincter tone and suppression of detrusor contraction inhibit micturition until it is appropriate. Conversely, parasympathetic nerves arising from S2–4 stimulate detrusor contraction, promoting micturition.

The micturition cycle has a storage (filling) phase and a voiding (micturition) phase. During the filling phase, the high compliance of the detrusor muscle allows the bladder to fill steadily without a rise in intravesical pressure. As bladder volume increases, stretch receptors in its wall cause reflex bladder relaxation and increased sphincter tone. The act of

micturition is initiated first by voluntary and then by reflex relaxation of the pelvic floor and distal sphincter mechanism, followed by reflex detrusor contraction. These actions are coordinated by the pontine micturition centre. Intravesical pressure remains greater than urethral pressure until the bladder is empty.

### The prostate gland

The prostate gland is situated at the base of the bladder, surrounding the proximal urethra (p. 559). Exocrine glands within the prostate produce fluid, which comprises about 20% of the volume of ejaculated seminal

**Fig. 18.1** Functional anatomy of the kidney. **A** Anatomical relationships of the kidney. **B** A single nephron. For the functions of different segments, see Fig. 19.2. **C** Histology of a normal glomerulus. **D** Schematic cross-section of a glomerulus, showing five capillary loops, to illustrate structure and show cell types. **E** Electron micrograph of the filtration barrier. (GBM = glomerular basement membrane) (C) Courtesy of Dr J.G. Simpson, Aberdeen Royal Infirmary.

fluid and is rich in zinc and proteolytic enzymes. The remainder of the ejaculate is formed in the seminal vesicles and bulbo-urethral glands, with spermatozoa arising from the testes.

Smooth muscle fibres within the prostate, which are under sympathetic control, play a role in controlling urine flow through the bulbar urethra, and also contract at orgasm to move seminal fluid through ejaculatory ducts into the bulbar urethra (emission). Contraction of the bulbocavernosus muscle (via a spinal muscle reflex) then ejaculates the semen out of the urethra.

## The penis

Blood flow into the corpus cavernosum of the penis is controlled by sympathetic nerves from the thoracolumbar plexus, which maintain smooth muscle contraction (p. 559). In response to afferent input from the glans penis and from higher centres, pelvic splanchnic parasympathetic nerves actively relax the cavernosal smooth muscle via neurotransmitters such as nitric oxide, acetylcholine, vasoactive intestinal polypeptide (VIP) and prostacyclin, with consequent dilatation of the lacunar space. At the same time, draining venules are compressed, trapping blood in the lacunar space with consequent elevation of pressure and erection (tumescence) of the penis.

## Investigation of renal and urinary tract disease

### Glomerular filtration rate

The glomerular filtration rate (GFR) is the sum of the ultrafiltration rates from plasma into the Bowman's space in each nephron and is a measure of renal excretory function. It is proportionate to body size and the reference value is usually expressed after correction for body surface area as  $150 \pm 25$  mL/min/1.73 m<sup>2</sup>. The GFR may be measured directly by injecting and measuring the clearance of compounds such as inulin or radiolabelled ethylenediamine-tetra-acetic acid (EDTA), which are completely filtered at the glomerulus and are not secreted or reabsorbed by the renal tubules (Box 18.1). This is not performed routinely, however, and is usually reserved for special circumstances, such as the assessment of renal function in potential live kidney donors. Instead, GFR is usually assessed indirectly in clinical practice by measuring serum levels of endogenously produced compounds that are excreted by the kidney. The most widely used is serum creatinine, which is produced by muscle at a constant rate, is almost completely filtered at the glomerulus, and is not reabsorbed. Although creatinine is secreted to a small degree by the proximal tubule, this is only usually significant in terms of GFR estimation in severe renal impairment, where it accounts for a larger proportion of the creatinine excreted. Accordingly, provided muscle mass remains constant, changes in serum creatinine concentrations closely reflect changes in GFR. The relationship between serum creatinine and GFR is not linear, however, and a modest elevation in serum creatinine above the normal range may therefore reflect a substantial decline in GFR (Fig. 18.2). For this reason, several methods have been developed to estimate GFR from serum creatinine measurements (see Box 18.1) but the most widely used are the Modification of Diet in Renal Disease (MDRD) and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations. Routine reporting by laboratories of estimated GFR (eGFR) has increased recognition of moderate kidney damage and encouraged early deployment of protective therapies; however, some limitations remain (Boxes 18.2 and 18.3). In particular, the MDRD formula is based on the serum creatinine value and so is heavily influenced by muscle mass; eGFR may therefore be misleading in individuals whose muscle bulk is outside the normal range for their sex and age. Measurement of other endogenous metabolites, such as cystatin C, may provide a more accurate estimate of GFR in this setting, though this test is not yet widely available in routine clinical practice.

Direct measurement of creatinine clearance by collecting a 24-hour urine sample and relating serum creatinine levels to urinary creatinine excretion (see Box 18.1) is now less commonly performed due to the difficulty in obtaining accurate 24-hour urine collections. It may still have a role in assessing renal function in patients at extremes of muscle mass, where the creatinine-based equations perform poorly.

## Urine investigations

Screening for the presence of blood, protein, glucose, ketones, nitrates and leucocytes, and assessment of urinary pH and osmolality can be achieved by dipstick testing. The presence of leucocytes and nitrites in urine is indicative of renal tract infection. Urine pH can provide diagnostic information in the assessment of renal tubular acidosis and urinary tract stones (p. 630).

Urine microscopy (Fig. 18.3) may detect dysmorphic erythrocytes or red cell casts, which suggest the presence of glomerular disease. White cell casts are strongly suggestive of pyelonephritis but may also occur in other forms of inflammation such as interstitial nephritis. Microscopy may also detect the presence of bacteria in those with urinary infection and crystals in patients with renal stone disease. It should be noted that calcium oxalate and urate crystals can sometimes be found in normal urine that has been left to stand, due to crystal formation *ex vivo*.

Urine collection over a 24-hour period may be performed to measure excretion of solutes, such as calcium, oxalate and urate, in patients with recurrent renal stone disease (p. 602). Proteinuria can also be measured

### 18.1 How to estimate glomerular filtration rate (GFR)

#### Measuring GFR

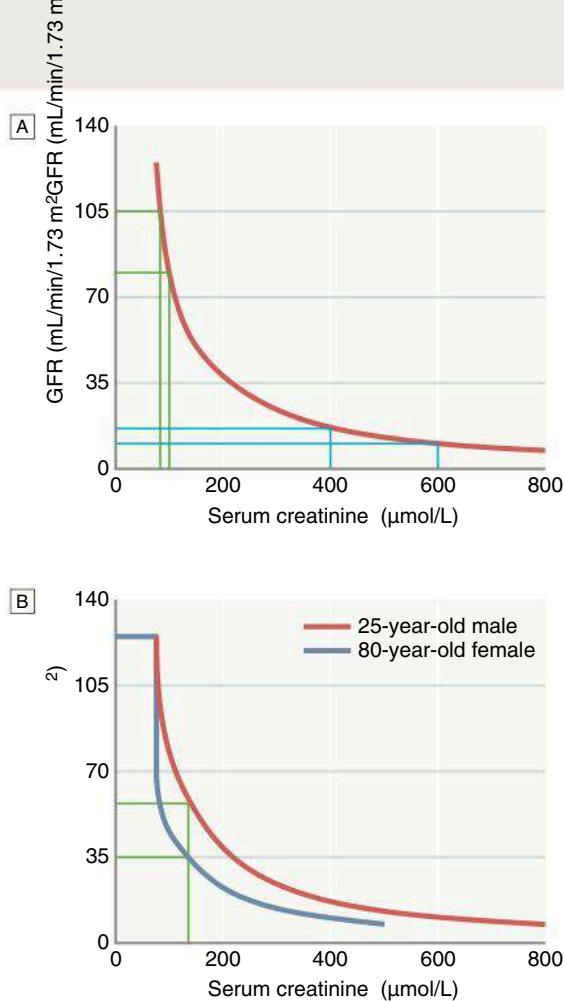

- Direct measurement using labelled ethylenediamine-tetra-acetic acid (EDTA) or inulin
- Creatinine clearance (CrCl):
  - Minor tubular secretion of creatinine causes CrCl to exaggerate GFR when renal function is poor; can be affected by drugs (e.g. trimethoprim, cimetidine)
  - Needs 24-hr urine collection (inconvenient and often unreliable)

$$\text{CrCl (mL/min)} = \frac{\text{urine creatinine concentration (micromol/L)} \times \text{volume (mL)}}{\text{plasma creatinine concentration (micromol/L)} \times \text{time (min)}}$$

#### Estimating GFR with equations

- The Modification of Diet in Renal Disease (MDRD) study equation (see [www.renal.org/eGFR](http://www.renal.org/eGFR)):
  - Requires knowledge of age and sex only; it can therefore be reported automatically by laboratories
  - For limitations, see Box 18.2
$$\text{eGFR} = 175^* \times (\text{creatinine in micromol/L } 88.4)^{-1.154} \times (\text{age in yrs})^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if Black})$$
- The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation:
  - More accurately estimates the actual GFR than the MDRD eGFR in those with relatively preserved renal function
$$\text{eGFR} = 141 \times \min(\text{SCr}/\kappa, 1)^\alpha \times \max(\text{SCr}/\kappa, 1)^{-1.206} \times 0.993^{\text{Age}} \times (1.018 \text{ if female}) \times (1.21 \text{ if Black})$$
  - Where SCr = serum creatinine in micromol/L
  - $\kappa = 61.9$  if female and  $79.6$  if male
  - $\alpha = -0.329$  if female and  $-0.411$  if male
  - min = whichever is the minimum of serum creatinine/ $\kappa$  or 1
  - max = whichever is the maximum of serum creatinine/ $\kappa$  or 1
- No equations perform well in unusual circumstances, such as extremes of body (and muscle) mass or in acutely unwell patients (see Box 18.2)

\*A correction factor of 175 is used for isotope dilution mass spectrometry traceable creatinine measurements. To convert creatinine in mg/dL to  $\mu\text{mol/L}$ , multiply by 88.4.

**Fig. 18.2** Serum creatinine and the glomerular filtration rate (GFR). **A** The relationship between serum creatinine and estimated GFR (eGFR) is non-linear: small increases above the normal range (e.g. 80–100 μmol/L; green lines) can indicate a substantial decline in renal function (e.g. 105–80 mL/min/1.73 m<sup>2</sup>); conversely, in the high range, large changes in creatinine (e.g. 400–600 μmol/L; blue lines) can occur with only small declines in renal function (e.g. 20–15 mL/min/1.73 m<sup>2</sup>). **B** Creatinine is dependent on muscle mass; the same creatinine value may therefore reflect very different levels of renal function depending on the age and sex of the individual. To convert creatinine in mg/dL to μmol/L, multiply by 88.4.

on 24-hour collections but is usually now quantified by protein:creatinine ratio on single urine samples.

Other dynamic tests of tubular function, including concentrating ability (p. 700), ability to excrete a water load (p. 624), ability to excrete acid (p. 588) and calculation of fractional calcium, phosphate or sodium excretion are valuable in some circumstances but are usually performed in very specific contexts. The fractional excretion of these ions can be calculated by the general formula:  $100 \times (\text{urine concentration of analyte} \times \text{serum creatinine}) / (\text{serum concentration of analyte} \times \text{urinary creatinine})$ . Calculation of fractional excretion of sodium (FENa) can help in the setting of acute kidney injury (AKI) to differentiate pre-renal failure, when the intact tubules are avidly conserving sodium in response to volume depletion (FENa typically <1.0%), from acute tubular necrosis, when the tubules are damaged and are less able to conserve sodium (FENa typically >1.0%). In clinical practice this is seldom required.

## Blood tests

### Haematology

A normochromic normocytic anaemia is common in CKD and is due in part to deficiency of erythropoietin and bone marrow suppression secondary to toxins retained in CKD. Other causes of anaemia include iron deficiency from urinary tract bleeding, and haemolytic anaemia

## 18.2 Limitations of estimated glomerular filtration rate (eGFR)

- It is only an estimate, with wide confidence intervals (90% of patients will have eGFR within 30% of their measured GFR, and 98% within 50%)
- It is based on serum creatinine, and so may overestimate actual GFR in patients with low muscle mass (e.g. those with cachexia, amputees) and underestimate actual GFR in individuals taking creatine supplements (creatinine is a metabolite of creatine) or trimethoprim (inhibits secretion of creatinine)
- Creatinine level must be stable over days; eGFR is not valid in assessing acute kidney injury
- It tends to underestimate true GFR at normal or near-normal function, so slightly low values should not be over-interpreted
- In older adults, who constitute the majority of those with low eGFR, there is controversy about categorising people as having chronic kidney disease (see Box 18.3) on the basis of eGFR alone, particularly at stage 3A, since there is little evidence of adverse outcomes when eGFR is >45 mL/min/1.73 m<sup>2</sup> unless there is also proteinuria
- eGFR is not valid in under-18s or during pregnancy
- Ethnicity is not taken into account in routine laboratory reporting; the laboratory eGFR value should therefore be multiplied by 1.21 for Black people
- Few patients will understand eGFR in terms of mL/min/1.73 m<sup>2</sup>; it may therefore be helpful to assume that a GFR of 100 mL/min/1.73 m<sup>2</sup> is approximately normal and to discuss eGFR values in terms of a percentage of normal, e.g. 25 mL/min/1.73 m<sup>2</sup> = 25% of normal kidney function

secondary to disorders such as haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Other abnormalities may be observed that reflect underlying disease processes, such as neutrophilia and raised erythrocyte sedimentation rate (ESR) in vasculitis or sepsis, and lymphopenia and raised ESR in systemic lupus erythematosus (SLE). Fragmented red cells on blood film and low platelets may be observed in thrombotic microangiopathies such as HUS/TTP and malignant hypertension. Pancytopenia may occur in SLE or bone marrow suppression due to myeloma.

## Biochemistry

Abnormalities of routine biochemistry are common in renal disease. Serum levels of creatinine may be raised, reflecting reduced GFR (see above), as may serum potassium. Serum levels of urea are often increased in kidney disease but this analyte has limited value as a measure of GFR since levels are dependent on factors other than renal function. Serum urea increases with high protein intake, following gastrointestinal haemorrhage and in catabolic states. Conversely, urea levels may be reduced in patients with chronic liver disease and in patients who are anorexic or malnourished. In the absence of the other causes mentioned above, an elevated urea:creatinine ratio is indicative of volume depletion and pre-renal failure (see AKI section). Serum calcium tends to be reduced and phosphate increased in CKD, in association with high parathyroid hormone (PTH) levels caused by reduced production of 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D) by the kidney (secondary hyperparathyroidism). In some patients, this may be accompanied by raised serum alkaline phosphatase levels, which are indicative of renal osteodystrophy. Serum bicarbonate may be low in renal failure and also in renal tubular acidosis independently of renal function. Serum albumin may be low in malnutrition/malabsorption, in liver disease, or as a negative acute phase response, however, if it is a new finding it should prompt urinalysis to exclude nephrotic syndrome. Other biochemical abnormalities that may reflect underlying disease processes include: raised glucose and HbA<sub>1c</sub> in diabetes mellitus (p. 711) and raised serum C-reactive protein (CRP) in sepsis and vasculitis.

## Immunology

Antinuclear antibodies, antibodies to extractable nuclear antigens and anti-double-stranded DNA antibodies may be detected in patients with renal disease secondary to SLE (Ch. 26). Antineutrophil cytoplasmic antibodies

18.3 Stages of chronic kidney disease (CKD)				
Stage <sup>1</sup>	Definition <sup>2</sup>	Description	Prevalence <sup>4</sup>	Clinical presentation <sup>5</sup>
1	Kidney damage <sup>3</sup> with normal or high GFR (>90)	Normal function	3.5%	Asymptomatic
2	Kidney damage and GFR 60–89	Mild CKD	3.9%	Asymptomatic
3A	GFR 45–59	Mild to moderate CKD	7.6% (3A and 3B combined)	Usually asymptomatic
3B	GFR 30–44	Moderate to severe CKD		Anaemia in some patients at 3B Most are non-progressive or progress very slowly
4	GFR 15–29	Severe CKD	0.4%	First symptoms often at GFR <20 Electrolyte problems likely as GFR falls
5	GFR <15 or on dialysis	Kidney failure	0.1%	Significant symptoms and complications usually present Dialysis initiation varies but usually at GFR <10

<sup>1</sup>Stages of CKD 1–5 were originally defined by the US National Kidney Foundation Kidney Disease Quality Outcomes Initiative 2002. In the 2013 Kidney Disease Outcomes Quality Initiative (K/DOQI) CKD guideline update, the suffices A1, A2 and A3 are recommended, indicating the presence of albuminuria of <30, 30–300 and >300 mg/24 hrs respectively, in view of the prognostic importance of albuminuria. <sup>2</sup>Two glomerular filtration rate (GFR) values 3 months apart are required to assign a stage. All GFR values are in mL/min/1.73 m<sup>2</sup>. <sup>3</sup>Kidney damage means pathological abnormalities or markers of damage, including abnormalities in urine tests or imaging studies. <sup>4</sup>From Hill NR, Fatoba ST, Oke JL, et al. Global prevalence of chronic kidney disease – a systematic review and meta-analysis. PLoS One 2016; 11:e0158765. <sup>5</sup>For further information, see page 588.

**Fig. 18.3 Urine microscopy.** **A** Intact erythrocytes due to bleeding from lower in the urinary tract ( $\times 400$ ). **B** Dysmorphic erythrocytes due to glomerular inflammation ( $\times 400$ ). **C** Hyaline casts in normal urine. **D** Erythrocytes and a red cell cast in glomerulonephritis ( $\times 100$ ). Bosco Hospital, Turin (from [www.sin-italia.org/imagen/sediment/sed.htm](http://www.sin-italia.org/imagen/sediment/sed.htm)).

(ANCA) may be detected in patients with glomerulonephritis secondary to systemic vasculitis (Ch. 26), as may antibodies to GBM in patients with Goodpasture's disease, and low levels of complement may be observed in a number of kidney diseases (see Box 18.17). Antibodies directed against M-type phospholipase A<sub>2</sub> receptor (anti-PLA2R) are positive in about 70%–80% of cases of primary membranous nephropathy.

## Imaging

### Ultrasound

Renal ultrasound is a valuable non-invasive technique that may be performed to assess renal size and to investigate patients suspected of having urinary tract obstruction (Fig. 18.4), renal tumours, cysts or stones. Ultrasound can also be used to provide images of the prostate gland

and bladder, and to estimate the completeness of bladder emptying in patients with suspected bladder outflow obstruction. Increased echogenic signal in the renal cortex on ultrasonography with loss of distinction between cortex and medulla is characteristic of intrinsic renal disease, but not specific for any particular pathology. Doppler imaging can be used to study blood flow in extrarenal and larger intrarenal vessels, and to assess the resistivity index (peak systolic velocity – end-diastolic velocity/peak systolic velocity in the intrarenal arteries), which may be elevated (>0.7) in various diseases, including acute tubular necrosis and rejection of a renal transplant. However, renal ultrasound is operator-dependent and the results are often less clear in obese patients.

### Computed tomography

Computed tomography urography (CTU) is used to evaluate cysts and mass lesions in the kidney or filling defects within the collecting system. It usually entails an initial scan without contrast medium, and subsequent scans following injection of contrast to obtain a nephrogram image and images during the excretory phases. CTU has largely replaced the previous gold-standard investigation of intravenous urography (IVU) for investigation of the upper urinary tract, having the advantage of providing complete staging information and details of surrounding organs. Contrast enhancement is particularly useful for characterising mass lesions within the kidney and differentiating benign from malignant lesions (see Fig. 18.32A). CT without contrast gives clear definition of retroperitoneal anatomy regardless of obesity and is superior to ultrasound in this respect. Non-contrast CT of kidneys, ureters and bladder (CTKUB) is the method of choice for demonstrating stones within the kidney or ureter (see Fig. 18.28). For investigation of patients with renal trauma, a triple-phase CT scan with a delayed phase, to assess the integrity of the collecting system, is performed. Drawbacks of contrast-enhanced CT scans include the significant radiation dose required and the fact that contrast medium may cause AKI. The incidence of contrast nephropathy is probably lower than previously thought and the AKI is typically mild and reversible, therefore this potential risk should not preclude CT scanning when indicated (Box 18.4).

### Magnetic resonance imaging

Magnetic resonance imaging (MRI) offers excellent resolution and distinction between different tissue types (see Fig. 18.15). It is very useful for local staging of prostate, bladder and penile cancers. Magnetic resonance angiography (MRA) provides an alternative to CT for imaging renal vessels but involves administration of gadolinium-based contrast media, which may carry risks for patients with impaired renal function

**Fig. 18.4 Renal ultrasound.** **A** Normal kidney. The normal cortex is less echo-dense (blackier) than the adjacent liver. **B** Simple renal cyst: round, echo-free fluid content, no septa, posterior acoustic enhancement. **C** The renal pelvis and calyces are dilated due to obstruction. The thinness of the parenchyma (P) indicates chronic obstruction. **D** A typical renal stone with posterior shadowing. **E** A T1b renal tumour arising from the renal cortex. (AS = posterior acoustic shadow; C = calyx; K = kidney; L = liver; RC = renal cortex; RP = renal pelvis; RS = renal sinus – calyx, renal pelvis, blood vessels, sinus fat; T = tumour; U = ureter) (A–E) Courtesy of Dr Tobias Klatte, Addenbrooke's Hospital, Cambridge.

## 18.4 Renal complications of radiological investigations

### Contrast nephrotoxicity

- Acute deterioration in renal function commencing <48 hrs after administration of IV radiographic contrast media. Typically modest and reversible AKI

### Risk factors

- Pre-existing renal impairment (eGFR <45 mL/min/1.73m<sup>2</sup>)
- Use of ionic contrast media and repetitive dosing in short time periods
- Diabetes mellitus and myeloma

### Prevention

- Provide hydration with free oral fluids plus IV isotonic saline 500 mL, then 250 mL/hr during procedure
- Withhold NSAIDs. Omit metformin for 48 hrs after the procedure, in moderate or high-risk patients
- If the risks are high (eGFR <30 mL/min/1.73m<sup>2</sup>), consider alternative methods of imaging, but proceed if benefit of imaging exceeds risk of nephropathy, which is often the case

### Cholesterol atheroembolism

- Typically follows days to weeks after intra-arterial investigations or interventions

### Nephrogenic sclerosing fibrosis after MRI contrast agents

- Chronic progressive sclerosis of skin, deeper tissues and other organs, associated with gadolinium-based contrast agents
- Only reported in patients with renal impairment, typically on dialysis or with GFR <15 mL/min/1.73 m<sup>2</sup>, but caution is advised in patients with GFR <30 mL/min/1.73 m<sup>2</sup>
- Rare since switch to more stable gadolinium-based agents

(AKI = acute kidney injury; eGFR = estimated glomerular filtration rate; IV = intravenous; NSAIDs = non-steroidal anti-inflammatory drugs)

(see Box 18.4). Whilst MRA provides good images of the main renal vessels, stenosis of small branch arteries may be missed.

## Renal arteriography

Renal arteriography involves obtaining X-rays following an injection of contrast medium directly into the renal artery via a catheter that is usually inserted into the femoral artery. The main indication is to investigate renal artery stenosis (p. 580) or haemorrhage following renal trauma. Renal angiography can be combined with therapeutic balloon dilatation or stenting of the renal artery. It can be used to occlude bleeding vessels and arteriovenous fistulae by the insertion of thin platinum wires (coils), which promote thrombosis, thereby securing haemostasis.

## Pyelography

Pyelography involves direct injection of contrast medium into the collecting system from above (antegrade) or below (retrograde). It offers the best views of the collecting system and upper tract, and is often

**Fig. 18.5 Retrograde pyelography.** The best views of the collecting system are obtained by pyelography. A catheter has been passed into the left renal pelvis at cystoscopy. In the image shown the calyces are sharp-edged and normal. Courtesy of Dr A.P. Bayliss and Dr P. Thorpe, Aberdeen Royal Infirmary.

used to identify the cause of urinary tract obstruction. Antegrade pyelography requires the insertion of a fine needle into the pelvicalyceal system under ultrasound or radiographic control. In addition to visualising the cause of obstruction, percutaneous nephrostomy drainage can be established and an antegrade stent can be passed through any obstruction. Retrograde pyelography can be performed by inserting a ureteric catheter into the ureteric orifice at cystoscopy (Fig. 18.5) and again a stent can be inserted to bypass an obstruction.

## Radionuclide studies

These are functional studies requiring the injection of gamma ray-emitting radiopharmaceuticals that are taken up and excreted by the kidney, a process that can be monitored by an external gamma camera.

Dynamic radionuclide studies are performed with mercaptoacetyltri-glycine labelled with technetium (<sup>99m</sup>Tc-MAG3), which is filtered by the glomerulus and excreted into the urine. Imaging following <sup>99m</sup>Tc-MAG3 injection can provide valuable information about the perfusion of each kidney but is not a reliable method for identifying renal artery stenosis. In patients with significant obstruction of the outflow tract, <sup>99m</sup>Tc-MAG3 persists in the renal pelvis and a loop diuretic fails to accelerate its disappearance. This study can be useful in determining the functional significance of a collecting system that appears obstructed on imaging.

Formal measurements of GFR can be made by radionuclide studies following the injection of diethylenetriamine penta-acetic acid ( $^{99m}\text{Tc}$ -DPTA) or  $^{51}\text{Cr}$ -EDTA.

Static radionuclide studies are performed with dimercaptosuccinic acid labelled with technetium ( $^{99m}\text{Tc}$ -DMSA), which is taken up by proximal tubular cells. Following intravenous injection, images of the renal cortex are obtained to show the shape, size and relative function of each kidney (Fig. 18.6). This is a sensitive method for demonstrating cortical scarring in reflux nephropathy and a way of assessing the individual function of each kidney.

Radionuclide bone scanning following the injection of methylene diphosphonate ( $^{99m}\text{Tc}$ -MDP) can assess the presence and extent of bone metastases in men with prostate cancer (p. 610).

## Renal biopsy

Renal biopsy is used to establish the diagnosis and severity of renal disease in order to judge the prognosis and need for treatment (Box 18.5). Renal tumour biopsy may be performed to determine the aetiology of a renal mass. The procedure is performed percutaneously under local anaesthetic with ultrasound guidance to ensure accurate needle placement into a renal pole. Light microscopy, electron microscopy and immunohistological assessment of the specimen may all be required.

## Presenting problems in renal and urinary tract disease

It is important to recognise that many forms of kidney disease and urological diseases are asymptomatic. For example, most causes of chronic kidney disease do not present with symptoms until kidney function is severely impaired (GFR  $<20\text{ mL/min/1.73 m}^2$ ), and even then the symptoms are non-specific, such as lethargy, swelling and loss of appetite and weight. Hence, for many patients kidney disease will only be detected through investigations such as serum creatinine or urinalysis. People at high risk of disease, for example those with diabetes, hypertension or SLE, should therefore be screened regularly using these tests, as should people presenting with symptoms such as oedema. Patients with renal or prostate cancer often have no relevant symptoms and the diagnosis is made serendipitously.

## Oliguria/anuria

Oliguria and anuria are defined as a urine output of less than 400 mL/day or 100 mL/day, respectively. The volume of urine produced represents a

**Fig. 18.6** DMSA radionuclide scan. A posterior view is shown of a normal left kidney and a small right kidney (with evidence of cortical scarring at upper and lower poles) that contributes only 39% of total renal function.

balance between the amount of fluid filtered at the glomerulus and that reabsorbed by the renal tubules. When GFR is low, urine volumes may still be normal if tubular reabsorption is also reduced; hence patients with advanced kidney disease may not report a reduction in urinary output. Complete anuria, particularly when sudden in onset, may indicate a structural problem such as complete urinary obstruction or vascular occlusion, though it may occur with severe renal disease of any cause (Box 18.6).

Oliguria is common in pre-renal AKI, as the intravascular volume depletion activates the renin–angiotensin–aldosterone system to promote sodium retention and stimulates release of ADH to promote water retention. Indeed, oliguria may precede and predict the onset of AKI and hence urinary output  $<0.5\text{ mL/kg/hr}$  should prompt assessment of fluid status and correction of volume depletion where present. Urine volume may remain normal in pre-renal failure when there is an osmotic diuresis as occurs in diabetic ketoacidosis with marked glycosuria.

Urine volumes are variable in AKI due to intrinsic renal disease, but a rapid decline in urine volume may be observed. Marked oliguria predicts

## 18.5 Renal biopsy

### Indications

- Acute kidney injury and chronic kidney disease of uncertain aetiology
- Nephrotic syndrome or glomerular proteinuria (protein:creatinine ratio  $>100\text{ mg/mol}$ ) in adults
- Nephrotic syndrome in children that has atypical features or is not responding to treatment
- Nephritic syndrome
- Renal transplant dysfunction
- Rarely performed for isolated haematuria or isolated low-grade proteinuria in the absence of impaired renal function or evidence of a multisystem disorder

### Contraindications

- Disordered coagulation or thrombocytopenia. Aspirin and other antiplatelet agents increase bleeding risk
- Uncontrolled hypertension
- Kidneys  $<60\%$  predicted size
- Solitary kidney\* (except transplants)

### Complications

- Pain, usually mild
- Bleeding into urine, usually minor but may produce clot colic and obstruction
- Bleeding around the kidney, occasionally massive and requiring angiography with intervention, or surgery
- Arteriovenous fistula, rarely significant clinically

\*Relative contraindication.

## 18.6 Causes of anuria ( $<100\text{ mL}$ urine output per day)

Condition	Examples
<b>Urinary obstruction (complete)</b>	Urinary retention due to prostatic enlargement, urethral stenosis, bladder tumour Bilateral ureteric obstruction due to retroperitoneal fibrosis, cancer, bilateral ureteric stones, radiation injury Bilateral renal stones (usually staghorn calculi) Massive crystalluria obstruction of tubules (rare)
<b>Lack of renal perfusion (bilateral)</b>	Aortic dissection involving renal arteries Severe acute tubular necrosis Severe functional hypoperfusion (cardiorenal, hepatorenal)
<b>Rapidly progressive glomerulonephritis</b>	Anti-glomerular basement membrane disease, severe antineutrophil cytoplasmic antibody (ANCA) vasculitis (100% glomerular crescents on biopsy)

poor renal outcome in those with glomerulonephritis and poor patient survival in those with acute tubular necrosis in ICU.

Obstruction of the renal tract can result in oliguria and anuria; however, for this to occur the obstruction must be complete and affect both kidneys, unless the patient has a single functioning kidney. Hence, the obstruction is most likely to occur at the level of the bladder outlet, for example in benign prostatic hypertrophy (see Fig. 18.18). It is less common for both ureters to become obstructed simultaneously, though this can occur with retroperitoneal fibrosis or bilateral renal calculi. Partial obstruction can be associated with normal or even high urine volume due to chronic tubular injury, which causes loss of tubular concentrating ability.

## Polyuria

Polyuria is defined as a urine volume in excess of 3L/24 hrs. Various underlying conditions, both renal and extrarenal, may be responsible, as outlined in Box 18.7.

Investigation of polyuria includes measurement of urea, creatinine, sodium, potassium, osmolarity, glucose and calcium. A 24-hour urine collection may be helpful to confirm the severity of polyuria. The presence of nocturnal polyuria suggests a pathological cause. Investigation and management of suspected diabetes insipidus are described in Chapter 20.

## Frequency

Frequency describes daytime micturition more often than a patient would expect. It may be a consequence of polyuria, when urine volume is normal or high, but is also found in patients with urinary infection and prostatic diseases, when small amounts of urine are passed each time and the total daily urine volume is normal.

## Nocturia

Nocturia is defined as waking to pass urine during the main sleep period. Nocturia occurs in the recovery phase of AKI and in many patients with CKD due to loss of urine-concentrating ability due to tubular injury. It may also be due to prostatic enlargement when it is associated with other lower urinary tract symptoms such as poor stream, hesitancy, incomplete bladder emptying, terminal dribbling and urinary frequency due to partial urethral obstruction (p. 609). Nocturia may be exacerbated by increased fluid intake or diuretic use in the late evening (including caffeine). It may also occur due to sleep disturbance without any functional abnormalities of the urinary tract.

## Urinary incontinence

Urinary incontinence is defined as any involuntary leakage of urine. It may occur in patients with a normal urinary tract, as the result of dementia or poor mobility, or transiently during an acute illness or hospitalisation, especially in older people (see Box 18.52). The pathophysiology,

investigation and management of urinary incontinence are discussed in detail later in the chapter.

## Abdominal pain

Loin pain is more often musculoskeletal in origin but can be a manifestation of urinary tract disease; in the latter case, it may arise from renal stones, ureteric stones, renal tumours, acute pyelonephritis and urinary tract obstruction. Acute loin pain radiating to the groin is termed renal colic. This is typical of ureteric obstruction due to calculi and is often accompanied by haematuria. Precipitation of dull loin pain by a large fluid intake (Dietl's crisis) suggests upper urinary tract obstruction such as caused by a congenital pelvi-ureteric junction obstruction (p. 604). Obstruction at the bladder neck is associated with lower midline abdominal discomfort. Chronic obstruction rarely produces pain but may give rise to a dull ache.

## Dysuria

Dysuria refers to painful urination, often described as burning or stinging, and is commonly accompanied by suprapubic pain. It is often associated with frequency of micturition and a feeling of incomplete emptying of the bladder. By far the most common cause is urinary tract infection, as described on page 599. Other diagnoses that need to be considered in patients with dysuria include sexually transmitted infections (Ch. 15) and bladder stones (p. 602).

## Oedema

Oedema is caused by an excessive accumulation of fluid within the interstitial space. Clinically, this can be detected by persistence of an indentation in tissue following pressure on the affected area (pitting oedema). Non-pitting oedema is typical of lymphatic obstruction and may also occur as the result of excessive matrix deposition in tissues: for example, in hypothyroidism (Ch. 20) or systemic sclerosis (Ch. 26). Oedema may be due to a number of causes (Box 18.8).

### Clinical assessment

Dependent areas, such as the ankles and lower legs, are typically affected first but oedema can be restricted to the sacrum in bed-bound

### 18.7 Causes of polyuria

- Excess fluid intake (characterised by low serum osmolarity)
- Osmotic diuresis: hyperglycaemia, hypercalcaemia, sodium-glucose transporter inhibitors
- Cranial diabetes insipidus
- Nephrogenic diabetes insipidus:
  - Rare inherited mutations in vasopressin receptor or aquaporin 2 genes
  - Vasopressin receptor antagonists (tolvaptan)
  - Lithium
  - Interstitial nephritis
  - Hypokalaemia
  - Transiently following recovery from acute tubular necrosis (ATN) or relief of urinary obstruction

### 18.8 Causes of oedema

#### Increased total extracellular fluid

- Congestive heart failure
- Renal failure
- Liver disease

#### High local venous pressure

- Deep venous thrombosis or venous insufficiency
- Pregnancy
- Pelvic tumour

#### Low plasma oncotic pressure/serum albumin

- Nephrotic syndrome
- Liver failure
- Malnutrition/malabsorption

#### Increased capillary permeability

- Local infection/inflammation
- Severe sepsis
- Calcium channel blockers

#### Lymphatic obstruction

- Infection: filariasis, lymphogranuloma venereum
- Malignancy
- Radiation injury
- Congenital abnormality

patients. Pitting oedema tends to accumulate in the ankles during the day and improves overnight as the interstitial fluid is reabsorbed. Conversely, facial oedema on waking is common. With increasing severity, oedema spreads to affect the upper parts of the legs, the genitalia and abdomen. Ascites is common and often an earlier feature in children or young adults, and in liver disease. Pleural effusions are common, particularly on the right side. Raised JVP and pulmonary oedema are uncommon in patients with low oncotic pressure such as nephrotic syndrome, but common in the context of increased total extracellular fluid such as in cardiac and renal failure. Features of intravascular volume depletion (tachycardia, postural hypotension) may occur when oedema is due to decreased oncotic pressure or increased capillary permeability. If oedema is localised – for example, to one ankle but not the other – then local inflammation, venous thrombosis or lymphatic disease should be suspected.

### Investigations

Blood should be taken for measurement of creatinine and electrolytes, liver function and serum albumin, and the urine tested for protein. Further imaging of the liver, heart or kidneys may be indicated, based on history and clinical examination. Where ascites or pleural effusions occur in isolation, measurement of protein, glucose and LDH, and microscopy for cells in the aspirate will usually differentiate a transudate (typical of oedema) from an exudate (more suggestive of local pathology, p. 494).

### Management

Mild oedema usually responds to elevation of the legs, compression stockings, or a thiazide or a low dose of a loop diuretic. In nephrotic syndrome, renal failure and severe cardiac failure, very large doses of diuretics, sometimes in combination, may be required to achieve a negative sodium and fluid balance. Restriction of sodium and fluid intake may be required. Diuretics are not helpful in the treatment of oedema caused by increased capillary permeability or by venous or lymphatic obstruction. Specific causes of oedema, such as venous thrombosis, should be treated.

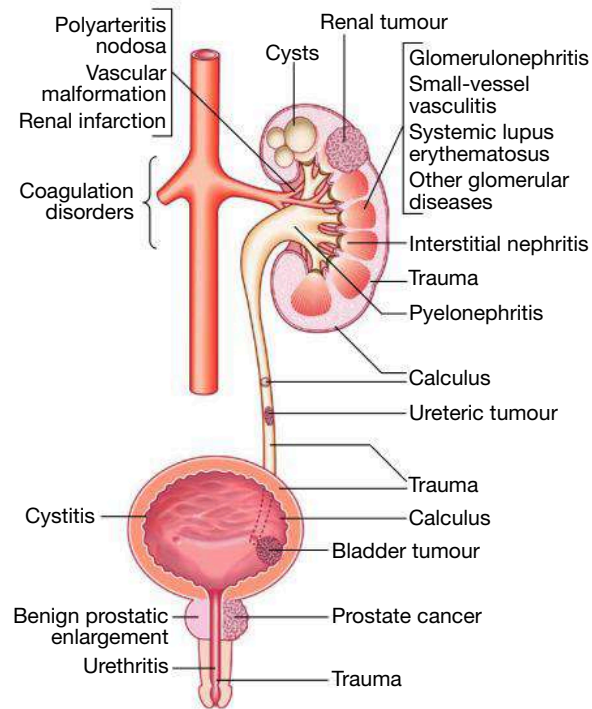

## Hypertension

Hypertension is a very common feature of renal disease. Additionally, the presence of hypertension identifies a population at risk of developing CKD and current recommendations are that hypertensive patients should have renal function checked annually. Control of hypertension is very important in patients with renal impairment because of its close relationship with further decline of renal function (p. 593) and increased cardiovascular risk. Pathophysiology and management are discussed in [Chapter 16](#).

## Haematuria

Healthy individuals may have occasional red blood cells in the urine (<3 red blood cells/high power field), but the presence of visible (macroscopic) haematuria or non-visible (microscopic, only detectable on dipstick testing) haematuria is indicative of bleeding from somewhere in the urinary tract ([Fig. 18.7](#)). Once infection, menstruation and causes of a positive urinary dipstick in the absence of red cells (haemoglobinuria/myoglobinuria) have been excluded ([Box 18.9](#)), both visible and persistent non-visible haematuria require investigation, as they may be caused by malignancy or indicate glomerulonephritis.

Visible haematuria is most likely to be caused by malignancy (14% of patients present with visible haematuria), which can affect any part of the urogenital tract (see [Fig. 18.7](#)). Patients with visible haematuria must therefore be referred to urology for imaging (ultrasound or CT scan) and cystoscopy ([Fig. 18.8](#)). Other common causes of visible haematuria are urine infection and stones. Visible haematuria may also be encountered in patients with IgA nephropathy, typically following an upper respiratory tract infection.

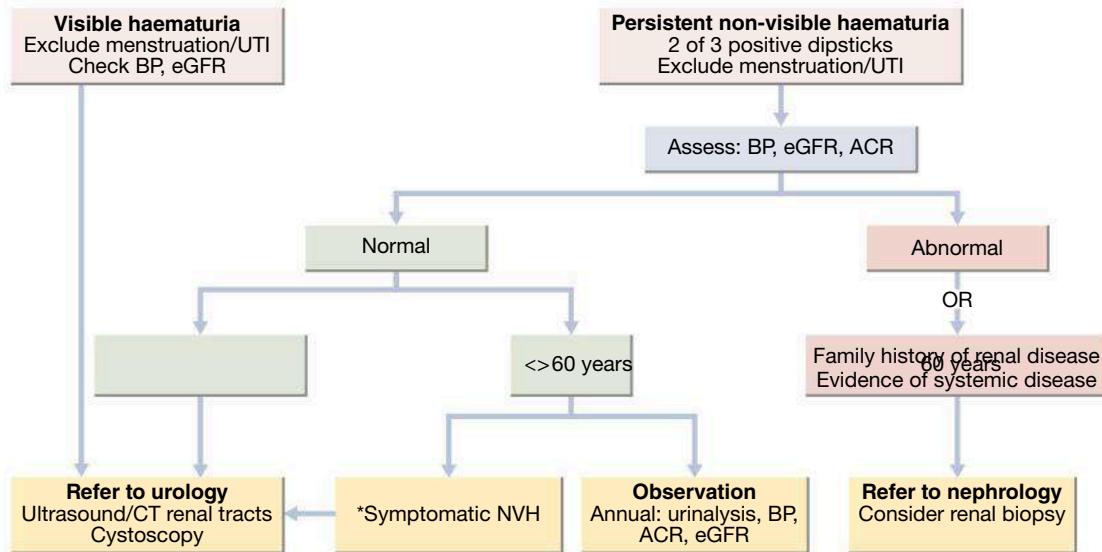

**Fig. 18.7** Causes of haematuria.

18.9 Interpretation of non-visible haematuria		
Dipstick test positive	Urine microscopy	Suggested cause
<b>Haematuria</b>	White blood cells Abnormal epithelial cells Red cell casts Dysmorphic erythrocytes (phase contrast microscopy)	Infection Tumour Glomerular bleeding*
<b>Haemoglobinuria</b>	No red cells	Intravascular haemolysis
<b>Myoglobinuria (brown urine)</b>	No red cells	Rhabdomyolysis

\*Glomerular bleeding implies that the glomerular basement membrane (GBM) is ruptured. It can occur physiologically following very strenuous exertion but usually indicates intrinsic renal disease and is an important feature of the nephritic syndrome.

Non-visible haematuria may also indicate an underlying cancer, and although guidelines vary, current UK guidelines are that all patients over 60 years old with persistent (detected on at least two of three consecutive dipstick tests) non-visible haematuria and either dysuria or an elevated serum white cell count should therefore undergo imaging and cystoscopy. In younger patients, an underlying tumour is much less likely, and if a glomerular cause is not suspected (see below), it may be appropriate to manage them by periodic observation in primary care, although occasionally these individuals develop significant overt renal disease during follow-up.

Glomerular bleeding occurs when inflammatory, destructive or degenerative processes disrupt the GBM, permitting passage of red blood cells into the urine. A characteristic feature of glomerular bleeding is an 'active urinary sediment' (the presence of dysmorphic red blood cells or red cell casts on microscopy); this is not always present, however. Patients with visible and non-visible haematuria should also be assessed for hypertension, proteinuria, reduced/declining renal function, family history of renal

**Fig. 18.8 Investigation of haematuria.** \*Symptomatic: lower urinary tract voiding symptoms such as hesitancy, frequency, urgency and dysuria. (ACR = albumin:creatinine ratio; BP = blood pressure; CT = computed tomography; eGFR = estimated glomerular filtration rate; NVH = non-visible haematuria; UTI = urinary tract infection)

disease or features of systemic disease (see Fig. 18.8). The presence of any of these features raises the possibility of intrinsic renal pathology and warrants referral to nephrology for further investigation, including consideration of renal biopsy.

## Nephritic syndrome

The nephritic syndrome is characterised by the presence of haematuria in association with hypertension, oliguria, fluid retention and reduced/declining renal function. Many patients with glomerulonephritis, particularly those with milder disease, do not exhibit all of these features; however, their combined presence is typical of a rapidly progressive glomerulonephritis and warrants urgent investigation. In many cases, investigation will include a renal biopsy to confirm diagnosis and guide management, but less invasive investigations may also be useful (Box 18.10).

Patients with nephritic syndrome may also exhibit varying degrees of proteinuria, including nephrotic-range proteinuria; the prominence of haematuria on dipstick should, however, alert the physician to the possibility of a glomerulonephritis. Indeed, it is important to recognise that the characteristic features of nephritic syndrome and nephrotic syndrome do not always present in isolation, but should be considered to be the extreme phenotypes at either end of a spectrum of presentations (Fig. 18.9).

## Proteinuria

While small amounts of high-molecular-weight proteins and moderate amounts of low-molecular-weight proteins pass through the healthy GBM, these proteins normally are completely reabsorbed by tubular cells. Hence, in healthy individuals, less than 150mg of protein is excreted in the urine each day, much of which is derived from tubular cells. This includes Tamm-Horsfall protein (uromodulin), encoded by the *UMOD* gene, mutations in which have been linked to tubulo-interstitial disease (see Box 18.20). The presence of larger amounts of proteinuria indicates significant renal disease, with greater than 1g/day indicative of glomerular pathology.

Proteinuria is usually asymptomatic and is often picked up by urinalysis, although large amounts of protein may make the urine frothy. Transient proteinuria can occur after vigorous exercise, during fever, in heart failure and in people with urinary tract infection. Patients should be assessed for the presence of these conditions and urine testing repeated once the potential trigger has been treated or resolved.

## 18.10 Investigation of nephritic syndrome

Cause	Investigations
<b>Rapidly progressive glomerulonephritis (RPGN)</b>	
Post-infectious glomerulonephritis	ASOT, C3, C4
Anti-GBM disease	Anti-GBM antibody
Small-vessel vasculitis	p-ANCA, c-ANCA
Lupus nephritis	ANA, dsDNA, C3, C4
<b>Mild glomerulonephritic presentation</b>	
IgA nephropathy	Serum IgA (polyclonal rise in 50% of patients)
Mesangioproliferative glomerulonephritis	C3, C4, hepatitis B, C + HIV serology, ANA, dsDNA, immunoglobulins, PPE
Alport syndrome*	Genetic screening, hearing test
*Not a glomerulonephritis but may present in a similar manner with haematuria, variable proteinuria, hypertension and slowly declining renal function. (ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; ASOT = anti-streptolysin O titre; C3, C4 = complement proteins 3, 4; dsDNA = double-stranded DNA; GBM = glomerular basement membrane; HIV = human immunodeficiency virus; IgA = immunoglobulin A; PPE = plasma protein electrophoresis)	

Testing for proteinuria is best done on an early morning sample, as some individuals exhibit orthostatic proteinuria. In these patients, urinary dipstick is positive only when upright, with the first morning sample being negative. Orthostatic proteinuria is regarded as a benign disorder that does not require treatment.

## Moderately elevated albuminuria (microalbuminuria)

In healthy individuals, there is virtually no urinary excretion of large-molecular-weight serum proteins, such as albumin, in contrast to modest urinary excretion of tubule-derived proteins. The presence of even moderate amounts of albuminuria (previously referred to as microalbuminuria) is therefore abnormal, and is the most sensitive marker of early glomerular pathology, when the standard dipstick test remains negative (Box 18.11). Screening for moderately elevated albuminuria should be performed regularly in patients with diabetes, as persistently high levels warrant therapy with inhibitors of the renin-angiotensin-aldosterone system,

**Fig. 18.9 Nephritic and nephrotic syndrome.** At one extreme, specific injury to podocytes causes proteinuria and nephrotic syndrome. The histology to the left shows diabetic nephropathy. At the other end of the spectrum, inflammation leads to cell damage and proliferation, breaks form in the glomerular basement membrane (GBM) and blood leaks into urine. In its extreme form, with acute sodium retention and hypertension, such disease is labelled nephritic syndrome. The histology to the right shows a glomerulus with many extra nuclei from proliferating intrinsic cells, and influx of inflammatory cells leading to crescent formation (arrows) in response to severe post-infectious glomerulonephritis. (FSGS = focal and segmental glomerulosclerosis; IgA = immunoglobulin A; MCGN = mesangiocapillary glomerulonephritis; SLE = systemic lupus erythematosus)

18.11 Quantifying proteinuria in random urine samples			
ACR <sup>1</sup> mg/mmol	PCR <sup>1</sup> mg/mmol	Typical dipstick results <sup>2</sup>	Significance
<3.5 (female) <2.5 (male)	< 25	–	Normal
3.5–30	25–50	–	Moderately elevated
30–70	50–100	+ to ++	Dipstick positive
70–300	100–350	++ to +++	Glomerular disease more likely; equivalent to >1 g/24 hrs
>300	>350	+++ to ++++	Nephrotic range: almost always glomerular disease, equivalent to >3.5 g/24 hrs

<sup>1</sup>Values are given for mg/mmol; if urine creatinine is measured in mg/dL, reference values for PCR and ACR can be derived by dividing by 11.31. <sup>2</sup>Dipstick results are affected by urine concentration and are occasionally weakly positive on concentrated samples from healthy individuals.

even in normotensive individuals (see Box 21.30). Persistent moderately increased albuminuria has also been associated with cardiovascular mortality.

### Overt (dipstick-positive) proteinuria

Urinary dipstick testing is a valuable screening tool for the detection of proteinuria; it is only semi-quantitative, however, as it is highly dependent on the concentration of the urine. Typically, standard dipsticks test positive for protein once the urinary protein exceeds approximately 0.5 g/24 hrs; however, trace to 1+ may be observed on dipstick in very concentrated urine from healthy individuals. After urinary tract infection has been excluded, all patients with persistent proteinuria on dipstick should have the amount of protein quantified to guide further investigations (Fig. 18.10). When more than 1 g of protein per day is excreted, glomerular disease is likely and this is an indication for renal biopsy. Since 24-hour urine collection is often inaccurate, the protein:creatinine ratio (PCR) in a single sample of urine is preferred. This makes an allowance for the variable degree of urinary dilution and can be used to extrapolate to 24-hour values (see Box 18.11). Changes in PCR also give valuable information about the progression of

renal disease and response to therapy in CKD. It is possible to measure albumin:creatinine ratio (ACR), but this requires a more expensive immunoassay and is usually reserved for situations when high sensitivity is required, such as detection of moderately elevated albuminuria in the early stages of diabetic nephropathy (p. 749).

It is sometimes helpful to identify the type of protein in the urine. Large amounts of low-molecular-weight proteins, such as  $\beta_2$ -microglobulin (molecular weight 12 kDa), in the urine suggest renal tubular damage and are referred to as tubular proteinuria. This rarely exceeds 1.5–2 g/24 hrs (maximum PCR 150–200 mg/mmol; see Box 18.11 for conversion of mg/mmol to mg/dL).

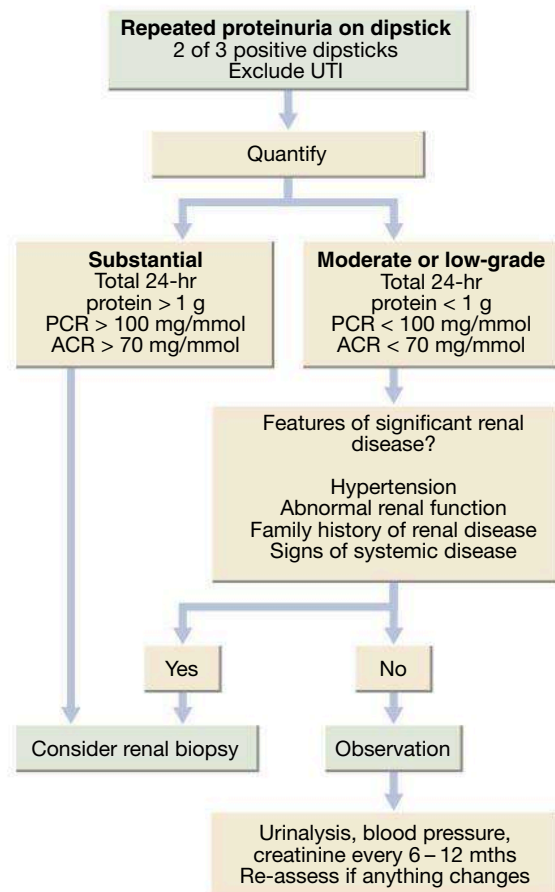

Free immunoglobulin light chains (molecular weight 25 kDa) are filtered freely at the glomerulus but are poorly identified by dipstick tests. Their presence may also be indicated by a 'protein gap', where the PCR is markedly greater than the ACR (i.e. by more than the normal gap of 30 mg/mmol, see Box 18.11). In this context, electrophoresis of the urine and specific immunodetection methods are required to detect immunoglobulin light chains, known as 'Bence Jones protein'. This may occur in AL amyloidosis (Ch. 4) and in plasma-cell dyscrasias such as myeloma (Ch. 25).

## Nephrotic syndrome

Nephrotic syndrome is characterised by very heavy proteinuria (>3.5 g/24 hrs), hypoalbuminaemia and oedema. Blood volume may be normal, reduced or increased. Renal sodium retention is an early and universal feature; the mechanisms of this are shown in [Figure 19.4](#). The diseases that cause nephrotic syndrome all affect the glomerulus (see [Fig. 18.9](#)), either directly, by damaging podocytes, or indirectly, by causing scarring or deposition of exogenous material such as amyloid into the glomerulus.

Investigation of nephrotic syndrome usually involves renal biopsy, although non-invasive tests may also be helpful in suggesting the underlying cause ([Box 18.12](#)). In children, minimal change disease is by far the most common cause of nephrotic syndrome and therefore renal biopsy is not usually required unless the patient fails to respond to high-dose glucocorticoid therapy. Similarly, most patients with diabetes presenting with nephrotic syndrome will have diabetic nephropathy, and so renal biopsy is usually not performed unless the course of the disease is atypical (rapidly increasing proteinuria or rapid decline in renal function; p. 749).

Management of nephrotic syndrome should be directed at the underlying cause. In addition, nephrotic syndrome is associated with a number of complications ([Box 18.13](#)), which may require supportive management unless the nephrosis is expected to resolve rapidly, such as in glucocorticoid-responsive minimal change disease. Diuretics are often required to reduce oedema. ACE inhibitors or angiotensin receptor blockade are indicated to reduce intraglomerular pressure and proteinuria, which may lead to an increase in serum albumin concentration.

**Fig. 18.10** Investigation of proteinuria. (ACR = albumin:creatinine ratio; PCR = protein:creatinine ratio; UTI = urinary tract infection)

## Glomerular diseases

Glomerular diseases account for a significant proportion of acute and chronic kidney disease. Most patients with glomerular disease do not present acutely and are asymptomatic until abnormalities are detected on routine screening of blood or urine samples.

There are many causes of glomerular damage, including immunological injury, inherited diseases such as Alport syndrome (p. 577), metabolic diseases such as diabetes mellitus (Ch. 21), and deposition of abnormal proteins such as amyloid in the glomeruli (Ch. 4). The glomerular cell types that may be the target of injury are shown in [Fig. 18.11](#). Proteinuria is the hallmark of glomerular disease; however, the response of the glomerulus to injury and hence the predominant clinical features vary according to the nature of the insult, ranging from fulminant nephrotic syndrome when the primary target is usually the podocyte to rapidly progressive glomerulonephritis (see [Fig. 18.9](#)). Several prognostic indicators are common to all causes of glomerulonephritis ([Box 18.14](#)) and may be helpful in assessing the need for immunosuppressive therapy.

### Glomerulonephritis

While glomerulonephritis literally means 'inflammation of glomeruli', the term is often used more broadly to describe all types of glomerular disease, even though some of these (e.g. minimal change nephropathy) are not associated with inflammation.

Most types of glomerulonephritis are immunologically mediated and several respond to immunosuppressive drugs. Deposition of antibody occurs in many types of glomerulonephritis and testing for circulating or glomerular deposition of antibodies may aid diagnosis (see [Fig. 18.11](#) and [Boxes 18.10](#) and [18.12](#)). In small-vessel vasculitis, no glomerular antibody deposition is observed (pauci-immune), but the antibodies may be indirectly pathogenic by activating neutrophils to promote endothelial injury (see [Fig. 18.11](#)).

Glomerulonephritis is generally classified in terms of the histopathological appearances, as summarised in [Box 18.15](#) and [Fig. 18.12](#). Many non-specialists find the terminology used in describing glomerulonephritis confusing, therefore some definitions are provided in [Box 18.16](#). It is important to stress that the histological appearance rarely confirms a specific renal disease but rather suggests a limited range of

### 18.12 Investigation of nephrotic syndrome

Cause	Typical age group	Investigations
Minimal change disease	Children, young adults, occasionally seen in older patients	None specific
Primary focal segmental glomerulosclerosis	Young adults	None specific
Membranous nephropathy	Middle-aged to older patients	Anti-phospholipase A2 receptor antibody (primary disease) Hepatitis B, C + HIV serology, ANA, dsDNA
Amyloid	Older patients	Immunoglobulins, PPE, Bence Jones protein, serum free light chains
Diabetic nephropathy	Any age, but rarely <10 years from diagnosis of type 1 diabetes	Glucose, glycosylated haemoglobin

(ANA = antinuclear antibody; dsDNA = double-stranded DNA; HIV = human immunodeficiency virus; PPE = plasma protein electrophoresis)

### 18.13 Consequences of the nephrotic syndrome and their management

Feature	Mechanism	Consequence	Management
<b>Hypoalbuminaemia</b>	Urinary protein losses exceed synthetic capacity of liver	Reduced oncotic pressure Oedema	Treatment of underlying cause
<b>Avid sodium retention</b>	Secondary hyperaldosteronism Additional poorly characterised intrarenal mechanisms	Oedema	Diuretics and a low-sodium diet*
<b>Hypercholesterolaemia</b>	Non-specific increase in lipoprotein synthesis by liver in response to low oncotic pressure	High rate of atherosclerosis	Statins, ezetimibe
<b>Hypercoagulability</b>	Relative loss of inhibitors of coagulation (antithrombin III, protein C and S) and increase in liver synthesis of procoagulant factors	Venous thromboembolism	Consideration of prophylaxis in chronic or severe nephrotic syndrome
<b>Infection</b>	Hypogammaglobulinaemia due to urinary loss of immunoglobulins	Pneumococcal and meningococcal infection	Consideration of vaccination

\*Severe nephrotic syndrome may need very large doses of combinations of diuretics acting on different parts of the nephron (e.g. loop diuretic plus thiazide plus amiloride). Over-diuresis risks secondary impairment of renal function through hypovolaemia.

#### Circulating immune complexes

Cryoglobulinaemia (*Cryoglobulins in serum*)  
Serum sickness  
Endocarditis

**Endothelium** (indirectly)  
Small-vessel vasculitis  
*ANCA (serum)*

**GBM**  
Goodpasture's disease  
*Anti-GBM antibody (serum + IF on biopsy; see Fig. 18.12H)*

**Mesangium**  
IgA nephropathy (*polyclonal rise in serum IgA in 50% patients; IF on biopsy; see Fig. 18.12G*)

**Podocyte**  
Membranous nephropathy  
*Anti-phospholipase A2 receptor 1 (serum + IF on biopsy; see Fig. 18.12F)*

**Fig. 18.11** Glomerulonephritis associated with antibody production. Antibodies and antigen–antibody (immune) complexes may target or be deposited in specific components of the glomerulus, resulting in different patterns of histological injury and clinical presentation. Testing for antibody deposition in the glomerulus by immunofluorescence (IF) on renal biopsy tissue or for antibodies in the serum may aid diagnosis. Diagnostic tests are shown in italics. (ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; dsDNA = double-stranded DNA; GBM = glomerular basement membrane; IgA = immunoglobulin A; SLE = systemic lupus erythematosus)

diagnoses, which may be confirmed by further investigation. Conversely, some diseases, such as lupus, are associated with more than one histological pattern of injury. The most common histological subtypes may be categorised according to their typical clinical presentation, as discussed below. Genetic disorders associated with glomerular disease are described later in this chapter.

### 18.14 Poor prognostic indicators in glomerular disease

- Male sex
- Hypertension
- Persistent and severe proteinuria
- Elevated creatinine at time of presentation
- Rapid rate of decline in renal function
- Tubulo-interstitial fibrosis observed on renal biopsy

#### Diseases typically presenting with nephrotic syndrome

In these diseases, the injury is focused on the podocyte and there is little histological evidence of inflammation or cell proliferation in the glomerulus (non-proliferative, see Fig. 18.12). Minimal change and primary focal segmental glomerulosclerosis (FSGS) typically present with fulminant nephrotic syndrome, whereas in membranous nephropathy and secondary FSGS, the nephrosis tends to be more indolent. Other causes of nephrotic syndrome due to systemic disease are discussed elsewhere, including diabetic nephropathy (p. 749) and amyloid (p. 77).

#### Minimal change nephropathy

Minimal change disease can occur at all ages but accounts for most cases of nephrotic syndrome (see Box 18.15) in children and about one-quarter of adult cases. It is caused by reversible dysfunction of podocytes. On light microscopy, the glomeruli appear normal (Fig. 18.12A), but fusion of podocyte foot processes is observed on electron microscopy. The presentation is with nephrotic syndrome, which typically is severe. High-dose glucocorticoid therapy (1 mg/kg prednisolone for 6 weeks) usually promotes rapid remission of nephrosis, though the response to therapy is often less satisfactory in older patients. Some patients who respond incompletely (glucocorticoid-resistant) or relapse frequently need maintenance glucocorticoids (glucocorticoid dependence) or additional agents such as cytotoxics or calcineurin inhibitors. Glucocorticoid resistance in children warrants a biopsy to exclude an alternative diagnosis, but if minimal change is confirmed, a genetic cause should be considered. Minimal change disease typically does not progress to CKD but can present with problems related to the nephrotic syndrome (see Box 18.11) and complications of treatment.

#### Focal segmental glomerulosclerosis

Primary focal segmental glomerulosclerosis (FSGS) (Fig. 18.12B) can occur in all age groups and is thought to be due to an as yet undiscovered circulating factor. Histological analysis shows sclerosis initially

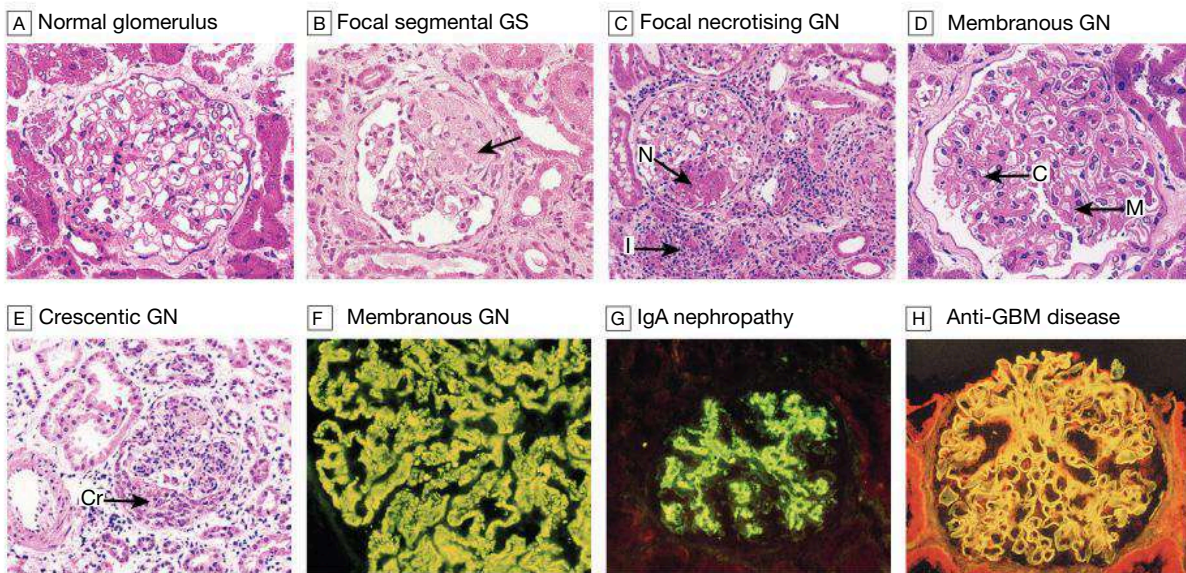

## 18.15 Glomerulonephritis categorised by clinical presentation and histological classification

Histology	Immune deposits	Pathogenesis	Associations	Comments
<b>Nephrotic presentation</b>				
<b>Minimal change</b>				
Normal, except on electron microscopy, where fusion of podocyte foot processes is observed (non-specific finding)	None	Unknown; probable circulating factor promoting podocyte injury Some cases are genetic (p. 577)	Atopy Drugs, most commonly NSAIDs Haematological malignancies	Acute and often severe nephrotic syndrome Good response to glucocorticoids Dominant cause of idiopathic nephrotic syndrome in childhood
<b>Focal segmental glomerulosclerosis (FSGS)</b>				
Segmental scars in some glomeruli No acute inflammation Podocyte foot process fusion seen in primary FSGS	Non-specific trapping in focal scars	Unknown; circulating factors may increase glomerular permeability Injury to podocytes may be common feature Some cases are genetic (p. 577)	<i>APOL1</i> variant in people of West African descent Causes of secondary FSGS include: Healing of previous local glomerular injury HIV infection Heroin misuse Morbid obesity Chronic hypertension	<i>Primary FSGS</i> presents as idiopathic nephrotic syndrome but is less responsive to treatment than minimal change; may progress to renal impairment, and can recur after transplantation <i>Secondary FSGS</i> presents with variable proteinuria and outcome
<b>Membranous nephropathy</b>				
Thickening of GBM Progressing to increased matrix deposition and glomerulosclerosis	Granular subepithelial IgG	Antibodies to a podocyte surface antigen (commonly phospholipase A <sub>2</sub> receptor 1), with complement-dependent podocyte injury	<i>HLA-DQA1</i> (for idiopathic) Drugs: Penicillamine, NSAIDs, heavy metals Hepatitis B virus Malignancy Lupus <sup>1</sup>	Common cause of adult idiopathic nephrotic syndrome One-third progress, one-third spontaneously remit and one-third remain stable; may respond to glucocorticoids and immunosuppressants
<b>Mild glomerulonephritic presentation</b>				
<b>IgA nephropathy</b>				
Increased mesangial matrix and cells Focal segmental nephritis in acute disease	Mesangial IgA (and C3)	Unknown Mucosal infections (e.g. helminths) may be involved	Usually idiopathic, flares triggered by upper respiratory infection Liver disease Coeliac disease	Common disease with range of presentations, usually including haematuria and hypertension Henoch–Schönlein purpura is an acute IgA variant common in children
<b>Mesangiocapillary glomerulonephritis</b>				
Immunoglobulin type	Immunoglobulins	Deposition of circulating immune complexes or 'planted' antigens	Infections, autoimmunity or monoclonal gammopathies	Most common pattern found in association with subacute bacterial infection, but also with cryoglobulinaemia ± hepatitis C virus, and others
Complement type	Complement components	Complement abnormalities, inherited or acquired Dense deposit disease is associated with abnormal activation of alternative complement pathway	Complement gene mutations C3 nephritic factor and partial lipodystrophy	In dense deposit disease, intramembranous deposits No proven treatments
<b>Rapidly progressive glomerulonephritis presentation</b>				
<b>Focal necrotising glomerulonephritis</b>				
Segmental inflammation and/or necrosis in some glomeruli ± crescent formation	Variable according to cause but typically negative (or 'pauci-immune')	Small-vessel vasculitis, often ANCA-mediated	Primary or secondary small-vessel vasculitis	Often occurs in systemic disease Responds to treatment with glucocorticoids and immunosuppressants
<b>Diffuse proliferative glomerulonephritis<sup>2</sup></b>				
<i>Infection-related diffuse proliferative glomerulonephritis<sup>3</sup></i>				
Diffuse proliferation of endothelial and mesangial cells Infiltration by neutrophils and macrophages ± crescent formation	Subendothelial and subepithelial	Immune complex-mediated (e.g. to streptococcal infection with presumed cross-reactive epitopes)	Post-streptococcal Concurrent infection with staphylococci, endocarditis	Presents with severe sodium and fluid retention, hypertension, haematuria, oliguria Usually resolves spontaneously

### 18.15 Glomerulonephritis categorised by clinical presentation and histological classification—continued

Histology	Immune deposits	Pathogenesis	Associations	Comments
<b>Anti-glomerular basement membrane disease</b>				
Usually crescentic nephritis	Linear IgG along GBM	Autoantibodies to $\alpha 3$ chain of type IV collagen in GBM	<i>HLA-DR15</i> (previously known as <i>DR2</i> )	Associated with lung haemorrhage but renal or lung disease may occur alone Treat with glucocorticoids, cyclophosphamide and plasma exchange

<sup>1</sup>Systemic lupus erythematosus can cause almost any histological injury pattern, most commonly membranous nephropathy or diffuse proliferative glomerulonephritis. <sup>2</sup>In addition to the association with infection and anti-GBM disease, a diffuse proliferative glomerulonephritis picture may also be seen with lupus and occasionally IgA nephropathy. <sup>3</sup>Infection may also present with mesangioproliferative glomerulonephritis and membranous nephropathy (HIV).  
(ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; APOL1 = apolipoprotein L1; FSGS = focal segmental glomerulosclerosis; GBM = glomerular basement membrane; HLA = human leucocyte antigen; IgA = immunoglobulin A; NSAIDs = non-steroidal anti-inflammatory drugs)

**Fig. 18.12 Histopathology of glomerular disease.** (A–E) *Light microscopy* [A] A normal glomerulus. Note the open capillary loops and thinness of their walls. [B] Focal segmental glomerulosclerosis (GS). The portion of the glomerulus arrowed shows loss of capillary loops and cells, which are replaced by matrix. [C] Focal necrotising glomerulonephritis (GN). A portion of the glomerulus (N = focal necrotising lesion) is replaced by bright pink material with some 'nuclear dust'. Neutrophils may be seen elsewhere in the glomerulus. There is surrounding interstitial inflammation (I). This is most commonly associated with small-vessel vasculitis and may progress to crescentic nephritis (see [E]). [D] Membranous glomerulonephritis. The capillary loops (C) are thickened (compare with the normal glomerulus) and there is expansion of the mesangial regions by matrix deposition (M). However, there is no gross cellular proliferation or excess of inflammatory cells. [E] Crescentic glomerulonephritis. The lower part of Bowman's space is occupied by a semicircular formation ('crescent', Cr) of large pale cells, compressing the glomerular tuft. This is seen in aggressive inflammatory glomerulonephritis. *Antibody deposition in the glomerulus* ([F]–[H]) *Direct immunofluorescence*. [F] Granular deposits of IgG along the basement membrane in a subepithelial pattern, typical of membranous GN. [G] Immunoglobulin A (IgA) deposits in the mesangium, as seen in IgA nephropathy. [H] Ribbon-like linear deposits of anti-GBM antibodies along the glomerular basement membrane in Goodpasture's disease. The glomerular structure is well preserved in all of these examples. (A, C, D, E) Courtesy of Dr J.G. Simpson, Aberdeen Royal Infirmary; (F, G, H) Courtesy of Dr R. Herriot.

limited to segments of the glomeruli, which may also show positive staining for deposits of C3 and IgM on immunofluorescence. Since FSGS is a focal process, abnormal glomeruli may not be detected on renal biopsy if only a few are sampled, leading to an initial diagnosis of minimal change nephropathy.

In most cases the underlying cause is unknown (primary FSGS) and these patients typically present with abrupt onset of severe nephrotic syndrome. Primary FSGS may respond to high-dose glucocorticoid therapy (0.5–2.0 mg/kg/day) but the response is rarely as rapid as in minimal change disease. Immunosuppressive drugs, such as calcineurin inhibitors, cyclophosphamide and mycophenolate mofetil, have also been used but their efficacy is uncertain. Progression to CKD is common in patients who do not respond to glucocorticoids and the disease frequently recurs after renal transplantation.

FSGS is particularly common in people of West African descent, who, compared with other ethnicities, have a much higher carriage rate

of apolipoprotein L1 (*APOL1*) gene variants that are associated with increased risk of FSGS. In addition, mutations in other podocyte proteins may cause FSGS (see Genetic renal diseases section below). FSGS may also be secondary to other diseases such as human immunodeficiency virus (HIV) renal disease (particularly in African Americans), morbid obesity or chronic hypertension. In addition, it may reflect scarring from previous focal glomerular injury resulting from HUS, cholesterol embolism or vasculitis. Patients with secondary FSGS typically present with more modest proteinuria than those with primary disease and rarely exhibit full-blown nephrotic syndrome. Management of secondary FSGS is focused on treating the underlying cause and reducing proteinuria by inhibiting the renin–angiotensin system.

#### Membranous nephropathy

Membranous nephropathy is the most common cause of nephrotic syndrome in people of European descent. It is caused by antibodies

## 18.16 Terminology used in glomerulonephritis

### Light microscopy

- *Focal*: affecting some but not all glomeruli
- *Diffuse*: affecting > 50% of glomeruli
- *Segmental*: affecting a portion of a glomerulus
- *Global*: affecting all of the glomerulus
- *Necrotising*: severe injury leading to an area of necrosis, usually associated with vasculitis
- *Crescentic*: a crescent-shaped area of inflammatory cells responding to severe glomerular injury

### Electron microscopy

- *Subendothelial immune deposits*: found between the endothelial cell and the GBM – often found in nephritic presentations
- *Intramembranous immune deposits*: found within the GBM – found in the dense deposit variant of mesangiocapillary glomerulonephritis
- *Subepithelial immune deposits*: found between the epithelial cell and the GBM – often found in nephritic presentations, including membranous presentation of lupus

(GBM = glomerular basement membrane)

(usually autoantibodies) directed at antigen(s) expressed on the surface of podocytes, including the M-type phospholipase A<sub>2</sub> receptor 1, and is characterised by thickening of the glomerular basement membrane on light microscopy (see Fig. 18.12). While most cases are idiopathic, a proportion are associated with other causes, such as heavy metal poisoning, drugs, infections, lupus and tumours (see Box 18.15). Approximately one-third of patients with idiopathic membranous nephropathy undergo spontaneous remission, one-third remain in a nephrotic state, and one-third develop progressive CKD. Management includes tight blood pressure control, in particular with inhibitors of the renin–angiotensin–aldosterone system. In idiopathic disease immunosuppression treatment may improve both the nephrotic syndrome and the long-term prognosis and regimens include steroids with either cyclophosphamide or rituximab. However, because of the toxicity of these regimens, many nephrologists reserve such treatment for those with severe nephrotic syndrome or deteriorating renal function. Treatment of secondary membranous nephropathy is directed at the underlying cause.

## Diseases typically presenting with mild nephritic syndrome

Patients with mild glomerulonephritis typically present with non-visible haematuria and modest proteinuria, and their renal disease tends to follow a slowly progressive course. IgA nephropathy and mesangiocapillary glomerulonephritis (MCGN) typically fall in this category. However, their presentation is highly variable: IgA nephropathy occasionally presents with rapidly progressive glomerulonephritis while MCGN may present with nephrotic syndrome. Other diseases that present with haematuria, modest proteinuria and slow progression include Alport syndrome.

### IgA nephropathy

This is one of the most common types of glomerulonephritis and can present in many ways. Haematuria is the earliest sign and non-visible haematuria is almost universal, while hypertension is also very common. These are often detected during routine screening: for example, at occupational medical examinations. Proteinuria can also occur but is usually a later feature. In many cases, there is slowly progressive loss of renal function leading to end-stage renal disease (ESRD), though in others, renal function is persistently normal. A particular hallmark of IgA nephropathy in young adults is the occurrence of acute self-limiting exacerbations, often with visible haematuria, in association with minor respiratory infections. This may be so acute as to resemble acute post-infectious glomerulonephritis, with fluid retention, hypertension and oliguria with dark or red urine. Characteristically, the latency from clinical infection to

nephritis is short, in contrast to post-infectious glomerulonephritis, which typically occurs after the infection has resolved. Asymptomatic presentations dominate in older adults, with non-visible haematuria, hypertension and reduced GFR. Occasionally, IgA nephropathy progresses rapidly in association with crescent formation on biopsy. Management is largely directed towards the control of blood pressure, with renin–angiotensin system inhibitors preferable in those with proteinuria. There is some evidence for additional benefit from several months of high-dose glucocorticoid treatment in those at high risk of progressive disease (see Box 18.14), but no strong evidence for other immunosuppressive agents. A role for other therapies, such as fish oil, remains uncertain.

### Henoch–Schönlein purpura

This condition most commonly occurs in children but can also be observed in adults. It is a systemic vasculitis that often arises in response to an infectious trigger. It presents with a tetrad of features:

- a characteristic petechial rash typically affecting buttocks and lower legs
- abdominal pain due to vasculitis involving the gastrointestinal tract
- arthralgia
- renal disease characterised by visible or non-visible haematuria, with or without proteinuria.

Renal biopsy shows mesangial IgA deposition and appearances that are indistinguishable from acute IgA nephropathy (Fig. 18.12G). Treatment is supportive in nature; in most patients, the prognosis is good, with spontaneous resolution, though relapses are common. Some patients, particularly adults and those with severe or persistent proteinuria, progress to develop ESRD.

### Mesangiocapillary glomerulonephritis

Mesangiocapillary glomerulonephritis (MCGN), also known as membranoproliferative glomerulonephritis, is a pattern of injury seen on renal biopsy that is characterised by an increase in mesangial cellularity with thickening of glomerular capillary walls. The typical presentation is with proteinuria and haematuria. Several underlying causes have been identified, as summarised in Box 18.15. It can be classified into two main subtypes. The first is characterised by deposition of immunoglobulins within the glomeruli. This subtype is associated with chronic infections, autoimmune diseases and monoclonal gammopathy. The second is characterised by deposition of complement in the glomeruli and is associated with inherited or acquired abnormalities in the complement pathway. This category comprises ‘dense deposit disease’, which is typified by electron-dense deposits within the GBM, and C3 glomerulonephritis that shows deposits of C3 in the glomerulus.

Treatment of MCGN associated with immunoglobulin deposits consists of the identification and treatment of the underlying disease, if possible, and the use of immunosuppressive drugs such as mycophenolate mofetil or cyclophosphamide. There are few specific treatments for MCGN associated with complement dysregulation, although eculizumab, the anti-C5 inhibitor that prevents formation of the membrane attack complex, has shown promise.

## Diseases typically presenting with rapidly progressive glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is characterised by rapid loss of renal function over days to weeks, usually in association with hypertension and oedema. Non-visible haematuria is almost always present, with variable amounts of proteinuria, while characteristic red cell casts and dysmorphic red cells may be observed on urine microscopy (see Fig. 18.3). Renal biopsy typically shows crescentic lesions (Fig. 18.12E), often associated with necrotising lesions within the glomerulus (Fig. 18.12C), particularly in small-vessel vasculitides.

This pattern of presentation is typical of post-infectious glomerulonephritis, anti-GBM disease and small-vessel vasculitides (Ch. 26). It can

also be observed in SLE and occasionally in IgA and other nephropathies (see Fig. 18.9).

### Anti-glomerular basement membrane disease

Anti-GBM disease is a rare autoimmune disease in which antibodies develop against the  $\alpha 3$  chain of type 4 collagen in the GBM. Expression of the  $\alpha 3$  chain is largely restricted to the basement membranes of glomeruli and lungs, and hence the disease may present with rapidly progressive glomerulonephritis, lung haemorrhage, or disease of both organs, when it is known as Goodpasture's disease. Goodpasture's disease is more common in younger patients, while older adult patients often present with renal-limited disease. Patients with anti-GBM disease should be treated with plasma exchange combined with glucocorticoids and immunosuppressants, but early diagnosis is essential, as renal function is rarely recoverable in those requiring dialysis at presentation.

The combination of glomerulonephritis and pulmonary haemorrhage may also be observed with small-vessel vasculitis (particularly granulomatosis with polyangiitis, previously known as Wegener's granulomatosis) and lupus.

### Infection-related glomerulonephritis

RPGN may occur either during or following an infection. In both cases, circulating immune complexes are present and activation of the complement system promotes consumption of complement factors, resulting in low serum C3 and C4 concentration, as observed in many causes of glomerulonephritis (Box 18.17).

Post-infectious glomerulonephritis is observed most commonly in children and young adults, and typically presents 10 days after a streptococcal throat infection or longer after a skin infection. The clinical presentation ranges from mild abnormalities on urinalysis to RPGN with severe AKI. The anti-streptolysin (ASO) test is positive in up to 95% of patients with streptococcal throat infections. Treatment is supportive, with control of blood pressure and fluid overload with salt restriction, diuretics and dialysis if required. Antibiotic therapy is rarely needed, as the renal disease occurs after the infection has subsided. The medium-term prognosis for children and most adults is good, with recovery of renal function typical even in those requiring dialysis therapy. Some patients may develop CKD 20–30 years after the original presentation.

An immune complex-mediated disease may also be observed during an infection, typically a staphylococcal infection such as endocarditis, skin infection or pneumonia, but also with subacute endocarditis due to *Streptococcus viridans*. This occurs more commonly in older adults and the presentation tends not to be as fulminant as with post-streptococcal disease. In addition to supportive measures, antibiotic therapy is required, as infection is usually concurrent with renal disease.

## Tubulo-interstitial diseases

These diseases primarily affect the renal tubules and interstitial components of the renal parenchyma. They are characterised by tubular dysfunction with electrolyte abnormalities, moderate levels of proteinuria and varying degrees of renal impairment. Often the urinary output may be relatively preserved for any given GFR, and indeed there may be polyuria and nocturia due to loss of concentrating ability in damaged tubules.

### Acute interstitial nephritis

Acute interstitial nephritis (AIN) is an immune-mediated disorder, characterised by acute inflammation affecting the tubulo-interstitium of the kidney. It is commonly drug-induced, typically due to antibiotics and proton pump inhibitors (PPIs), but can be caused by other toxins, and can complicate a variety of systemic diseases and infections (Box 18.18). Ingestion of mushrooms within the *Cortinarius* genus can cause a devastating and irreversible AIN. It is encountered occasionally in Scandinavia and Scotland.

### 18.17 Causes of glomerulonephritis associated with low serum complement

- Post-infectious glomerulonephritis
- Subacute bacterial infection, especially endocarditis
- Systemic lupus erythematosus
- Cryoglobulinaemia
- Mesangiocapillary glomerulonephritis, usually complement type

### 18.18 Causes of acute interstitial nephritis

#### Allergic

Many drugs but particularly:

- Penicillins
- Non-steroidal anti-inflammatory drugs (NSAIDs)
- Proton pump inhibitors
- Mesalazine (delayed)

#### Immune

- Autoimmune nephritis  $\pm$  uveitis
- Transplant rejection

#### Infections

- Acute bacterial pyelonephritis
- Leptospirosis
- Tuberculosis
- Hantavirus

#### Toxic

- Myeloma light chains
- Mushrooms (*Cortinarius*)

### Clinical features

The clinical presentation is typically with AKI and it may cause a rapid deterioration in renal function. AIN should always be considered in patients with non-oliguric AKI. In some patients with drug-induced AIN there may be signs of a generalised drug hypersensitivity reaction with fever and rash. Eosinophilia occurs in 20%–30% of cases, so its absence does not rule out AIN, but its presence should prompt a drug history. Proteinuria is generally modest (PCR <100 mg/mmol; see Box 18.11 for conversion of mg/mmol to mg/dL). The urine may contain white blood cells and white cell casts but is sterile on culture. Leucocytes are commonly present on urinalysis.

### Investigations

Renal biopsy is usually required to confirm the diagnosis (Fig. 18.13D). This typically shows evidence of intense inflammation, with infiltration of the tubules and interstitium by lymphocytes. The presence of eosinophils may suggest drug-induced AIN and a predominant neutrophil infiltration suggests infection. Often granulomas may be evident, especially in drug-induced AIN. The degree of chronic inflammation in a biopsy is a useful predictor of long-term renal function. Eosinophiluria may be present but is not a good discriminator for AIN.

### Management

Some patients with drug-induced AIN recover following withdrawal of the drug alone, but high-dose glucocorticoids (prednisolone 1 mg/kg/day) may accelerate recovery and prevent long-term scarring. Other specific causes (see Box 18.18) should be treated, if possible.

### Chronic interstitial nephritis

Chronic interstitial nephritis (CIN) is characterised by renal dysfunction. It may follow on from AIN that does not resolve, or may be associated with ingestion of various toxins and drugs, particularly those taken chronically, such as lithium or non-steroidal anti-inflammatory drugs (NSAIDs). In addition, it is associated with metabolic and chronic inflammatory diseases, as summarised in Box 18.19. In many patients, CIN presents at a late stage and no underlying cause can be identified.

**Fig. 18.13 Tubular histopathology.** **A** Normal tubular histology. The tubules are densely packed with minimal space between. Brush borders can be seen on the luminal borders of cells in the proximal tubule. **B** Acute tubular necrosis. There are scattered breaks (B) in tubular basement membranes, swelling and vacuolation of tubular cells, and, in places, apoptosis and necrosis of tubular cells with shedding of cells into the lumen. During the regenerative phase, there is increased tubular mitotic activity. The interstitium (I) is oedematous and infiltrated by inflammatory cells. **C** Acute bacterial pyelonephritis. There is a widespread inflammatory infiltrate that includes many neutrophils. Granulocyte casts (G) are forming within some dilated tubules (T). Other tubules are scarcely visible because of the extent of the inflammation and damage. **D** Acute (allergic) interstitial nephritis. In this patient who received a non-steroidal anti-inflammatory drug (NSAID), an extensive mononuclear cell infiltrate (no neutrophils) in the tubule-interstitium (T) is seen. Sometimes eosinophils are prominent.

### Pathophysiology

Genetic causes may underlie many of these cases (p. 577) while autoimmune mechanisms are also common. Toxins that have been associated with CIN include those contained within the plant *Aristolochia clematitis* (birthwort). These are probably responsible for the severe nephrotoxicity that can be associated with treatment with herbal medicines in Asia and for Balkan nephropathy, which affects isolated rural communities in Bosnia, Bulgaria, Croatia, Romania and Serbia, possibly through contaminated flour. The nephropathy is commonly linked with tumours of the collecting system and is probably due to the mutagenic effects of the plant toxin on the urothelial epithelium. Chronic interstitial nephritis in agricultural communities (also known as CKD of unknown cause, CKDu) is observed in central American countries and Sri Lanka. The cause is unknown, but is likely to reflect a toxin used in agriculture exacerbated by episodes of dehydration due to heat exposure.

### Clinical features

Most patients with CIN present in adult life with CKD. A minority have salt-losing nephropathy due to impairment of urine-concentrating ability and sodium conservation. This presents with polyuria, nocturia and hypotension and puts them at risk of AKI during an acute illness. Renal tubular acidosis (p. 631) may complicate CIN but is seen most often in myeloma, sarcoidosis, cystinosis, amyloidosis and Sjögren syndrome. Typically, urinalysis is unremarkable and small kidneys are observed on ultrasound scan. Renal biopsy demonstrates infiltration of the renal parenchyma by lymphocytes, plasma cells and macrophages, in association with tubular atrophy and interstitial fibrosis.

### Management

Management is to identify and withdraw or treat the primary cause. Otherwise, treatment is supportive in nature, with correction of acidosis and hyperkalaemia; replacement of fluid and electrolytes, as required; and renal replacement therapy if irreversible renal damage has occurred.

### Papillary necrosis

The renal papillae lie within a hypoxic and hypertonic environment in the renal medulla, at the end of the vasa recta. They are

susceptible to ischaemic damage because of this and can undergo necrosis when their vascular supply is impaired as the result of diabetes mellitus, sickle-cell disease or long-term ingestion of NSAIDs. The condition may occasionally occur in other diseases. There is an association with pyelonephritis but it is difficult to determine whether this is a cause of papillary necrosis or a complication. The clinical presentation is variable. Some patients are asymptomatic and clinically silent, whereas others present with renal colic and renal impairment as necrosed papillae slough off and cause ureteric obstruction. Urinalysis may be normal but more frequently haematuria and sterile pyuria are present. Significant proteinuria is unusual. The imaging method of choice to make the diagnosis is CTU or intravenous pyelography. Management is based on relieving obstruction, where present, and withdrawal of the offending drugs.

## Genetic renal diseases

The advent of modern genetic techniques such as next-generation sequencing has allowed us to understand the breadth of inherited renal diseases on a much deeper level than before.

### Inherited glomerular diseases

#### Alport syndrome

A number of uncommon diseases may involve the glomerulus in childhood but the most important one affecting adults is Alport syndrome. Most cases arise from a mutation or deletion of the *COL4A5* gene on the X chromosome, which encodes the alpha 5 subunit of type IV collagen, resulting in inheritance as an X-linked recessive disorder (Ch. 3). Mutations in *COL4A3* or *COL4A4* genes are less common and cause autosomal disease, which may be recessive or dominant and affect males and females equally. The accumulation of abnormal collagen results in a progressive degeneration of the GBM (Fig. 18.14). Affected patients progress from haematuria to ESRD in late adolescence or their twenties. Female carriers of *COL4A5* mutations usually have haematuria but less commonly develop significant renal disease. Some other

basement membranes containing the same collagen isoforms are similarly involved, notably in the cochlea, so that Alport syndrome is associated with sensorineural deafness and ocular abnormalities.

Angiotensin-converting enzyme (ACE) inhibitors may slow but not prevent loss of kidney function. Patients with Alport syndrome are good candidates for renal replacement therapy (RRT), as they are young and usually otherwise healthy. They can develop an immune response to the normal collagen antigens present in the GBM of the donor kidney and, in a small minority, anti-GBM disease develops and destroys the allograft.

## Thin glomerular basement membrane disease

In thin glomerular basement membrane disease there is non-visible haematuria without associated hypertension, proteinuria or a reduction in GFR. The glomeruli appear normal by light microscopy but, on electron microscopy, the GBM is abnormally thin. The condition may be familial and some patients are carriers of Alport mutations. This does not appear to account for all cases, and in many patients the cause is unclear. Monitoring of these patients is advisable, as proteinuria may develop in some and there appears to be an increased rate of progressive CKD in the long term.

## Hereditary nephrotic syndrome

Many genes have been discovered that cause early-onset nephrotic syndrome, often with an FSGS pattern of injury on histology. Inheritance may be autosomal dominant or recessive, the former conditions having a less severe and later-onset phenotype and often exhibiting incomplete penetrance. The involved genes almost all code for podocyte proteins, including nephrin ('Finnish-type' nephropathy) and podocin, which both cause early congenital nephrotic syndrome. Autosomal dominant mutations in various genes may cause FSGS as part of systemic syndromes; the genes include *INF2* (Charcot-Marie-Tooth disease), *LMX1B* (nail-patella syndrome) and *WT1* (abnormal genitalia, Wilms' tumour, mental retardation).

Inheriting certain polymorphisms in the *APOL1* gene, which occur predominantly in people of West African ancestry, leads to a greatly increased risk of kidney disease in adults, including FSGS.

## Inherited tubulo-interstitial diseases

It has become evident in recent years that a significant number of cases of CKD with low or absent proteinuria have genetic causes, which may be inherited in an autosomal dominant or recessive pattern and include genes predominantly expressed in tubular cells ([Box 18.20](#)). This is a heterogeneous group of inherited disorders. Small cysts are sometimes evident, explaining the previous name of medullary cystic kidney disease, but tubulo-interstitial nephritis is the predominant pattern of injury. Many of these conditions, especially those formerly known as nephronophthisis, are associated with retinal dystrophies and brain or other abnormalities, and some may be associated with hyperuricaemia or gout (*UMOD* or *HNF1-beta* mutations). Many patients will progress to ESRD in later life. Modern genetics have brought clarity to a disease spectrum comprising many different conditions with previous descriptive names.

## Isolated defects of tubular function

An increasing number of disorders have been identified that are caused by specific defects in transporter molecules expressed in renal tubular cells. Only the most common are mentioned here. Renal glycosuria is a

**Fig. 18.14 Alport syndrome.** **A** Diagrammatic structure of the normal glomerular basement membrane (GBM). **B** The normal GBM (electron micrograph) contains mostly the tissue-specific ( $\alpha 3$ ,  $\alpha 4$  and  $\alpha 5$ ) chains of type IV collagen. **C** In Alport syndrome, this network is disrupted and replaced by  $\alpha 1$  and  $\alpha 2$  chains. Although the GBM appears structurally normal in early life, in time thinning appears, progressing to thickening, splitting and degeneration. (B, C) Courtesy of Dr J. Collar, St Mary's Hospital, London.

benign autosomal recessive defect of tubular reabsorption of glucose, caused by mutations of the sodium/glucose co-transporter *SGLT2*. Glucose appears in the urine in the presence of a normal blood glucose concentration. Notably, *SGLT2* inhibitors have been developed as a treatment for diabetes mellitus.

Cystinuria is a rare condition, in which reabsorption of filtered cystine, ornithine, arginine and lysine is defective. It is caused by mutations in the *SLC3A1* amino acid transporter gene. The high concentration of cystine in urine leads to cystine stone formation (p. 602).

Other uncommon tubular disorders include hereditary hypophosphataemic rickets, in which reabsorption of filtered phosphate is reduced; nephrogenic diabetes insipidus (Ch. 20), in which the tubules are resistant to the effects of vasopressin (antidiuretic hormone, ADH). In Bartter and Gitelman syndromes, there are inactivating mutations in the genes that encode the Na-K-2Cl and NaCl transporters, the targets of loop and thiazide diuretics respectively. Hence, both disorders present with sodium-wasting and hypokalaemia (Ch. 19).

The term 'Fanconi syndrome' is used to describe generalised proximal tubular dysfunction. The condition typically presents with low blood phosphate and uric acid concentrations, glycosuria, aminoaciduria and proximal renal tubular acidosis. In addition to the causes of interstitial nephritis described above, some congenital metabolic disorders are associated with Fanconi syndrome, notably Wilson's disease, cystinosis and hereditary fructose intolerance.

Renal tubular acidosis describes the common end-point of a variety of diseases affecting distal (classical or type 1) or proximal (type 2) renal tubular function. These syndromes may also be inherited and are described in Chapter 19.

## Cystic diseases of the kidney

It is common to encounter patients with a single renal cyst or even multiple cysts as an incidental finding, especially in those aged 50 years and over. Usually, these cysts are of no clinical consequence and are asymptomatic, but occasionally they can cause pain or haematuria. In addition, several specific diseases are recognised as being caused by the formation of multiple renal cysts. These are discussed in more detail below.

### Autosomal dominant polycystic kidney disease

Autosomal dominant polycystic kidney disease (PKD) is a common condition, with a prevalence of approximately 1:1000. Small cysts lined by tubular epithelium develop from infancy or childhood and enlarge slowly and irregularly. The surrounding normal kidney tissue is compressed and progressively damaged. Mutations in the *PKD1* gene account for 80% of cases and those in *PKD2* for about 15% (coding for polycystin 1 and 2 genes, respectively) with some other rare genes

accounting for the remainder. The median age of ESRD is approximately 52 years with a *PKD1* mutation and 70 years with a *PKD2* mutation. It has been estimated that between 5% and 10% of patients with ESRD have PKD.

### Clinical features

Common clinical features are shown in Box 18.21. Affected people are usually asymptomatic until later life but hypertension occurs from the age of 20 onwards. One or both kidneys may be palpable and the surface may feel nodular. About 30% of patients with PKD also have hepatic cysts (see Fig. 24.39) but disturbance of liver function is rare. Sometimes (almost always in women) the cysts cause massive and symptomatic hepatomegaly, usually concurrent with renal enlargement but occasionally with only minor renal involvement. Berry aneurysms of cerebral vessels are an associated feature in about 5% of patients with PKD. This feature appears to be largely restricted to certain families (and presumably specific mutations). Mitral and aortic regurgitation is frequent but rarely severe, and colonic diverticula and abdominal wall hernias may occur.

### Investigations

The diagnosis is usually based on family history, clinical findings and ultrasound examination. Ultrasound demonstrates cysts in approximately 95% of affected patients over the age of 20 and is the screening method of choice, but may not detect small developing cysts in younger subjects. Cysts may also be identified by other imaging modalities, such as MRI (Fig. 18.15). Simple renal cysts may occur in normal individuals but are uncommon below the age of 30. The following criteria exist for an ultrasound diagnosis of PKD in patients with a family history but unknown genotype:

- 15–39 years of age: at least three unilateral or bilateral kidney cysts
- 40–59 years of age: at least two cysts in each kidney
- 60 years or older: at least four cysts in each kidney.

It is possible to make a molecular diagnosis by next-generation sequencing of *PKD1* or *PKD2*. This is used in cases with an uncertain

#### 18.21 Autosomal dominant polycystic kidney disease: common clinical features

- Vague discomfort in loin or abdomen due to increasing mass of renal tissue
- Acute loin pain or renal colic due to cyst rupture, haemorrhage into a cyst or ureteric stones
- Hypertension
- Haematuria – often visible, but with little or no proteinuria
- Urinary tract or cyst infections
- Renal failure

#### 18.20 Hereditary tubulo-interstitial kidney diseases

Inheritance	Gene(s)	Other name(s)	Clinical features
Autosomal dominant	<i>UMOD</i>	MCKD type 2 Juvenile hyperuricaemic nephropathy	Gout
	<i>MUC1</i>	MCKD type 1	Progressive CKD without other manifestations
	<i>HNF1-beta</i>	Juvenile hyperuricaemic nephropathy	Cystic kidneys, solitary kidney; gout; MODY; abnormal LFTs; pancreatic atrophy; hypomagnesaemia
	<i>REN</i> (codes for renin)	Juvenile hyperuricaemic nephropathy	Gout; hyperkalaemia; salt-losing nephropathy
Autosomal recessive	<i>NPHP</i> genes (>20 genes discovered so far)	Nephronophthisis Part of many syndromes (Bardet–Biedl)	Common cause of paediatric ESRD Occurs earlier than AD interstitial nephritis Extrarenal manifestation common (learning difficulty, eye/limb problems)

(AD = autosomal dominant; CKD = chronic kidney disease; ESRD = end-stage renal disease; LFTs = liver function tests; MCKD = medullary cystic kidney disease; MODY = maturity-onset diabetes of the young)

**Fig. 18.15** MRI images of the kidneys. **A** Normal kidneys. **B** Polycystic kidneys; although the kidney enlargement is extreme, this patient had only slightly reduced GFR.

diagnosis (young patients, few cysts, lack of family history), for workup of living kidney donors, or for screening for mutations associated with a worse prognosis (see below). Screening for intracranial aneurysms is not generally indicated but can be done by MR angiography in families with a history of subarachnoid haemorrhage. The yield of screening is low, however, and the risk:benefit ratio of intervention in asymptomatic aneurysms in this disease is not clear.

### Management

Blood pressure control is important because cardiovascular morbidity and mortality are so common in renal disease, but evidence is lacking that controlling blood pressure to generally recommended CKD targets (e.g. <130/80mmHg) influences renal outcomes. There are data suggesting that targeting a very low blood pressure (<110/75mmHg) with ACE inhibitors or angiotensin II receptor blocker (ARBs) leads to slower increases in kidney volume, but no improvements in eGFR decline were observed and these targets are often not tolerated. This tight blood pressure target did lead to a greater decline in left ventricular mass index, which may have implications for improved cardiovascular risk later in life.

The vasopressin V2 receptor antagonist tolvaptan slows the increase in kidney volume and the rate of GFR decline. It has been licensed in many countries for patients at high risk of progression. Risk factors for progression include large kidneys (more specifically height-adjusted kidney volume), truncating *PKD1* mutations, and family history of early progression, as well as male sex, hypertension, proteinuria and development of early symptomatic cysts.

Patients with PKD are usually good candidates for dialysis and transplantation. Sometimes kidneys are so large that one or both have to be removed to make space for a renal transplant. Otherwise, they are usually left in situ unless they are a source of pain or infection.

### Other cystic diseases

Renal cysts and diabetes syndrome is caused by *HNF1-beta* mutations; it has a varying renal phenotype that often causes cysts but also may cause a tubulo-interstitial pattern of injury or congenital anomalies of the kidneys. It also causes a form of maturity-onset diabetes of the young (MODY).

Autosomal recessive PKD is caused by mutations in the *PKHD1* gene, encoding fibrocystin. It is less common than autosomal dominant PKD (about 1:20000 live births). Patients often present in infancy or young childhood with renal cysts and congenital hepatic fibrosis.

Some uncommon autosomal dominantly inherited conditions are associated with multiple renal cysts and tumours in adult life. In tuberous sclerosis, replacement of renal tissue by multiple angiomyolipomas

may occasionally cause renal failure in adults. Patients may also develop renal cysts and have a higher risk of renal cell carcinoma. Other organs affected include the skin (adenoma sebaceum on the face) and brain (causing seizures and mental retardation). von Hippel–Lindau syndrome is associated with multiple renal cysts, renal adenomas and renal cell carcinoma. Other involved organs include the central nervous system (haemangioblastomas), pancreas (serous cystadenomas) and adrenals (phaeochromocytoma).

A number of other rarer inherited cystic diseases are recognised that have some similarities to PKD but distinct genetic causes. Multicystic dysplastic kidneys are often unilateral and are a developmental abnormality found in children. Most of these seem to involute during growth, leaving a solitary kidney in adults.

Acquired cystic kidney disease can develop in patients with a very long history of renal failure, so it is not an inherited cystic disease. It is associated with increased erythropoietin production and sometimes with the development of renal cell carcinoma. The kidneys are usually normal or small in size and with a smooth outline, which can be useful to distinguish acquired from genetic disease.

## Renal vascular diseases

Diseases that affect renal blood vessels may cause renal ischaemia, leading to acute or chronic kidney disease or secondary hypertension. The rising prevalence of atherosclerosis and diabetes mellitus in ageing populations has made renovascular disease an important cause of ESRD.

### Renal artery stenosis

A stenosis of more than 50% may be observed on imaging of the renal arteries in up to 20% of older patients with advanced kidney disease; however, a haemodynamically significant effect will be present in only a relatively small proportion. Renal artery stenosis is the most common cause of secondary hypertension, with an estimated prevalence of about 2% in unselected patients, but this may increase to 4% in older patients who have evidence of atherosclerotic disease elsewhere. Most cases of renal artery stenosis are caused by atherosclerosis but fibromuscular dysplasia involving the vessel wall may be responsible in younger patients. Rare causes include vasculitis, thromboembolism and aneurysms of the renal artery.

### Pathophysiology

Renal artery stenosis results in a reduction in renal perfusion pressure, which activates the renin–angiotensin system, leading to increased

circulating levels of angiotensin II. This results in hypertension by provoking vasoconstriction and increasing aldosterone production by the adrenal, causing sodium retention by the renal tubules (p. 619). Significant reduction of renal blood flow occurs when there is more than 70% narrowing of the artery, and this is commonly associated with distal, post-stenotic dilatation. Atherosclerotic lesions are typically ostial and are associated with more widespread atherosclerosis within the aorta and other vessels, particularly the iliac vessels. There is often concurrent small-vessel disease in affected kidneys, due to subclinical atheroemboli. As the stenosis becomes more severe, global renal ischaemia leads to shrinkage of the affected kidney and may cause renal failure if bilateral or if unilateral in the presence of a single kidney (ischaemic nephropathy).

In younger patients, fibromuscular dysplasia is a more likely cause of renal artery stenosis. This is an uncommon disorder of unknown cause. It is characterised by hypertrophy of the media (medial fibroplasia), which narrows the artery but rarely leads to total occlusion. It may be associated with disease in other arteries; for example, those who have carotid artery dissections are more likely to have renal arteries with this appearance. It most commonly presents with hypertension in patients aged 15–30 years, and women are affected more frequently than men. Irregular narrowing (beading) may occur in the distal renal artery and this sometimes extends into the intrarenal branches of the vessel. Rarely, renal artery stenosis may occur as a complication of large-vessel vasculitis, such as Takayasu's arteritis and polyarteritis nodosa (see Ch. 26).

Untreated, atheromatous renal artery stenosis is thought to progress to complete arterial occlusion in about 15% of cases. This figure increases with more severe degrees of stenosis. If the progression is gradual, collateral vessels may develop and some function may be preserved, preventing infarction and loss of kidney structure. Conversely, at least 85% of patients with renal artery stenosis will not develop progressive renal impairment, and many patients die from coronary, cerebral or other vascular disease rather than renal failure. Unfortunately, methods of predicting which patients are at risk of progression or who will respond to treatment are still imperfect.

### Clinical features

Renal artery stenosis can present in various ways, including hypertension, acute pulmonary oedema, progressive renal failure (with bilateral disease) or a deterioration in renal function when ACE inhibitors or ARBs are administered. Although many patients experience a slight drop in GFR when commencing these drugs, an increase in serum creatinine of 30% or more raises the possibility of renal artery stenosis. Acute pulmonary oedema is particularly characteristic of bilateral renovascular disease. It typically occurs at night and is associated with severe hypertension, often in the context of normal or only mildly impaired renal and cardiac function. Clinical evidence of generalised vascular disease may be observed, particularly in the legs and in older patients with atherosclerotic renal artery stenosis. Clinical features associated with an increased risk of renal artery stenosis in hypertensive patients are summarised in Box 18.22. However, given the risk of imaging and angiography in patients with renal disease (see Box 18.4), further investigation should be performed only if intervention is being contemplated (see below).

### Investigations

When appropriate, imaging of the renal vasculature with either CT angiography or MR angiography should be performed to confirm the diagnosis (Fig. 18.16). Both give good views of the main renal arteries, the vessels most amenable to intervention. Biochemical testing may reveal impaired renal function and an elevated plasma renin activity, sometimes with hypokalaemia due to hyperaldosteronism. Ultrasound may also reveal a discrepancy in size between the two kidneys, although this is insufficiently sensitive or specific to be of value in diagnosis of renovascular disease in hypertensive patients.

### Management

The first-line management in patients with renal artery stenosis is medical therapy with antihypertensive drugs, supplemented, where appropriate,

## 18.22 Presentation and clinical features of renal artery stenosis

Renal artery stenosis is more likely if:

- hypertension is severe, of recent onset or difficult to control
- kidneys are asymmetrical in size
- flash pulmonary oedema occurs repeatedly\*
- there is peripheral vascular disease of the lower limbs
- there is renal impairment\*
- renal function has deteriorated on angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers

\*Particularly with bilateral disease.

**Fig. 18.16 Renal artery stenosis.** A magnetic resonance angiogram following injection of contrast. The abdominal aorta is severely irregular and atheromatous. The left renal artery is stenosed (arrow).

by statins and low-dose aspirin in those with atherosclerotic disease. Interventions to correct the vessel narrowing should be considered in:

- young patients (age below 40) suspected of having renal artery stenosis
- those whose blood pressure cannot easily be controlled with anti-hypertensive agents
- those who have a history of 'flash' pulmonary oedema
- those with accelerated phase (malignant) hypertension
- those whose renal function is deteriorating.

The most commonly used technique is angioplasty. The best results are obtained in non-atheromatous fibromuscular dysplasia, where correction of the stenosis has a high chance of success in improving blood pressure and protecting renal function. Beyond the indications above, angioplasty and stenting is now rarely performed in atherosclerotic disease, as randomised trials such as ASTRAL and CORAL have produced no convincing evidence for overall benefit in terms of renal function, blood pressure control or cardiovascular outcomes. The risks of angioplasty and stenting include renal artery occlusion, renal infarction and atheroemboli (see below) from manipulations in a severely diseased aorta. Small-vessel disease distal to the stenosis may preclude substantial functional recovery.

### Acute renal infarction

This is an uncommon condition that occurs as the result of sudden occlusion of the renal artery. The presentation is typically with loin pain

of acute onset, usually in association with non-visible haematuria, but pain may be absent in some cases. Severe hypertension is common but not universal. Blood levels of lactate dehydrogenase (LDH) and CRP are commonly raised. The condition may be caused by thrombosis of a renal artery or by thromboemboli from a distant source, when occlusion may occur in branch arteries distal to the main renal artery. This can cause multiple infarcts within the renal parenchyma of both kidneys, which may be visualised by CT scanning. If occlusion of the main renal arteries is bilateral or if there is occlusion in a single functioning kidney, the presentation is with AKI and the patient is typically anuric. Patients with bilateral occlusion usually have evidence of widespread vascular disease and may show evidence of aortic occlusion, with absent femoral pulses and reduced lower limb perfusion. Management is largely supportive, and includes anticoagulation if a source of thromboembolism is identified. It is sometimes possible to perform stenting of an acutely blocked main renal artery to try to restore renal blood flow; in most cases, however, presentation is too late to salvage renal function.

## Diseases of small intrarenal vessels

### Thrombotic microangiopathies

A number of conditions are associated with acute damage and occlusion of small blood vessels (arterioles and capillaries) in the kidney (Box 18.23) and other organs. A common feature of these syndromes is microangiopathic haemolytic anaemia (MAHA), in which haemolysis and red cell fragmentation arise as a consequence of damage incurred to red blood cells during passage through the abnormal vessels. The red blood cell fragments (schistocytes) may be observed on blood films, together with laboratory features of intravascular haemolysis (p. 955), including an elevated unconjugated bilirubin level, raised serum LDH concentration and decreased circulating levels of haptoglobin. A reticulocytosis is often seen. Endothelial injury is pronounced, leading to increased platelet adherence and a marked reduction in the platelet count. These abnormal blood parameters should alert the physician to the possibility of a thrombotic microangiopathy and may also be useful in monitoring response to

treatment. The key is to distinguish between the various aetiologies, as the management differs according to the primary cause (see Box 18.23).

### Haemolytic uraemic syndrome

Haemolytic uraemic syndrome (HUS) is characterised by thrombotic microangiopathy that predominantly affects the renal microcirculation, with involvement of other organs (including the brain) observed in more severe cases.

The most common cause of HUS is infection with organisms that produce enterotoxins called Shiga-like toxin or verotoxins. The organisms most commonly implicated are enterohaemorrhagic *Escherichia coli* and *Shigella dysenteriae*. The *E. coli* O157:H7 serotype is the best known but other serotypes that produce verotoxins may also be responsible. Although these bacteria live as commensals in the gut of cattle and other livestock, they can cause haemorrhagic diarrhoea in humans when the infection is contracted from contaminated food products, water or other infected individuals. In a proportion of cases, verotoxin produced by the organisms enters the circulation and binds to specific glycolipid receptors that are expressed on the surface of microvascular endothelial cells. Most cases are sporadic but large outbreaks related to poor sanitation may occur. In developed countries, Shiga-like toxin-associated HUS is now the most common cause of AKI in children. Recovery is good in most patients but sometimes RRT may be required, usually temporarily. Some patients may initially recover, but develop CKD in later life. No specific treatments have been shown to accelerate renal recovery.

In the absence of bloody diarrhoea, other (atypical) causes of HUS should be considered, in particular, abnormalities of the complement system. Familial forms are due to mutations in various genes that encode components or regulators of the complement cascade, including factor H (CFH), factor I (CFI), factor B (CFB), membrane co-factor protein (MCP) and complement component 3 (C3). The penetrance of familial HUS is incomplete, indicating that environmental triggers are also involved: often infection, including diarrhoea. Sporadic cases may be associated with the development of autoantibodies to complement factor H. In addition to supportive care, including RRT if necessary, management of complement-mediated HUS includes plasma exchange to replace complement

## 18.23 Thrombotic microangiopathies associated with acute renal damage

Condition	Typical features	Management
<b>Primary thrombotic microangiopathies</b>		
Haemolytic uraemic syndrome:	Renal failure prominent in all causes	
Shiga toxin +ve HUS	Bloody diarrhoea; check stool for <i>Escherichia coli</i> O157:H7	Supportive therapy
Complement-mediated	Positive family history; screen for complement factor mutations	Plasma exchange, eculizumab
Drug-induced: quinine, calcineurin and VEGF-A inhibitors	Drug exposure, fever with quinine	Cessation of offending drug
Thrombotic thrombocytopenic purpura	Neurological manifestations prominent; check ADAMTS-13 activity	Plasma exchange
<b>Thrombotic microangiopathy associated with systemic disorders</b>		
Disseminated intravascular coagulation (DIC)	Clotting system involvement: elevated D-dimers, low fibrinogen, prolonged PT and APTT	Treatment of primary cause
Malignancy	May occur with breast, prostate, lung, pancreas and GI tumours	Treatment of tumour where possible
Systemic sclerosis	Cutaneous features of systemic sclerosis	Blood pressure control with ACE inhibitors
Pre-eclampsia and HELLP syndrome	Typically in third trimester; abnormal LFTs	Resolution with delivery
Malignant hypertension	Blood pressure typically very high; evidence of hypertensive retinopathy including papilloedema	Blood pressure control

(ACE = angiotensin-converting enzyme; ADAMTS-13 = a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; APTT = activated partial thromboplastin time; GI = gastrointestinal; HELLP = haemolysis, elevated liver enzymes and low platelets; HUS = haemolytic uraemic syndrome; LFTs = liver function tests; PT = prothrombin time; VEGF = vascular endothelial growth factor)

components and remove pathogenic autoantibodies. Impressive results have been reported with the anti-C5 monoclonal antibody, eculizumab, which binds to C5, thereby preventing activation of the terminal complement cascade.

### Thrombotic thrombocytopenic purpura

Like HUS, thrombotic thrombocytopenic purpura (TTP) is characterised by microangiopathic haemolytic anaemia and thrombocytopenia; in contrast, however, the brain is more commonly affected in TTP and involvement of the kidney is usually less prominent. TTP is an autoimmune disorder caused by antibodies against ADAMTS-13, which is involved in regulating platelet aggregation, and a low (<10%) serum ADAMTS-13 activity level may be useful in distinguishing TTP from HUS. This distinction is important, as early therapy with plasma exchange is crucial in TTP. More details are provided on page 988.

### Cholesterol emboli

These present with renal impairment, haematuria, proteinuria and sometimes eosinophilia with inflammatory features that can mimic a small-vessel vasculitis. The symptoms are provoked by showers of cholesterol-containing microemboli, arising in atheromatous plaques in major arteries. The diagnosis should be suspected when these clinical features occur in patients with widespread atheromatous disease, who have undergone interventions such as surgery or arteriography. They may also be precipitated by anticoagulants and thrombolytic agents. On clinical examination, signs of large-vessel disease and microvascular occlusion in the lower limbs (ischaemic toes, livedo reticularis) are common but not invariable (Fig. 18.17). There is no specific treatment.

### Small-vessel vasculitis

Renal disease caused by small-vessel vasculitis usually presents with a clinical picture typical of a glomerulonephritis (see Figs. 18.9 and 18.12C). More information is given below.

## Renal involvement in systemic conditions

The kidneys may be directly involved in a number of multisystem diseases or secondarily affected by diseases of other organs. Involvement may be at a pre-renal, renal (glomerular or interstitial) or post-renal level. Many of the diseases are described in other sections of this chapter or in other chapters of the book.

### Diabetes mellitus

Diabetic nephropathy is the most common cause of CKD in developed countries. In patients with diabetes, there is a steady advance from moderately elevated albuminuria (microalbuminuria) to dipstick-positive proteinuria, in association with evolving hypertension and progressive renal failure, as described on page 749. Few patients require renal biopsy to establish the diagnosis, but atypical features such as very rapid

Fig. 18.17 The foot of a patient who suffered extensive atheroembolism following coronary artery stenting.

progression of proteinuria/decline in renal function or the absence of microvascular disease in other organs, including retinopathy, should lead to suspicion that an alternative condition could be present.

Management with ACE inhibitors and ARBs to slow progression is described on page 749. In some patients, proteinuria may be eradicated and progression completely halted, although most still have progressive disease, albeit at a slower rate. SGLT2 inhibitors, reduce cardiovascular mortality and progression of kidney disease at the expense of increased risk of genital infections.

### Multiple myeloma

In myeloma, a malignant clone of plasma cells produces a paraprotein, often a monoclonal light chain. Renal manifestations are dominated by these toxic light chains, which may cause a variety of insults (Box 18.24). Hypercalcaemia may also occur due to bony metastases.

### Hepatic–renal disease

Severe hepatic dysfunction may cause a haemodynamically mediated type of renal failure, hepatorenal syndrome (HRS), described on page 877. Patients with chronic liver disease are also predisposed to develop AKI (acute tubular necrosis) in response to relatively minor insults, including bleeding, diuretic therapy and infection. Differentiating true HRS from acute tubular necrosis (ATN) can be difficult, but in HRS the urinary sodium is typically low. Patients with true HRS are often difficult to treat by dialysis and have a poor prognosis. Where treatment is justified – for example, if there is a good chance of recovery or of a liver transplant – slow or continuous renal replacement therapy treatments are less likely to precipitate or exacerbate hepatic encephalopathy. IgA nephropathy (p. 575) is more common in patients with chronic liver disease.

### Sarcoidosis

Sarcoidosis may lead to a granulomatous interstitial nephritis, sometimes presenting acutely, where renal function may improve with glucocorticoid therapy. Postmortem examinations reveal a chronic interstitial nephritis in 15%–30% of patients with sarcoidosis but clinically relevant disease appears to be much less common.

#### 18.24 Renal manifestations of multiple myeloma

Condition	Presentation	Pathogenesis
Cast nephropathy ('myeloma kidney')	AKI Little/no proteinuria	Light chains combine with Tamm–Horsfall protein precipitating in tubules
Fanconi syndrome	Aminoaciduria, phosphaturia, glycosuria Proximal (type II) RTA	Proximal tubular injury due to light chain deposition in tubular epithelium
AL (primary) amyloidosis*	Proteinuria/nephrotic syndrome Renal impairment	Misfolded light chains (usually lambda) form amyloid, which is deposited in glomeruli
Monoclonal immunoglobulin deposition disease*	Proteinuria (may be in nephrotic range) Renal impairment	Usually light chains (frequently kappa) are deposited in glomeruli, causing a nodular glomerulosclerosis
Hypercalcaemia	Thirst, polyuria, bony and abdominal pain, headache	Bony destruction from metastases

\*These may also occur as primary conditions without myeloma being present. (AKI = acute kidney injury; RTA = renal tubular acidosis)

## Systemic vasculitis

Small-vessel vasculitis (Ch. 26) commonly affects the kidneys, with rapid and profound impairment of glomerular function. Histologically, there is a focal inflammatory glomerulonephritis, usually with focal necrosis (see [Box 18.15](#) and [Fig. 18.12C](#)) and often with crescentic changes (see [Fig. 18.12C](#)). Typically, the patient is systemically unwell with an acute phase response, weight loss and arthralgia. In some patients, it presents as a kidney-limited disorder, with rapidly deteriorating renal function and crescentic nephritis (a rapidly progressive glomerulonephritis). In others, pulmonary haemorrhage may occur, which can be life-threatening.

The most important cause is ANCA vasculitis (Ch. 26). Two subtypes are recognized: microscopic polyangiitis (MPA) and granulomatosis with polyangiitis. Both may present with constitutional symptoms and glomerulonephritis, though lung and ENT involvement is more common with granulomatosis with polyangiitis. Gastrointestinal involvement, arthritis, scleritis/uveitis, purpuric rash and neuropathy may also occur. Serological testing for antibodies to myeloperoxidase (MPO) and proteinase 3 (PR3) is usually positive (see [Box 18.10](#)) but these are not specific and a biopsy of affected tissue should be obtained, if possible, to confirm the diagnosis.

The standard treatment of glomerulonephritis associated with systemic vasculitis is high-dose glucocorticoids combined with cyclophosphamide, or mycophenolate mofetil (p. 1012). Recent studies indicate that rituximab is as effective as oral cyclophosphamide, when combined with high-dose glucocorticoids. Plasma exchange can offer additional benefit in patients with progressive renal damage who are not responding adequately to immunosuppressive therapy.

Glomerulonephritis secondary to vasculitis may rarely be seen in rheumatoid arthritis, SLE and cryoglobulinaemia, although SLE can affect the kidney in several different ways (see below).

Medium- to large-vessel vasculitis, such as polyarteritis nodosa (Ch. 26), does not cause glomerulonephritis but can cause hypertension, renal aneurysms and infarction if the renal vessels are involved.

## Systemic sclerosis

Renal involvement is a serious complication of systemic sclerosis, which is more likely to occur in diffuse cutaneous systemic sclerosis (DCSS) than in limited cutaneous systemic sclerosis (LCSS). The renal lesion is caused by intimal cell proliferation and luminal narrowing of intrarenal arteries and arterioles. There is intense intrarenal vasospasm and plasma renin activity is markedly elevated. Renal involvement usually presents clinically with severe hypertension, microangiopathic features and progressive oliguric renal failure ('scleroderma renal crisis'). Use of ACE inhibitors to control the hypertension has improved the 1-year survival from 20% to 75% but about 50% of patients continue to require RRT. Onset or acceleration of the syndrome after glucocorticoid use or cessation of ACE inhibitors is well described.

## Systemic lupus erythematosus

Subclinical renal involvement, with non-visible haematuria and proteinuria but minimally impaired or normal renal function, is common in systemic lupus erythematosus (SLE). Usually, this is due to glomerular disease, although interstitial nephritis may also occur, particularly in patients with overlap syndromes such as mixed connective tissue disease and Sjögren syndrome.

Almost any histological pattern of glomerular disease can be observed in SLE and the clinical presentation ranges from florid, rapidly progressive glomerulonephritis to nephrotic syndrome (see [Fig. 18.9](#)). The most common presentation is with subacute disease and inflammatory features (haematuria, hypertension, variable renal impairment), accompanied by heavy proteinuria that often reaches nephrotic levels. In severely affected patients, the most common histological pattern is a proliferative glomerulonephritis with substantial deposits of immunoglobulins and complement on immunofluorescence. Randomised controlled trials have shown that high-dose glucocorticoids administered in combination with

either cyclophosphamide or mycophenolate mofetil is effective in both induction and maintenance treatment of lupus nephritis and lowers the risk of progression to ESRD.

Many patients with SLE who develop ESRD go into remission, possibly because of immunosuppression related to the ESRD. Patients with ESRD caused by SLE are usually good candidates for dialysis and transplantation. Although it may recur in renal allografts, the immunosuppression required to prevent allograft rejection usually controls SLE.

## Sickle-cell nephropathy

Improved survival of patients with sickle-cell disease means that a high proportion now live to develop chronic complications of microvascular occlusion. In the kidney, these changes are most pronounced in the medulla, where the vasa recta are the site of sickling because of hypoxia and hypertonicity. Loss of urinary concentrating ability and polyuria are the earliest changes; distal renal tubular acidosis and impaired potassium excretion are typical. Papillary necrosis may also occur (p. 577). A minority of patients develop ESRD. This is managed according to the usual principles, but response to recombinant erythropoietin is poor because of the haemoglobinopathy. Patients with sickle trait have an increased incidence of unexplained non-visible haematuria.

## Acute kidney injury

Acute kidney injury (AKI) is not a diagnosis, rather it describes the situation where there is a sudden and often reversible loss of renal function, which develops over days or weeks and is often accompanied by a reduction in urine volume. Approximately 7% of all hospitalised patients and 20% of acutely ill patients develop AKI. In uncomplicated AKI mortality is low, however when it is associated with sepsis and multiple organ failure mortality is 50%–70% and the outcome is usually determined by the severity of the underlying disorder and other complications, rather than by kidney injury itself. Older patients are at higher risk of developing AKI and have a worse outcome ([Box 18.25](#)).

### Pathophysiology

There are many causes of AKI and it is frequently multifactorial. It is helpful to classify it into three subtypes as these have different presentations and treatment ([Fig. 18.18](#)):

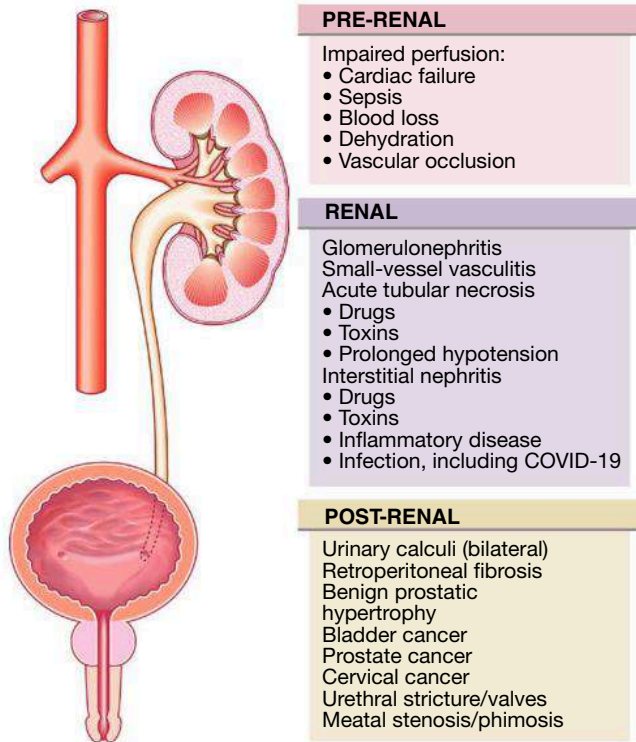

- 'pre-renal', when perfusion to the kidney is reduced
- 'renal', when the primary insult affects the kidney itself
- 'post-renal', when there is obstruction to urine flow at any point from the tubule to the urethra.

Pre-renal AKI results from a reduction in renal perfusion, typically due to a reduction in systemic blood pressure. The drop in renal perfusion activates the renin–angiotensin–aldosterone system, which promotes

### 18.25 Acute kidney injury in old age

- **Physiological change:** nephrons decline in number with age and average GFR falls progressively, so many older patients will have established CKD and less functional reserve. Small acute declines in renal function may therefore have a significant impact.
- **Creatinine:** as muscle mass falls with age, less creatinine is produced each day. Serum creatinine can therefore underestimate the severity of renal failure.
- **Renal tubular function:** declines with age, leading to loss of urinary concentrating ability.
- **Drugs:** increased drug prescription in older people (diuretics, ACE inhibitors and NSAIDs) may contribute to the risk of AKI.
- **Causes:** infection, renal vascular disease, prostatic obstruction, myeloma and severe cardiac dysfunction are common.
- **Mortality:** rises with age, primarily because of comorbid conditions.

**Fig. 18.18** Causes of acute kidney injury.

sodium retention in the kidney and systemic vasoconstriction (see Fig. 20.19), in order to restore blood pressure. Angiotensin also preferentially constricts the glomerular efferent arteriole, while prostaglandins are released locally to vasodilate the afferent arteriole (see Figs. 18.1D and 18.19). The combined effect increases glomerular pressure to maintain GFR, however if the blood pressure is very low, autoregulation fails and the GFR falls. Importantly, in pre-renal AKI, the kidney is not damaged, therefore GFR can improve rapidly if the renal perfusion is restored.

If the drop in renal perfusion is severe or sustained, pre-renal AKI may progress to renal AKI as ischaemic injury causes ATN, the most extreme example being with renal arterial or venous occlusion. Histologically, the kidney shows inflammatory changes, focal breaks in the tubular basement membrane and interstitial oedema (see Fig. 18.13B). Dead tubular cells may also be shed into the tubular lumen, leading to tubular obstruction. While ischaemia is the most common cause of ATN in hospital, it may also be caused by toxins and nephrotoxic drugs (see Boxes 18.26 and 18.42). Drugs can also cause allergic interstitial nephritis. The other common 'renal' cause of AKI is glomerulonephritis, in which there is direct inflammatory damage to the glomeruli. COVID-19 infection is also associated with AKI in a significant proportion of patients.

Post-renal AKI occurs as the result of obstruction to the renal tract (see Box 18.6). This leads to elevation of intraluminal ureteral pressure transmitted to the nephrons, with a subsequent fall in GFR. The obstruction needs to be bilateral to cause renal failure, therefore it is unusual for renal stones to cause AKI, while obstruction of the bladder outlet is a much more common cause. If the obstruction is not relieved, the low GFR is maintained by a drop in renal perfusion via thromboxane A<sub>2</sub> and angiotensin II. This leads to chronic renal injury over several weeks. If obstruction is reversed, the extent of recovery of renal function is dependent on the duration of obstruction and the pre-morbid GFR.

### Clinical features

All emergency admissions to hospital should have renal function, blood pressure, temperature and pulse checked on arrival and undergo risk assessment for the likelihood of developing AKI. Those with coexisting

diseases such as diabetes, cardiovascular, liver disease and existing CKD are at greater risk and need more regular assessment of renal function. If a patient is found to have a high serum creatinine, it is important to establish whether this is an acute or acute-on-chronic phenomenon, or a sign of CKD. Previous measurements of renal function are the best guide, but clinical features of AKI include short duration of symptoms, and an absence of markers of CKD such as anaemia, elevated PTH and small kidneys observed on imaging (see Fig. 18.22). Early recognition of AKI, assessment of volume status and prompt action to treat the underlying cause is required to prevent rapid progression of renal injury and to facilitate recovery as the damage may be potentially reversible if detected at an early stage. Importantly, eGFR is not accurate in AKI (see Box 18.2) and it may overestimate renal function in early AKI when creatinine is increasing rapidly.

Clinical features and pertinent investigations for the different causes of AKI are shown in Box 18.26 and are discussed below.

### Pre-renal AKI

Tachycardia and postural hypotension (a fall in blood pressure of >20/10 mmHg from lying to standing) are valuable early signs of intravascular volume depletion. More significant hypovolaemia is associated with hypotension and signs of poor peripheral perfusion, such as cold peripheries and delayed capillary return. Warm peripheries in the presence of hypotension may indicate sepsis, as peripheral vasodilatation may be triggered by bacterial toxins and immune mediators. Pre-renal AKI may also occur without systemic hypotension, particularly in patients who are dehydrated or who are taking NSAIDs or ACE inhibitors (Fig. 18.19).

The cause of hypotension is often obvious, but concealed blood loss can occur into the gastrointestinal tract, retroperitoneum, following trauma (particularly with pelvic and femoral fractures) and into the pregnant uterus. Large volumes of intravascular fluid may also be lost into tissues after crush injuries or burns, following abdominal surgery, in severe inflammatory skin diseases or sepsis.

While diagnosis of pre-renal failure is usually based on history and assessment of volume status, the most helpful investigations reflect activation of hormonal systems due to intravascular volume depletion. Activation of the renin-angiotensin-aldosterone system promotes sodium and urea reabsorption in the proximal tubule, leading to a low urinary sodium and a high serum urea:creatinine ratio; ADH release promotes water reabsorption leading to a high specific gravity on urinalysis.

### Renal AKI

Factors that can help differentiate the various causes of intrinsic renal AKI are summarised in Box 18.26. Patients with glomerulonephritis demonstrate haematuria and proteinuria, and may have clinical manifestations of an underlying disease, such as SLE or systemic vasculitis. Although blood tests, including an immunological screen, should be performed to clarify the diagnosis in glomerulonephritis, a renal biopsy is usually required. Drug-induced acute interstitial nephritis should be suspected in a previously well patient if there is an acute deterioration of renal function coinciding with introduction of a new drug treatment. Drugs that are commonly implicated include PPIs, NSAIDs and many antibiotics. Vascular disease is included here as diseases of the large and small renal vessels typically present with hypertension and volume expansion, in contrast to the volume depletion observed in pre-renal failure.

### Post-renal AKI

Patients should be examined clinically to look for evidence of a distended bladder and should also undergo imaging with ultrasound to detect evidence of obstruction above the level of the bladder. Post-renal AKI is usually accompanied by hydronephrosis.

### Management

Management options common to all forms of AKI are discussed in more detail below and summarised in Box 18.27.

18.26 Categorising acute kidney injury based on history, examination and investigations			
Type of AKI	History	Examination	Investigations
<b>Pre-renal</b>	Volume depletion (vomiting, diarrhoea, burns, haemorrhage) Sepsis Cardiac disease Liver disease Drugs (diuretics, ACE inhibitors, ARBs, NSAIDs, calcineurin inhibitors, iodinated contrast)	Low BP relative to normal for patient (including postural drop) Tachycardia Weight decrease Dry mucous membranes Decreased skin turgor JVP not visible even when lying down	Urine Na <20 mmol/L Fractional excretion Na < 1% High serum urea:creatinine ratio Urinalysis bland
<b>Renal</b>			
ATN	Ischaemic injury due to severe or prolonged pre-renal state Toxic ATN: drugs (aminoglycosides, cisplatin, tenofovir, methotrexate, iodinated contrast) Other (rhabdomyolysis, snake bite, <i>Amanita</i> mushrooms)	Vital signs Fluid assessment Limbs for compartment syndrome	Urine Na >40 mmol/L Fractional excretion Na ≥ 1% Dense granular ('muddy brown') casts Creatine kinase
Glomerular	Rash, weight loss, arthralgia, ENT and chest symptoms (pulmonary renal syndromes) IV drug use Recent infection	Hypertension Oedema Purpuric rash, uveitis, arthritis	Proteinuria, haematuria Red cell casts, dysmorphic red cells ANCA, anti-GBM, ANA, C3 and C4 Viral hepatitis screen, HIV Renal biopsy
Tubulo-interstitial	Interstitial nephritis: drugs (PPIs, penicillins, NSAIDs) Sarcoidosis  Tubular obstruction: Myeloma (cast nephropathy)  Tubular crystal nephropathy: Drugs (aciclovir, indinavir, triamterene, methotrexate) Oxalate (fat malabsorption, ethylene glycol) Urate (tumour lysis)	Fever Rash	Leucocyturia White cell casts Minimal proteinuria  Paraprotein, Bence Jones protein Calcium (myeloma, sarcoidosis)  Urine microscopy for crystals Serum urate Urine collection for oxalate
Vascular (including renal infarction, renal vein thrombosis, cholesterol emboli, malignant hypertension)	Flank pain, trauma Anticoagulation Recent angiography (cholesterol emboli) Nephrotic syndrome (renal vein thrombosis) Systemic sclerosis (renal crisis) Diarrhoea (HUS)	Hypertension Hypertensive changes on fundoscopy Livedo reticularis (cholesterol emboli) Sclerodactyly	Normal urinalysis or some haematuria CT angiography Doppler renal ultrasound C3 and C4 (cholesterol emboli) Platelets, haemolytic screen, LDH (HUS) Consider ADAMTS13 and complement genetics (if TMA)
<b>Post-renal</b>	Bladder outlet symptoms History of BPH or prostate, bladder or cervical cancer Retroperitoneal fibrosis Neurogenic bladder	Rectal examination (prostate and anal tone) Distended bladder Pelvic mass	Urinalysis frequently normal (may reveal haematuria depending on cause) Renal ultrasound (hydronephrosis) Isotope renogram (delayed excretion) if ultrasound inconclusive

(ACE = angiotensin-converting enzyme; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; ARBs = angiotensin receptor blockers; ATN = acute tubular necrosis; BP = blood pressure; BPH = benign prostatic hypertrophy; GBM = glomerular basement membrane; HIV = human immunodeficiency virus; HUS = haemolytic uraemic syndrome; IV = intravenous; JVP = jugular venous pulse; LDH = lactate dehydrogenase; NSAIDs = non-steroidal anti-inflammatory drugs; PPIs = proton pump inhibitors; TMA = thrombotic microangiopathy)

### Optimisation of volume status

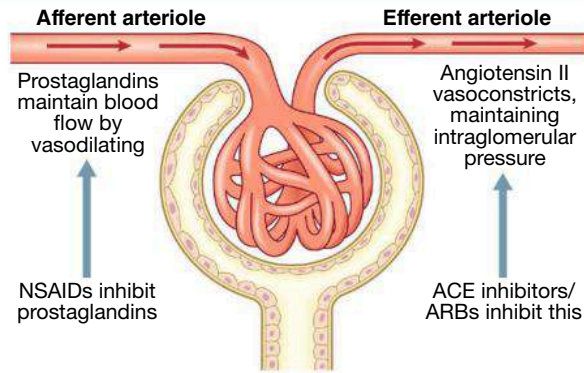

Regular assessment of volume status is essential to guide ongoing fluid requirements. Where clinical assessment is challenging, such as in obesity, invasive monitoring of central venous pressure may be of value. If hypovolaemia is present, it should be corrected by prompt replacement of intravenous fluid or blood. When large volumes of fluid are required, balanced crystalloid solutions, such as Plasma-Lyte or Hartmann's, may be preferable to isotonic saline (0.9% NaCl) in order to avoid hyperchloraemic acidosis. Once the patient is volume replete, fluid intake should be matched to urine output plus 500mL per day to cover insensible losses, unless additional losses are anticipated, such as with diarrhoea or high nasogastric aspirates. Excessive administration of fluid should be avoided, since this can provoke pulmonary oedema. In situations

where vasodilatation is a prominent cause of relative intravascular volume depletion, such as sepsis or liver failure, inotropes may be required to restore an effective blood pressure.

In patients with volume expansion, diuretics may be used, but in those with AKI high doses may be required and they are not always effective. If pulmonary oedema (Fig. 18.20) is present and urine output cannot be rapidly restored, treatment with dialysis may be required to remove excess fluid.

### Treatment of underlying cause

In pre-renal failure, rapid fluid resuscitation may be sufficient for resolution of AKI, though it is important to identify and manage underlying causes such as blood loss, sepsis and cardiac events.

**Fig. 18.19 Renal haemodynamics and autoregulation of glomerular filtration rate (GFR).** It is evident from this figure how angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers (ARBs) may be associated with profound drops in GFR in the context of bilateral renal artery stenosis or intravascular volume depletion (which decrease perfusion to afferent arterioles). (NSAIDs = non-steroidal anti-inflammatory drugs)

### 18.27 Management of acute kidney injury

- Assess fluid status as this will determine fluid prescription:
  - If hypovolaemic: optimise systemic haemodynamic status with fluid challenge and inotropes if necessary
  - Once euvoalaemic, match fluid intake to urine output plus an additional 500 mL/24 hrs to cover insensible losses
  - If fluid-overloaded, prescribe diuretics (loop diuretics at high dose will often be required); if the response is unsatisfactory, dialysis may be required
- Treat underlying cause
- If  $K^+ > 6.5$  mmol/L and ECG changes of hyperkalaemia are present administer calcium gluconate to stabilise myocardium, lower potassium by oral potassium exchange resin to prevent potassium absorption, or administering intravenous glucose/insulin or sodium bicarbonate to move potassium intracellularly (see Box 19.17). These are holding measures until a definitive method of removing potassium is achieved (restoration of renal function or dialysis)
- Discontinue potentially nephrotoxic drugs and reduce doses of therapeutic drugs according to level of renal function
- Ensure adequate nutritional support
- Consider proton pump inhibitors to reduce the risk of upper gastrointestinal bleeding
- Screen for intercurrent infections and treat promptly if present

(ECG = electrocardiogram)

In those with suspected ATN, volume status should be optimised, offending drugs should be discontinued, conditions such as sepsis, compartment syndrome or myeloma identified and treated. However, once ATN is established, even if the underlying cause has been corrected, regeneration of necrotic tubules and recovery of renal function may take days or even weeks and the patient may need support with renal replacement therapy in the interim.

In post-renal AKI, the obstruction should be relieved as soon as possible. This may involve urinary catheterisation for bladder outflow obstruction, or relief of ureteric obstruction with ureteric stents or percutaneous nephrostomies.

#### Electrolyte and acid–base disturbances

Hyperkalaemia is common, particularly in patients with rhabdomyolysis, burns, haemolysis or metabolic acidosis or in those taking medications that inhibit the renin–angiotensin–aldosterone system. If serum  $K^+$  concentration is  $>6.5$  mmol/L, an electrocardiogram (ECG) should be performed, and if there are changes consistent with hyperkalaemia, this should be treated immediately, as described in Box 19.17, to prevent life-threatening cardiac arrhythmias.

Severe acidosis can be ameliorated by treatment with sodium bicarbonate if volume status allows. This may also be helpful in lowering serum potassium.

**Fig. 18.20 Pulmonary oedema in acute kidney injury.** The appearances are indistinguishable from left ventricular failure but the heart size is usually normal. Blood pressure is often high.

Dilutional hyponatraemia may occur if the patient has continued to drink freely despite oliguria or has received inappropriate amounts of intravenous dextrose. This can be corrected by fluid restriction. Modest hypocalcaemia is common but rarely requires treatment. Serum phosphate levels are usually high but may fall in patients on daily or continuous renal replacement therapy (CRRT), necessitating phosphate replacement.

#### Dietary measures

Adequate nutritional support may be required to ensure sufficient calorie and protein intake. This is particularly important in patients in catabolic states such as with sepsis and burns. Enteral or parenteral nutrition may be required.

#### Infection

Sepsis may either be the cause of AKI or a consequence of the depression of humoral and cellular immune mechanisms found in patients with AKI. Regular clinical examination, supplemented by microbiological investigation where appropriate, is required to diagnose infection. If infection is discovered, it should be treated promptly according to standard principles (see Ch. 6).

#### Medications

Patients with drug-induced kidney injury (see Box 18.42) should have the offending drug withdrawn. Additionally, NSAIDs and drugs that block the renin–angiotensin–aldosterone system should be discontinued, as they may reduce GFR (see Fig. 18.19) and exacerbate hyperkalaemia. Other drug treatments should be reviewed and the doses adjusted if necessary, to take account of reduced renal function (see p. 31). Non-essential drug treatments should be stopped.

#### Renal replacement therapy (RRT)

Conservative management can be successful in AKI with meticulous attention to fluid balance, electrolytes and nutrition, but RRT may be required in patients who are not showing signs of recovery with these measures (see Box 18.27). No specific cut-off values for serum urea or creatinine have been identified at which RRT should be commenced, and clinical trials of earlier versus later initiation of RRT have not shown differences in outcome in patients with AKI. Furthermore, RRT can be a risky intervention, since it requires the placement of central venous catheters that may become infected and it may represent a major haemodynamic

challenge in unstable patients. Accordingly, the decision to institute RRT should be made on an individual basis, taking account of the potential risks and benefits, comorbidity and an assessment of whether early or delayed recovery is likely. Severe uraemia with pericarditis and neurological signs (uraemic encephalopathy) are uncommon in AKI but, when present, are strong indications for RRT; other indications are given in [Box 18.35](#). The two main options for RRT in AKI are intermittent haemodialysis and continuous renal replacement therapy. Peritoneal dialysis is also an option if haemodialysis is not available (p. 595).

### Recovery from AKI

Most cases of AKI will recover after the insult resolves but recovery may be impaired in those with pre-existing CKD or following a prolonged, severe or irreversible insult ([Fig. 18.21](#)). Recovery is heralded by a gradual return of urine output and a steady reduction in serum creatinine. There is often a diuretic phase in which urine output increases rapidly and remains excessive for several days before returning to normal. This is due to loss of the concentrating ability of the kidneys due to tubular damage and to temporary loss of the medullary concentration gradient. After a few days, urine volume falls to normal as the concentrating mechanism and tubular reabsorption are restored. During the recovery phase of AKI, it may be necessary to provide temporary supplementation of fluid, potassium and sometimes calcium, phosphate and magnesium.

## Chronic kidney disease

Chronic kidney disease (CKD) refers to an irreversible deterioration in renal function that usually develops over a period of years (see [Box 18.3](#)). Initially, it manifests only as a biochemical abnormality but, eventually, loss of the excretory, metabolic and endocrine functions of the kidney leads to the clinical symptoms and signs of renal failure, collectively referred to as uraemia. When death is likely without RRT (CKD stage 5), it is called end-stage renal disease (ESRD).

### Epidemiology

The social and economic consequences of CKD are considerable. In many countries, estimates of the prevalence of CKD stages 3–5 (eGFR  $<60\text{ mL/min/1.73 m}^2$ ) are around 5%–7%, mostly affecting people aged 65 years and above (see [Box 18.3](#)). The prevalence of CKD in patients with hypertension, diabetes and vascular disease is substantially higher, and targeted screening for CKD should be considered in these and other high-risk groups. More than 25% of the population aged over 75

years have an eGFR of  $<60\text{ mL/min/1.73 m}^2$ , mostly stage 3A CKD (see [Box 18.3](#)). In these patients, investigation and management should be focused on cardiovascular risk prevention, as very few will ever develop ESRD. Many primary renal diseases, however, are more common in older people, so investigation is warranted for those with declining renal function or with haematuria/proteinuria on dipstick.

### Pathophysiology

Common causes of CKD are shown in [Box 18.28](#). In many cases the underlying diagnosis is unclear, especially among the large number of older patients with stage 3 CKD. Many patients diagnosed at a late stage have bilateral small kidneys. Renal biopsy is rarely undertaken in this group since it is more risky, less likely to provide a histological diagnosis because of the severity of damage, and unlikely to alter management.

### Clinical features

The typical presentation is for a reduced eGFR to be found incidentally during routine blood tests, often during screening of high-risk patients, such as those with diabetes or hypertension. Most patients with slowly progressive disease are asymptomatic until GFR falls below  $30\text{ mL/min/1.73 m}^2$  and some can remain asymptomatic with much lower GFR values than this. An early symptom is nocturia, due to the loss of concentrating ability, but this is non-specific. When GFR falls below  $15\text{--}20\text{ mL/min/1.73 m}^2$ , symptoms and signs are common and can affect almost all body systems, but are often non-specific and may not immediately raise suspicion of kidney disease ([Fig. 18.22](#)). They typically include tiredness or breathlessness, which may, in part, be related to renal anaemia or fluid overload. With further deterioration in renal function, patients may suffer pruritus, anorexia, weight loss, nausea, vomiting and hiccups. In very advanced renal failure, respiration may be particularly deep (Kussmaul breathing) due to profound metabolic acidosis, and patients may develop muscular twitching, fits, drowsiness and coma.

### Investigations

The recommended investigations in patients with CKD are shown in [Box 18.29](#). Their main aims are:

- to exclude AKI requiring rapid investigation; in patients with unexpectedly high urea and creatinine (when there is an increase from previous results or no prior results are available), renal function should be retested within 2 weeks to avoid missing AKI
- to identify the underlying cause where possible, since this may influence the treatment

**Fig. 18.21** Recovery from acute kidney injury (AKI). Many patients make a full recovery of renal function (1). If the insult is prolonged or prior renal function not normal, however, patients may develop progressive chronic kidney disease (2) or, rarely, irreversible, complete loss of renal function (3). (ESRD = end-stage renal disease)

18.28 Common causes of chronic kidney disease		
Disease	Proportion	Comments
Diabetes mellitus	20%–45%	Large racial and geographical differences
Interstitial diseases	20%–30%	Drug-induced, reflux nephropathy
Glomerular diseases	10%–20%	IgA nephropathy is most common
Hypertension	5%–20%	Causality controversial, much may be secondary to another primary renal disease
Systemic inflammatory diseases	5%–10%	Systemic lupus erythematosus, vasculitis
Renovascular disease	5%	Mostly atheromatous, may be more common
Congenital and inherited	10%	Polycystic kidney disease, Alport syndrome
Unknown	5%–10%	

Fig. 18.22 Physical signs in advanced chronic kidney disease. (\*Features of renal replacement therapy.)

### 18.29 Suggested investigations in chronic kidney disease

Initial tests	Interpretation
<b>Creatinine, eGFR</b>	To assess stability/progression: compare to previous results
<b>Urinalysis and quantification of proteinuria</b>	Haematuria and proteinuria may indicate glomerular disease and need for biopsy (p. 566). Proteinuria indicates risk of progressive CKD requiring preventive ACE inhibitor or ARB therapy
<b>Electrolytes</b>	To identify hyperkalaemia and acidosis
<b>Calcium, phosphate, parathyroid hormone and 25(OH)D</b>	Assessment of renal osteodystrophy
<b>Albumin</b>	Low albumin: consider malnutrition, inflammation, nephrotic syndrome
<b>Full blood count (<math>\pm</math> Fe, ferritin, folate, B<sub>12</sub>)</b>	If anaemic, exclude common non-renal explanations, then manage as renal anaemia
<b>Lipids, glucose <math>\pm</math> HbA<sub>1c</sub></b>	Cardiovascular risk high in CKD: treat risk factors aggressively
<b>Renal ultrasound</b>	Consider with obstructive urinary symptoms, persistent haematuria, family history of polycystic kidney disease or progressive CKD. Small kidneys suggest chronicity. Asymmetric renal size suggests renovascular or congenital disease
<b>Hepatitis and HIV serology</b>	If dialysis or transplant is planned. Hepatitis B vaccination recommended if seronegative
<b>Other tests</b>	Consider relevant tests from Box 18.26, especially if the cause of CKD is unknown

(ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker; CKD = chronic kidney disease; HIV = human immunodeficiency virus; 25(OH)D = 25-hydroxyvitamin D)

- to identify reversible factors that may worsen renal function, such as hypertension or urinary tract obstruction
- to screen for complications of CKD, such as anaemia and renal osteodystrophy
- to screen for cardiovascular risk factors.

Referral to a nephrologist is appropriate for patients with potentially treatable underlying disease and those who are likely to progress to ESRD. Suggested referral criteria are listed in Box 18.30.

### Management

The aims of management in CKD are to:

- monitor renal function
- prevent or slow further renal damage
- limit complications of renal failure
- treat risk factors for cardiovascular disease
- prepare for RRT, if appropriate (p. 593).

### Monitoring of renal function

The rate of change in renal function varies between patients and may vary over time in each individual. Renal function should therefore be monitored every 6 months in patients with stage 3 CKD, but more frequently in patients who are deteriorating rapidly or have stage 4 or 5 CKD. A plot of GFR against time (Fig. 18.23) can demonstrate whether therapy has been successful in slowing progression, detect any unexpected increase in the rate of decline that may warrant further investigation, and help predict when ESRD will be reached to facilitate timely planning for RRT.

### Reduction of rate of progression

Slowing the rate of progression of CKD may reduce complications and delay symptom onset and the need for RRT (see Fig. 18.23). Therapies directed towards the primary cause of CKD should be employed where possible; tight blood pressure control is applicable to CKD regardless of cause, however, and reducing proteinuria is a key target in those with glomerular disease.

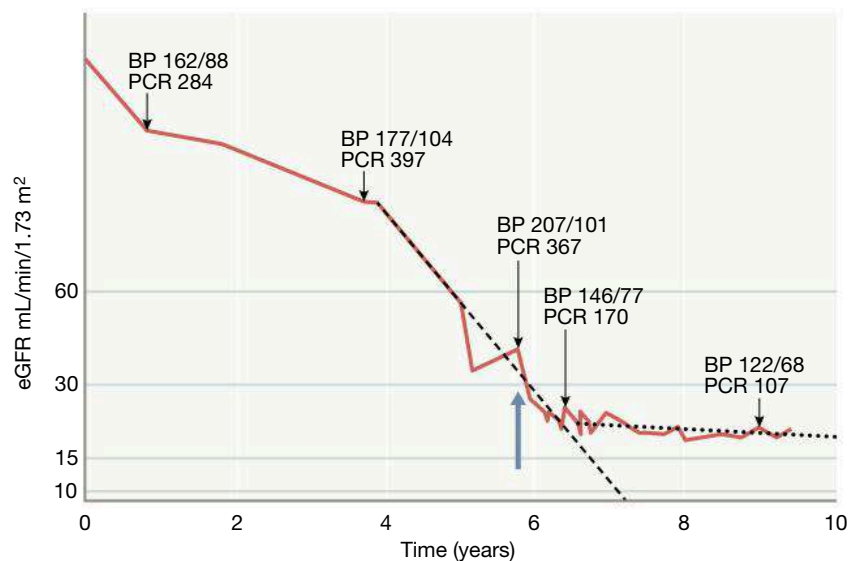

**Antihypertensive therapy** Lowering of blood pressure slows the rate at which renal function declines in CKD, independently of the agent used (apart from those with proteinuria; see below) and has additional benefits in lowering the risk of hypertensive heart failure and cardiovascular disease. No threshold for beneficial effects has been identified and any

reduction of blood pressure appears to be beneficial. A target blood pressure of less than 140/90 mmHg is recommended for patients with CKD and no albuminuria (ACR <3 mg/mmol; see Box 18.11 for conversion of mg/mmol to mg/dL). A lower target of 130/80 mmHg is recommended for those with diabetes or an ACR of more than 70 mg/mmol. Achieving these blood pressure targets often requires multiple drugs, and therapeutic success may be limited by adverse effects and poor adherence.

**Reduction of proteinuria** Patients with proteinuria are at higher risk of progression of renal disease, and there is strong evidence that reducing proteinuria reduces the risk of progression. ACE inhibitors and ARBs reduce proteinuria and retard the progression of CKD. These effects are partly due to the reduction in blood pressure but there is evidence for a specific beneficial effect in patients with proteinuria (PCR >50 mg/mmol or ACR >30 mg/mmol; see Box 18.11) through a reduction in glomerular perfusion pressure (see Fig. 18.19). In addition, ACE inhibitors have been shown to reduce the risk of cardiovascular events and all-cause mortality in CKD. Accordingly, ACE inhibitors or ARBs should be prescribed to all patients with diabetic nephropathy and patients with CKD and proteinuria, irrespective of whether or not hypertension is present.

While ACE inhibitors and ARBs are excellent drugs for patients with diabetes or CKD and proteinuria, they need to be prescribed with care in certain circumstances. Initiation of treatment with ACE inhibitors and ARBs may be accompanied by an immediate reduction in GFR; patients should therefore have their renal function checked within 7–10 days of initiating or increasing the dose of an ACE inhibitor or ARB. Treatment can be continued so long as the reduction in GFR is not greater than 25% and is not progressive. Angiotensin II is critical for autoregulation of GFR in the context of low renal perfusion (see Fig. 18.1D), and so ACE inhibitors or ARBs may exacerbate pre-renal failure (see Fig. 18.19). Patients on ACE inhibitors/ARBs should therefore be warned to stop taking the medication if they become unwell, such as with fever, vomiting or diarrhoea, restarting once they are better. This also applies to other common medications used in patients with CKD, such as diuretics, metformin and NSAIDs, and this advice may be reinforced by providing written information such as 'sick-day rule' cards (Box 18.31). ACE inhibitors and ARBs increase serum potassium and should not be commenced in patients with baseline potassium >5.5 mmol/L. In patients with serum potassium >6.0 mmol/L, the dose of ACE inhibitors or ARBs should be reduced or discontinued entirely, but only after all other measures to

i 18.30 Criteria for referral of chronic kidney disease patients to a nephrologist
<ul style="list-style-type: none"> <li>• eGFR &lt;30 mL/min/1.73 m<sup>2</sup></li> <li>• Rapid deterioration in renal function (&gt;25% from previous or &gt;15 mL/min/1.73 m<sup>2</sup>/year)</li> <li>• Significant proteinuria (PCR &gt;100 mg/mmol or ACR &gt;70 mg/mmol*), unless known to be due to diabetes and patient is already on appropriate medications</li> <li>• ACR &gt;30 mg/mmol* with non-visible haematuria</li> <li>• Hypertension that remains poorly controlled despite at least four antihypertensive medications</li> <li>• Suspicion of renal involvement in multisystem disease</li> </ul>
<p>*See Box 18.11 for conversion of mg/mmol to mg/dL. (ACR = albumin:creatinine ratio; eGFR = estimated glomerular filtration rate; PCR = protein:creatinine ratio)</p>

**Fig. 18.23** Plot of estimated glomerular filtration rate (eGFR) against time in a patient with type 1 diabetes mellitus. After approximately 6 years of monitoring (blue arrow), this patient entered an aggressive treatment programme aimed at optimising blood pressure (BP) and glycaemic control. The reduction in BP was accompanied by a fall in proteinuria (protein:creatinine ratio, PCR; shown in mg/mmol). At the previous rate of decline in renal function (dashed line), he was likely to reach the level of renal function at which dialysis therapy is typically required (eGFR = 10 mL/min/1.73 m<sup>2</sup>) within 18 months; however, the relative stabilisation in his renal function (dotted line) means that this has been deferred, potentially for several years.

reduce potassium have been considered (see below). Combination therapy with ACE inhibitors and ARBs or direct renin inhibitors has not been shown to reduce progression of kidney disease but is associated with higher rates of hyperkalaemia and AKI, and is therefore to be avoided.

### Treatment of complications

The kidneys have many functions in addition to excretion of waste (p. 560). Treatments that substitute for all of the normal roles of the kidneys must therefore be instigated to maintain normal body homeostasis and prevent complications.

**Maintenance of fluid and electrolyte balance** The kidneys excrete waste and regulate many electrolytes, and so patients with CKD may accumulate waste products and develop electrolyte abnormalities.

Urea is a key product of protein degradation and accumulates with progressive CKD. All patients with stages 4 and 5 CKD should be given dietetic advice aimed at preventing excessive consumption of protein. Severe protein restriction is not recommended, however; there is no evidence that this reduces the rate of decline in renal function but may lead to malnutrition.

Potassium often accumulates in patients with advanced CKD, who should be provided with dietary advice to reduce daily potassium intake to below 70 mmol (Box 18.32). Potassium-binding compounds limit absorption of potassium from the gut and may be a useful adjunctive therapy. Calcium resonium is not recommended, other than as a very short-term measure, as it can be associated with bowel necrosis; however, newer agents, such as sodium zirconium cyclosilicate and patiramer, appear promising for chronic use. Other measures that may help regulate potassium include diuretic therapy and control of acidosis with sodium bicarbonate (see below). Consideration should be given to stopping or reducing drugs that elevate potassium, such as potassium-sparing diuretics and ACE inhibitors/ARBs; however, this has to be balanced against the potential benefit that such drugs may have on retarding progression of renal and cardiovascular disease, and hence withdrawal should be reserved for when other measures have failed.

The inability of the failing kidney to excrete sodium and water commonly leads to their accumulation, which may manifest as oedema and drive hypertension. Patients with evidence of volume expansion should be instructed to consume a low-sodium diet (<100 mmol/24 hrs) and in severe cases fluid intake should also be restricted. Diuretics are commonly required, and as renal function deteriorates, increasing doses of

potent loop diuretics or synergistic combinations of loop, thiazide and potassium-sparing diuretics may be necessary.

Occasionally, some patients with tubulo-interstitial disease can develop 'salt-wasting' disease and may require a high sodium and water intake, including supplements of sodium salts, to prevent fluid depletion and worsening of renal function.

**Acid–base balance** Reduced ability to excrete organic acids in patients with CKD may lead to an anion-gap metabolic acidosis. In addition, in patients with tubulo-interstitial disease or diabetic nephropathy, there may be specific defects in acid–base regulation within the kidney, causing a non-anion-gap renal tubular acidosis (p. 631). Although acidosis is usually asymptomatic, it may be associated with increased tissue catabolism and decreased protein synthesis, and may exacerbate bone disease and the rate of decline in renal function. Hence, plasma bicarbonate concentrations should be maintained above 22 mmol/L by prescribing sodium bicarbonate supplements (starting dose of 1 g 3 times daily, increasing as required). There is some evidence that correcting acidosis may reduce the rate of decline in renal function.

**Renal bone disease** Disturbances of calcium and phosphate metabolism are almost universal in advanced CKD (Fig. 18.24). The sequence of events that leads to renal bone disease is complex, but two primary factors are: impaired excretion of phosphate and failure of the renal tubular cells to convert 25-hydroxyvitamin D to its active metabolite 1,25-dihydroxyvitamin D. A rise in serum phosphate levels promotes production of the hormone fibroblast growth factor 23 (FGF23) from osteocytes (see Fig. 26.3) and stimulates parathyroid hormone (PTH) release and hyperplasia of the parathyroid glands. The FGF23 and PTH promote tubular phosphate excretion, thereby partly compensating for the reduced glomerular filtration of phosphate. The reduced 1,25-dihydroxyvitamin D level stimulates PTH release and reduces intestinal absorption of calcium. In addition, raised levels of serum phosphate complex with calcium in the extracellular space, leading to calcium phosphate deposition in tissues including the cardiovascular system. The combination of reduced absorption and increased deposition of calcium promotes hypocalcaemia, which also stimulates PTH production by the parathyroid glands. Hence in many patients with CKD, compensatory responses initially maintain phosphate and calcium levels at the upper and lower ends of their respective normal ranges, at the expense of an elevated PTH level (secondary hyperparathyroidism). This is associated with bone resorption (osteitis fibrosa cystica), and in severe cases this may result in bony pain and increased risk of fractures. Conversely there is increased deposition of calcium phosphate in many tissues, most notably blood vessels and heart valves, which may contribute to the increased risk of cardiovascular disease in patients with CKD (see below). In some cases, tertiary hyperparathyroidism supervenes, due to autonomous production of PTH by the enlarged parathyroid glands; this presents with hypercalcaemia. Additional problems in bone metabolism include low bone turnover (adynamic bone disease) in patients who have been over-treated with vitamin D metabolites and osteoporosis in patients with poor nutritional intake.

The key focus in the management of renal bone disease should be directed towards the two main driving factors, hyperphosphataemia and inadequate activation of vitamin D. Hyperphosphataemia should be treated by dietary restriction of foods with high phosphate content (milk, cheese, eggs and protein-rich foods) and by the use of phosphate-binding drugs that inhibit phosphate reabsorption in the gut. Various drugs are available, including calcium carbonate, aluminium hydroxide, lanthanum carbonate and polymer-based phosphate binders such as sevelamer. The aim is to maintain serum phosphate values below 1.5 mmol/L (4.6 mg/dL) if possible, but many of these drugs are difficult to take and adherence can be a problem. Active vitamin D metabolites (either 1- $\alpha$ -hydroxyvitamin D or 1,25-dihydroxyvitamin D) should be administered in patients who are hypocalcaemic or have serum PTH levels more than twice the upper limit of normal. The dose should be adjusted to try to reduce PTH levels to between 2 and 4 times the upper limit of

## i

### 18.31 Exemplar medicine sick-day card

When you are unwell with vomiting, diarrhoea or fever, stop taking the following medications:

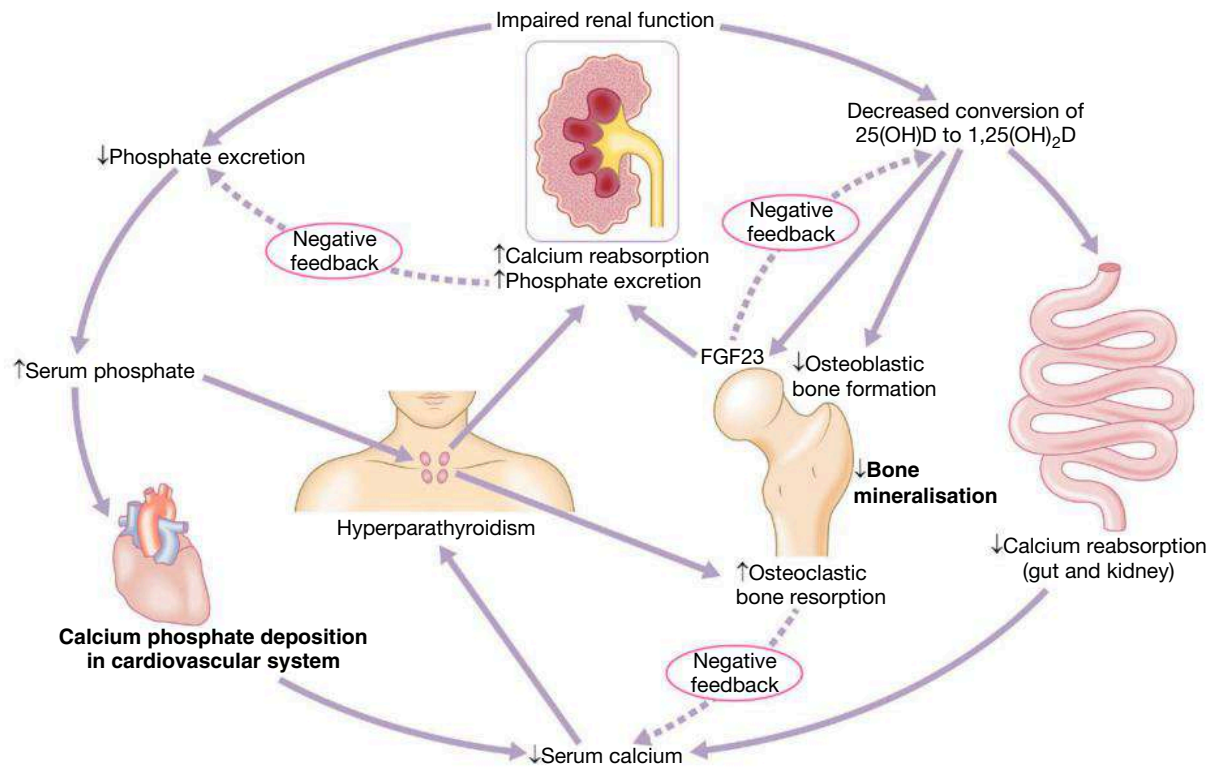

- ACE inhibitors: medicines ending in '-pril', e.g. lisinopril, ramipril
- Angiotensin receptor blockers: medicines ending in '-sartan', e.g. irbesartan, losartan, candesartan
- Non-steroidal anti-inflammatory painkillers: e.g. ibuprofen (Brufen), diclofenac (Voltarol)
- Diuretics: e.g. furosemide, bendroflumethiazide, indapamide, spironolactone
- Metformin: a medicine for diabetes.

Restart when you are well again (after 24–48 hours of eating and drinking normally).

## i

### 18.32 Foods high in potassium

- Fruit: bananas, avocados, figs, rhubarb
- Vegetables: tomatoes, spinach, parsnips, courgettes, sprouts, potatoes (including baked, fries, wedges; boiling vegetables reduces potassium content)
- Sweets/snacks: crisps, chocolate, toffee, nuts (including peanut butter)
- Drinks: beer, cider, wine (spirits contain less potassium), hot chocolate, fruit juice, milk, yoghurt
- Some salt substitutes, such as Lo-Salt: sodium chloride is substituted with potassium chloride

**Fig. 18.24 Pathogenesis of renal osteodystrophy.** Impaired renal clearance of phosphate promotes elevated serum phosphate, which binds to calcium, lowering the serum calcium and leading to calcium phosphate deposition in tissues including the cardiovascular system. Low 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ) levels reduce calcium absorption from gut and kidney exacerbating hypocalcaemia. Low serum calcium and  $1,25(\text{OH})_2\text{D}$  levels (arrow not shown in figure for ease of reading) and high phosphate stimulate release of parathyroid hormone (PTH) which increases osteoclastic bone resorption, contributing to renal osteodystrophy. The elevated PTH and production of fibroblast growth factor 23 (FGF23) from osteocytes promotes phosphate excretion, however this is insufficient to prevent hyperphosphataemia in advanced chronic kidney disease.

normal to limit hyperparathyroidism while avoiding over-suppression of bone turnover and adynamic bone disease, but care must be exercised in order to avoid hypercalcaemia. In patients with persistent hypercalcaemia (tertiary hyperparathyroidism), parathyroidectomy may be required. If parathyroidectomy is unsuccessful or not possible, calcimimetic agents, such as cinacalcet, may be used. These bind to the calcium-sensing receptor in the parathyroid glands and reduce PTH secretion.

**Anaemia** Anaemia is common in patients with CKD and contributes to many of the non-specific symptoms, including fatigue and shortness of breath. Haemoglobin can be as low as 50–70 g/L in CKD stage 5, although it is often less severe or absent in patients with polycystic kidney disease. Several mechanisms are implicated, as summarised in [Box 18.33](#). Iron deficiency is common in patients with CKD, and even more prevalent in those on haemodialysis as a result of haemolysis in the dialysis circuit. Hence many patients require iron supplements, which may be given intravenously for those with iron intolerance or in situations where adherence may be difficult. Once iron deficiency and other causes of anaemia have been excluded or corrected, recombinant human erythropoietin is very effective in correcting the anaemia of CKD and improving symptoms. However, correcting haemoglobin to normal levels confers higher risk of hypertension and thrombosis, therefore the target haemoglobin is usually between 100 and 120 g/L or avoidance of blood transfusions. Erythropoietin is less effective in the presence of iron deficiency, active inflammation or malignancy, in particular myeloma.

#### Treatment of risk factors for cardiovascular disease

The risk of cardiovascular disease is substantially increased in patients with a GFR below 60 mL/min/1.73 m<sup>2</sup> and in those with proteinuria, the

### 18.33 Causes of anaemia in chronic kidney disease

- Deficiency of erythropoietin
- Toxic effects of uraemia on marrow precursor cells
- Reduced intake, absorption and utilisation of dietary iron
- Reduced red cell survival
- Blood loss due to capillary fragility and poor platelet function

combination of reduced eGFR and proteinuria being particularly unfavourable. Patients with CKD have a higher prevalence of traditional risk factors for atherosclerosis, such as hypertension, hyperlipidaemia and diabetes; however, additional mechanisms of cardiovascular disease may also be implicated. Left ventricular hypertrophy is commonly found in patients with CKD, secondary to hypertension or anaemia. Calcification of the media of blood vessels, heart valves, myocardium and the conduction system of the heart is also common and may be due, in part, to the high serum phosphate levels. Reflecting this fact, serum FGF23 levels, which increase in response to serum phosphate, are an independent predictor of mortality in CKD. Both left ventricular hypertrophy and cardiac calcification may increase the risk of arrhythmias and sudden cardiac death, which is a much more common mode of death in patients with CKD than in the general population, particularly in those with more advanced disease and those on dialysis.

To reduce vascular risk, patients with CKD should be encouraged to adopt a healthy lifestyle, including regular exercise, and weight loss and smoking cessation where appropriate. Lipid-lowering drugs reduce cardiovascular events in patients with CKD, although their efficacy may be lower once patients require dialysis.

### Preparing for renal replacement therapy

It is crucial for patients who are known to have progressive CKD to be prepared well in advance for the institution of RRT. They should be referred to a nephrologist in a timely manner, as those who are referred late, when they are very close to requiring dialysis, tend to have poorer outcomes.

Several decisions need to be taken in discussion with the patient and family. The first is to decide whether RRT is an appropriate choice or whether conservative treatment might be preferable (see the next section). This is especially relevant in patients with significant comorbidity. For those who decide to go ahead with RRT, there are further choices between haemodialysis and peritoneal dialysis (Box 18.34), between hospital and home treatment, and on referral for renal transplantation.

Since there is no evidence that early initiation of RRT improves outcome, the overall aim is to commence RRT when symptoms of CKD begin to impact on quality of life but before serious complications have occurred. While there is wide variation between patients, this typically occurs when the eGFR approaches 10 mL/min/1.73 m<sup>2</sup>. This may be a useful marker to predict the timing of initiation of RRT by extrapolating from a plot of serial eGFR measurements over time (see Fig. 18.23).

Preparations for starting RRT should begin at least 12 months before the predicted start date. This involves providing the patient with psychological and social support, assessing home circumstances and discussing the various choices of treatment (Fig. 18.25). Depression is common in patients who are on or approaching RRT, and support from the renal multidisciplinary team should be provided both for them and for their relatives, to explain and help them adapt to the changes to lifestyle that may be necessary once RRT starts; this may help to reduce their anxieties about these changes. Physical preparations include establishment of timely access for haemodialysis or peritoneal dialysis and vaccination against hepatitis B.

## Renal replacement therapy

Renal replacement therapy (RRT) may be required on a temporary basis in patients with AKI or on a permanent basis for those with advanced CKD. Since the advent of long-term RRT in the 1960s, the number of patients with ESRD who are kept alive by dialysis and transplantation has increased considerably. By the end of 2017, almost 65 000 patients were on RRT in the UK, with a median age of 59 years. After a long period of expansion, the number of patients on dialysis in the UK and the United States has begun to stabilise; however, the total number of patients on RRT continues to expand, due to an increasing proportion (55%) of patients with a functional transplant. The remaining patients were on haemodialysis (39%) and peritoneal dialysis (6%).

There are variations in the number of patients receiving RRT in different countries because of differences in the incidence of predisposing disease, as well as differences in medical practice. For example, the incidence rate for RRT in the United States in 2017 was three times higher than in the UK (370 versus 121 patients per million population), and the prevalence rate at the end of 2017 was more than twice as high (2204 versus 983 per million population). Diabetic kidney disease is the most common cause of ESRD in many countries, accounting for 29% of all ESRD in the UK and almost 50% in the United States. The large increase in the prevalence of type 2 diabetes in developing countries is resulting in a predictable rise in cases of ESRD, which is challenging already stretched health-care resources.

Survival on dialysis is strongly influenced by age and presence of complications such as diabetes (Fig. 18.26). For this reason, conservative care rather than RRT may be a more appropriate option for older patients or those with extensive comorbidities. Although many young patients without extrarenal disease lead normal and active lives on RRT, those aged 30–34 have a mortality rate 25 times higher than that of age-matched controls.

The aim of RRT is to replace the excretory functions of the kidney and to maintain normal electrolyte concentrations and fluid balance. Various

### 18.34 Comparison of haemodialysis and peritoneal dialysis

Haemodialysis	Peritoneal dialysis
Efficient; 4 hrs three times per week is usually adequate	Less efficient; four exchanges per day are usually required, each taking 30–60 mins (continuous ambulatory peritoneal dialysis) or 8–10 hrs each night (automated peritoneal dialysis)
2–3 days between treatments	A few hours between treatments
Requires visits to hospital (although home treatment is possible with adaptations for some patients)	Performed at home
Requires adequate vascular access	Requires an intact peritoneal cavity without major scarring from previous surgery
Careful adherence to diet and fluid restrictions required between treatments	Diet and fluid less restricted
Fluid removal compressed into treatment periods; may cause symptoms and haemodynamic instability	Slow continuous fluid removal, usually asymptomatic
Infections related to vascular access may occur	Peritonitis and catheter-related infections may occur
Patients are usually dependent on others	Patients can take full responsibility for their treatment

options are available, including haemodialysis, haemofiltration, haemodiafiltration, peritoneal dialysis and renal transplantation, and each of these is discussed in more detail below. Indications for starting RRT in both AKI and CKD may be found in Box 18.35.

### Conservative treatment

In older patients and those with multiple comorbidities, conservative treatment of stage 5 CKD, aimed at limiting the adverse symptoms of ESRD without commencing RRT, is increasingly viewed as a positive choice (see Box 18.36). Current evidence suggests that survival of these patients without dialysis can be similar or only slightly shorter than that of patients who undergo RRT, but they avoid the hospitalisation and interventions associated with dialysis. Patients are offered full medical, psychological and social support to optimise and sustain their existing renal function and to treat complications, such as anaemia, for as long as possible, with appropriate palliative care in the terminal phase of their disease. Many of these patients enjoy a good quality of life for several years. When quality of life on dialysis is poor, it is appropriate to consider discontinuing it, following discussion with the patient and family, and to offer palliative care.

### Haemodialysis

Haemodialysis is the most common form of dialysis employed in ESRD and is also used in AKI. Haemodialysis involves gaining access to the circulation, either through a central venous catheter or an arteriovenous fistula or graft. The patient's blood is pumped through a haemodialyser, which allows bidirectional diffusion of solutes between blood and the dialysate across a semipermeable membrane down a concentration gradient (see Fig. 18.25A). The composition of the dialysate can be varied to achieve the desired solute gradient, and fluid can be removed by applying negative pressure to the dialysate side.

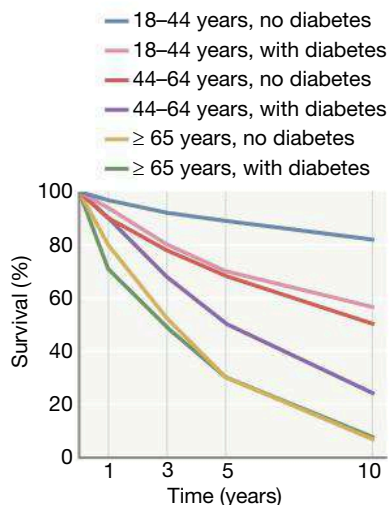

### Haemodialysis in AKI

Haemodialysis offers the best rate of small-solute clearance in AKI, compared with other techniques such as haemofiltration, but should be

**A Haemodialysis****B Haemofiltration****C Peritoneal dialysis****D Transplantation**

**Fig. 18.25 Options for renal replacement therapy.** **A** In haemodialysis, there is diffusion of solutes from blood to dialysate across a semipermeable membrane down a concentration gradient. **B** In haemofiltration, both water and solutes are filtered across a porous semipermeable membrane by a pressure gradient. Replacement fluid is added to the filtered blood before it is returned to the patient. **C** In peritoneal dialysis (PD), fluid is introduced into the abdominal cavity using a catheter. Solutes diffuse from blood across the peritoneal membrane to PD fluid down a concentration gradient, and water diffuses through osmosis (see text for details). **D** In transplantation, the blood supply of the transplanted kidney is generally anastomosed to the external iliac vessels and the ureter to the bladder. The transplanted kidney replaces all functions of the failed kidney.

**Fig. 18.26** Percentage survival after commencing renal replacement therapy according to age group and presence of diabetes.

started gradually because of the risk of delirium and convulsions due to cerebral oedema (dialysis disequilibrium). Typically, 1–2 hours of dialysis is prescribed initially but, subsequently, patients with AKI who are haemodynamically stable can be treated by 4–5 hours of haemodialysis on alternate days, or 2–3 hours every day. During dialysis, it is standard practice to anticoagulate patients, typically using heparin but the dose may be reduced if there is a bleeding risk. In patients undergoing short treatments and in those with abnormal clotting, it may be possible to avoid anticoagulation altogether. In AKI, dialysis is performed through a large-bore, dual-lumen catheter inserted into the femoral or internal jugular vein (Fig. 18.27A).

### Haemodialysis in ESRD

In ESRD, vascular access for haemodialysis is gained by formation of an arteriovenous fistula (AVF), usually in the forearm, up to a year before dialysis is contemplated (Fig. 18.27B). After 4–6 weeks, increased pressure transmitted from the artery to the vein leading from the fistula causes distension and thickening of the vessel wall (arterialisation). Large-bore needles can then be inserted into the vein to provide access for each haemodialysis treatment.

### 18.35 Indications for dialysis with examples for AKI and CKD

Indication*	Acute examples	Chronic examples
Uraemia	Pericarditis Encephalopathy	Uraemic syndrome including anorexia, nausea, lethargy (generally not seen until eGFR <10 mL/min/1.73 m <sup>2</sup> )
Fluid overload	Acute pulmonary oedema	Intractable dependent oedema resistant to diuretics Pulmonary oedema Severe hypertension
Hyperkalaemia	High potassium (generally >6.5 mmol/L) with ECG changes (especially broad QRS)	Potassium resistant to dietary control and medical intervention
Metabolic acidosis	Severe acidosis (H <sup>+</sup> >79 nmol/L; pH <7.1)	Chronic acidosis resistant to bicarbonate therapy
Other (often relative indications)	Bleeding diathesis considered due to uraemia-induced platelet dysfunction	Intractable anaemia despite erythropoietin and iron Hyperphosphataemia despite binders

\*The presence of anuria in AKI will modify the above indications, as these complications will not resolve if the patient is persistently anuric. Most indications to commence chronic dialysis are relative indications; a holistic approach is taken to making this decision.  
(AKI = acute kidney injury; CKD = chronic kidney disease; ECG = electrocardiogram; eGFR = estimated glomerular filtration rate)

### 18.36 Renal replacement therapy in old age

- **Quality of life:** age itself is not a barrier to good quality of life on RRT.
- **Coexisting cardiovascular disease:** older people are more sensitive to fluid balance changes, predisposing to hypotension during dialysis with rebound hypertension between dialysis sessions. A failing heart cannot cope with fluid overload, and pulmonary oedema develops easily.
- **Confusion:** sudden changes in serum electrolyte composition during dialysis may exacerbate confusion in patients with early dementia.
- **Provision of treatment:** peritoneal dialysis may avoid the problems due to sudden changes in fluid and electrolyte status; however, older patients often require assistance with performing peritoneal dialysis, typically assistance setting up fluids and connecting/disconnecting to automated peritoneal dialysis.
- **Survival on dialysis:** difficult to predict for an individual patient, but old age plus substantial comorbidity are associated with poor survival. In such patients similar survival may be achieved through conservative care, without the complications associated with dialysis.
- **Withdrawal from dialysis:** may be appropriate whenever quality of life deteriorates irreversibly, usually in the context of severe comorbidity.
- **Transplantation:** relative risks of surgery and immunosuppression exclude many older people from transplantation.
- **Conservative therapy:** without dialysis but with adequate support. This is an appropriate option for patients at high risk of complications from dialysis who have a limited prognosis.

Preservation of arm veins is thus very important in patients with progressive renal disease who may require haemodialysis in the future. If creation of an AVF is not possible, synthetic polytetrafluoroethylene (PTFE) grafts may be fashioned between an artery and a vein, or central venous catheters may be used for short-term access (Fig. 18.27C). These are tunnelled under the skin to reduce infection risk.

All patients starting dialysis must be screened in advance for hepatitis B, hepatitis C and HIV, and vaccinated against hepatitis B if they are not immune. All dialysis units should have segregation facilities for hepatitis B-positive patients, given its easy transmissibility. Patients with hepatitis C and HIV are less infectious and can be treated satisfactorily using machine segregation and standard infection control measures.

Haemodialysis is usually carried out for 3–5 hours three times weekly, either at home or in an outpatient dialysis unit. The intensity and frequency of dialysis should be adjusted to achieve a reduction in urea during dialysis (urea reduction ratio) of over 65%; below this level there is an increase in mortality. Most patients notice an improvement in symptoms during the first 6 weeks of treatment. The intensity of dialysis can be increased by:

- escalating the number of standard sessions to four or more per week
- performing short, frequent dialysis sessions of 2–3 hours 5–7 times per week

- performing nocturnal haemodialysis, when low blood-pump speeds are used for approximately 8 hours overnight 5–6 times per week
- including a filtration component (haemodiafiltration) to achieve greater clearance of larger molecules.

More frequent dialysis and nocturnal dialysis can achieve better fluid balance and phosphate control, improve left ventricular mass and possibly improve mortality, although the latter has not yet been robustly demonstrated. Box 18.37 summarises some of the problems related to haemodialysis.

### Haemofiltration

Haemofiltration is employed continuously for long periods daily using a dual-lumen intravenous catheter and is hence termed continuous venovenous haemofiltration (CVVH). This technique is principally used in the treatment of AKI in patients who are haemodynamically unstable and who therefore may not tolerate the rapid fluid and electrolyte changes associated with intermittent haemodialysis. Large volumes of water are filtered from blood across a porous semipermeable membrane under a pressure gradient. Solutes are removed via 'solvent drag' rather than by diffusion, therefore this method is less efficient at clearing urea and potassium than haemodialysis. Replacement fluid of a suitable electrolyte composition is added to the blood after it exits the haemofilter. If removal of fluid is required, then less fluid is added back than is removed (see Fig. 18.25B). Typically 1–2 L of filtrate is replaced per hour (equivalent to a GFR of 15–30 mL/min/1.73 m<sup>2</sup>); higher rates of filtration may be of benefit in patients with sepsis and multi-organ failure. Issues concerning anticoagulation are similar to those for haemodialysis, but may be more problematic because longer or continuous anticoagulation is necessary.

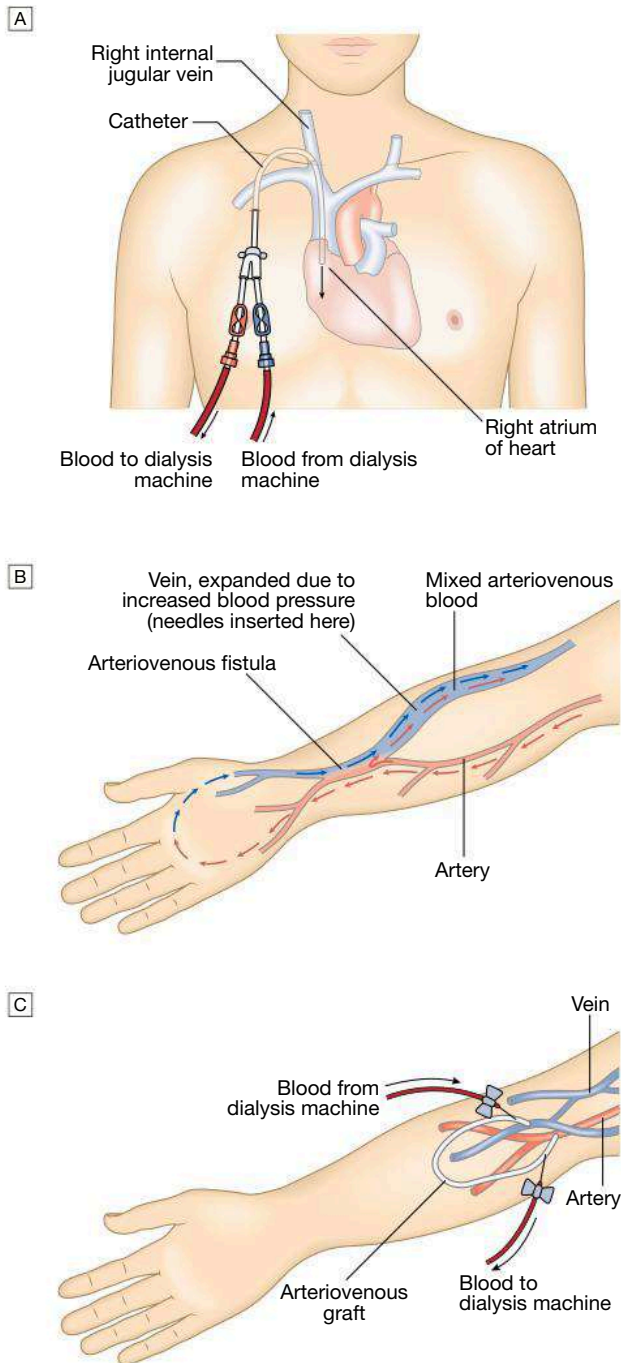

Haemodiafiltration combines haemodialysis with approximately 20–30 L of ultrafiltration (with replacement of filtrate) over a 3–5-hour treatment. It uses a large-pore membrane and combines the improved clearance of medium-sized molecules observed in haemofiltration with the higher small-solute clearance of haemodialysis. It is sometimes used in the treatment of AKI, often as continuous therapy. It is increasingly employed in patients on chronic dialysis but is more expensive than haemodialysis and the long-term benefits are not yet established.

### Peritoneal dialysis

Peritoneal dialysis is principally used in the treatment of CKD, though it may occasionally be employed in AKI. It requires the insertion of a permanent Silastic catheter into the peritoneal cavity (see Fig. 18.25C). Two types are in common use. In continuous ambulatory peritoneal dialysis (CAPD), about 2 L of sterile dialysis fluid are introduced and left in place

for approximately 4–6 hours. Metabolic waste products diffuse from peritoneal capillaries into the dialysis fluid down a concentration gradient. The fluid is then drained and fresh dialysis fluid introduced, in a continuous four-times-daily cycle. The inflow fluid is rendered hyperosmolar by the addition of glucose or glucose polymer; this results in net removal of fluid from the patient during each cycle, due to diffusion of water from the blood through the peritoneal membrane down an osmotic gradient (ultrafiltration). The patient is mobile and able to undertake normal daily activities. Automated peritoneal dialysis (APD) is similar to CAPD but uses a machine to perform the fluid exchanges during the night, typically leaving some fluid in the peritoneum during the day for ongoing dialysis.

CAPD is particularly useful in children, as a first treatment in adults with some residual renal function, and as a treatment for older patients

**Fig. 18.27** Haemodialysis access. **A** A tunneled cuffed dialysis catheter. **B** An arteriovenous fistula. **C** An arteriovenous graft.

with cardiovascular instability. The long-term use of peritoneal dialysis may be limited by episodes of bacterial peritonitis and damage to the peritoneal membrane, including encapsulating peritoneal sclerosis, but some patients have been treated successfully for more than 10 years. **Box 18.38** summarises some of the problems related to CAPD treatment.

## Renal transplantation

Renal transplantation offers the best chance of long-term survival in ESRD and is the most cost-effective treatment. All patients with ESRD should be considered for transplantation but many are not suitable due to a combination of comorbidity and advanced age (although no absolute age limit applies). Active malignancy, vasculitis and cardiovascular comorbidity are common contraindications to transplantation, with risk of recurrence of the original renal disease (generally glomerulonephritides) being a less common problem.

Kidney grafts may be taken from a deceased donor in the UK after brain death (37%) or circulatory death (25%), or from a living donor (38%). As described in the section on transplantation and graft rejection in **Chapter 4**, matching of a donor to a specific recipient is strongly influenced by immunological factors, since graft rejection is the major cause of transplant failure. Compatibility of ABO blood group between donor and recipient is usually required and the degree of matching for major histocompatibility (MHC) antigens, particularly human leucocyte antigens (HLA) A, B and DR, influences the incidence of rejection. Immediately prior to transplantation, cross-matching should be performed for anti-HLA antibodies (traditionally mixing of recipient serum with donor lymphocytes) (**Ch. 4**). Positive tests predict early rejection and worse graft survival. Although some ABO- and HLA-incompatible transplants are now possible, this involves appropriate preparation with pre-transplant plasma exchange and/or immunosuppression, so that recipient antibodies to the donor's tissue are reduced to acceptably low levels. This option is generally only available for living donor transplants because of the preparation required. Paired exchanges, in which a donor–recipient pair who are incompatible, either due to blood group or anti-HLA antibodies, are computer-matched with another pair to overcome the mismatch, are also used to increase the number of successful transplants that can be performed.

During the transplant operation, the kidney is placed in the pelvis; the donor vessels are usually anastomosed to the recipient's external iliac artery and vein, and the donor ureter to the bladder (see **Fig. 18.25D**). The native kidneys are typically left in place but may be removed pre-transplant if they are a source of repeated sepsis or to make room for a transplant kidney in patients with very large kidneys due to adult polycystic kidney disease.

All transplant patients require regular life-long follow-up to monitor renal function and complications of immunosuppression. Allograft dysfunction is often asymptomatic and picked up during routine surveillance blood tests. The common causes at different time points post transplant are summarised in **Box 18.39**. Immunosuppressive therapy (see **Box 4.21**) is required to prevent rejection and is more intensive in the early post-transplantation period, when rejection risk is highest. A common regimen is triple therapy with prednisolone; ciclosporin or tacrolimus; and azathioprine or mycophenolate mofetil. Sirolimus is an alternative that can be introduced later but is generally not used initially due to impaired wound healing. Basiliximab, an interleukin (IL)-2 receptor antagonist, is frequently used at induction to lower rates of rejection. Anti-lymphocyte preparations (e.g. anti-thymocyte globulin, ATG) may also be used as induction, especially in higher risk cases. Acute cellular rejection is usually treated, in the first instance, by high-dose glucocorticoids, such as intravenous methylprednisolone on three consecutive days. ATG is also used for glucocorticoid-resistant rejection. Antibody-mediated rejection is more difficult to treat and usually requires plasma exchange and intravenous immunoglobulin (**Ch. 4**). Complications of immunosuppression include infections and malignancy (**Ch. 4**).

## i

## 18.37 Problems with haemodialysis

Problem	Clinical features	Cause	Treatment
<b>During treatments</b>			
Hypotension	Sudden ↓BP; often leg cramps; sometimes chest pain	Fluid removal and hypovolaemia	Saline infusion; exclude cardiac ischaemia; quinine may help cramp
Cardiac arrhythmias	Hypotension; sometimes chest pain	Potassium and acid–base shifts	Check K <sup>+</sup> ; review dialysis prescription; stop dialysis
Haemorrhage	Blood loss (overt or occult); hypotension	Anticoagulation Venous needle disconnection	Stop dialysis; seek source; consider heparin-free treatment
Air embolism	Circulatory collapse; cardiac arrest	Disconnected or faulty lines and equipment malfunction	Stop dialysis
Dialyser hypersensitivity	Acute circulatory collapse	Allergic reaction to dialysis membrane or sterilisant	Stop dialysis; change to different artificial kidney
Systemic sepsis	Rigors; fever; ↓BP	Usually involves vascular access devices (catheter or fistula)	Blood cultures; antibiotics
<b>Between treatments</b>			
Pulmonary oedema	Breathlessness	Fluid overload	Ultrafiltration, fluid restriction, lower dry weight

(BP = blood pressure)

## i

## 18.38 Problems with continuous ambulatory peritoneal dialysis

Problem	Clinical features	Cause	Treatment
<b>Peritonitis</b>	Cloudy drainage fluid; abdominal pain and systemic sepsis are variable	Usually entry of skin contaminants via catheter; bowel organisms less common	Culture of peritoneal dialysis fluid Intraperitoneal antibiotics Catheter removal sometimes required
<b>Catheter exit site infection</b>	Erythema and pus around exit site	Usually skin organisms	Antibiotics; sometimes surgical drainage
<b>Peritoneal membrane leaks</b>	Fluid leak from tunnel or pleural effusion (typically unilateral and right-sided)	Leak adjacent to catheter or via congenital pleuroperitoneal communication	Temporary reduction in volume of dialysis fluid. However, pleuroperitoneal leaks are likely to require switch to haemodialysis
<b>Ultrafiltration failure</b>	Fluid overload	Damage to peritoneal membrane, leading to rapid transport of glucose and loss of osmotic gradient	Replacement of glucose with synthetic, poorly absorbed polymers for some exchanges (icodextrin)
<b>Peritoneal membrane failure</b>	Inadequate clearance of urea etc.	Scarring/damage to peritoneal membrane	Increase in exchange volumes; consideration of automated peritoneal dialysis or switch to haemodialysis
<b>Sclerosing peritonitis</b>	Intermittent bowel obstruction Malnutrition	Unknown; typically occurs after many years on peritoneal dialysis	Switch to haemodialysis (may still progress) Surgery and tamoxifen may be used

Approximately 50% of patients of European descent develop skin malignancy by 15 years after transplantation.

The prognosis after kidney transplantation is good. Recent UK statistics for transplants from deceased donors indicate 97% patient survival and 94% graft survival at 1 year, and 87% patient and 87% graft survival at 5 years. Even better figures are obtained with living donor transplantation (92% graft survival and 94% patient survival at 5 years).

## Renal disease in pregnancy

Pregnancy has important physiological effects on the renal system. Some diseases are more common in pregnancy (Box 18.40), the manifestations of others are modified during pregnancy, and a few diseases, such as pre-eclampsia (see Box 32.8), are unique to pregnancy. These are discussed in detail in Chapter 32.

## Renal disease in adolescence

Many causes of renal failure present during infancy or childhood, such as congenital urological malformations and inherited disorders like cystinosis and autosomal recessive polycystic kidney disease. The consequences continue throughout the patient's life and the situation often arises whereby patients transition from paediatric to adult nephrology services. Some of the issues and challenges surrounding this transition are summarised in Box 18.41.

## Drugs and the kidney

### Drug-induced renal disease

The kidney is susceptible to damage by drugs because it is the route of excretion of many water-soluble compounds, including drugs and

18.39 Common causes of renal allograft dysfunction		
Time post transplant	Cause	Risk factors
Hours to days	Renal artery/vein thrombosis  Ureteric anastomotic leak  Delayed graft function (i.e. transplant does not start working immediately)  Hyperacute rejection	Technically difficult surgery Thrombophilia/SLE  Small bladder/anuria pre-transplant  Prolonged cold ischaemia time* Donation after circulatory death Older, hypertensive donor with stroke as cause of death, high tacrolimus level  Pre-formed anti-HLA antibodies HLA mismatch Previous transplant
Weeks	Acute rejection (especially <3 months; can occur later with non-adherence/insufficient immunosuppression)	Pre-formed anti-HLA antibodies HLA mismatch Previous transplant
Months	BK virus nephropathy  Renal artery stenosis	Intensive immunosuppression Ureteric stent use  Donor disease Injury at organ retrieval
Years	Chronic allograft injury (often antibody-mediated)	Previous acute rejections Non-adherence/insufficient immunosuppression
Any time	Tacrolimus/ciclosporin toxicity  Sepsis (opportunistic and conventional) Recurrence of disease: Early (FSGS/MCGN/aHUS) Later (IgA nephropathy/membranous glomerulonephritis)	High doses/serum levels Concurrent use of drugs that inhibit cytochrome P450 system  Primary FSGS and MCGN Previous transplant recurrence

\*Time from organ retrieval in the donor until implantation into the recipient.  
(aHUS = atypical haemolytic uraemic syndrome; FSGS = focal segmental glomerulosclerosis; HLA = human leucocyte antigen; IgA = immunoglobulin A; MCGN = mesangiocapillary glomerulonephritis; SLE = systemic lupus erythematosus)

 **18.40 Renal diseases in pregnancy**

- **Eclampsia:** severe hypertension, encephalopathy and fits
- **Disseminated intravascular coagulation**
- **Thrombotic microangiopathy:** may be part of pre-eclampsia spectrum and can also occur post-partum (including thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome)
- **Acute fatty liver of pregnancy**
- **'HELLP' syndrome:** haemolysis, elevated liver enzymes, low platelets (thrombotic microangiopathy with abnormal liver function)

their metabolites. Some may reach high concentrations in the renal cortex as a result of proximal tubular transport mechanisms. Others are concentrated in the medulla by the operation of the countercurrent system.

Toxic renal damage may occur by a variety of mechanisms (Box 18.42). Very commonly, drugs contribute to the development of acute tubular necrosis as one of multiple insults. Numerically, reactions to NSAIDs and ACE inhibitors are the most important. Haemodynamic renal impairment, acute tubular necrosis and allergic reactions are usually reversible if recognised early enough. Other types, however, especially those associated with extensive fibrosis, are less likely to be reversible.

### Non-steroidal anti-inflammatory drugs

Impairment of renal function may develop in patients on NSAIDs, since prostaglandins play an important role in regulating renal blood flow by vasodilating afferent arterioles (see Fig. 18.19). This is particularly likely in patients with other disorders, such as volume depletion, heart failure, cirrhosis, sepsis and pre-existing renal impairment. In addition, idiosyncratic immune reactions may occur, causing minimal change nephrotic

 **18.41 Kidney disease in adolescence**

- **Adherence:** young adults moving from parental supervision may become disengaged. There may also be reduced adherence to prophylactic and therapeutic treatment, including immunosuppressive medications, diet and fluid restrictions and dialysis.
- **Adverse events:** there is an increased risk of transplant loss and other adverse events in young adults on renal replacement therapy.
- **Management:** joint transition clinics should be established with the paediatric team to facilitate transfer to adult specialist clinics.

syndrome, membranous nephropathy (p. 574) and acute interstitial nephritis (p. 576). Analgesic nephropathy (see Box 18.19) is now a rare complication of long-term use.

### ACE inhibitors

These abolish the compensatory angiotensin II-mediated vasoconstriction of the glomerular efferent arteriole that takes place in order to maintain glomerular perfusion pressure distal to a renal artery stenosis and in renal hypoperfusion (see Figs. 18.1 and 18.19). Monitoring of renal function before and after initiation of therapy is essential and an expected rise in creatinine of about 20% is frequently observed.

### Prescribing in renal disease

Many drugs and drug metabolites are excreted by the kidney and so the presence of renal impairment alters the required dose and frequency (p. 31). Immunosuppressive medications such as tacrolimus or ciclosporin are metabolised by the cytochrome P450 system, hence drug interactions need to be considered before prescribing other medications.

## i

## 18.42 Mechanisms and examples of drug-induced renal disease/dysfunction

Mechanism	Drug or toxin	Comments
Haemodynamic	NSAIDs	Reduce renal blood flow due to inhibition of prostaglandin synthesis causing afferent arteriolar vasoconstriction
	ACE inhibitors	Reduce efferent glomerular arteriolar tone, so especially problematic in the presence of renal artery stenosis and other causes of renal hypoperfusion (e.g. sepsis)
	Radiographic contrast media	Multifactorial aetiology may include intense vasoconstriction
Acute tubular necrosis	Aminoglycosides, amphotericin	In most examples there is evidence of direct tubular toxicity but haemodynamic and other factors probably contribute
	Paracetamol overdose	May occur with or without serious hepatotoxicity
	Radiographic contrast media	Directly toxic to proximal tubular cells
Loss of tubular/collecting duct function	Lithium	Dose-related, partially reversible loss of concentrating ability
	Cisplatin	Occurs at lower exposures than cause acute tubular necrosis
	Aminoglycosides, amphotericin	
Glomerulonephritis (immune-mediated)	Penicillamine, gold	Membranous nephropathy
	Penicillamine, propylthiouracil, hydralazine	Crescentic or focal necrotising glomerulonephritis in association with ANCA and systemic small-vessel vasculitis
	NSAIDs	Minimal change nephropathy, membranous nephropathy
Interstitial nephritis (immune-mediated)	NSAIDs, penicillins, proton pump inhibitors, many others	Acute interstitial nephritis
Interstitial nephritis (toxicity)	Lithium	As a consequence of acute toxicity
	Ciclosporin, tacrolimus	Chronic interstitial nephritis
Papillary necrosis	Various NSAIDs	Ischaemic damage secondary to NSAID effects on renal blood flow
Tubular obstruction (crystal formation)	Aciclovir	Crystals of the drug form in tubules Aciclovir is now more common than the original example of sulphonamides
	Chemotherapy	Uric acid crystals form as a consequence of tumour lysis (typically, a first-dose effect in haematological malignancy)
Nephrocalcinosis	Oral sodium phosphate-containing bowel cleansing agents	Precipitation of calcium phosphate occurring in 1%–4% and exacerbated by volume depletion Usually mild but damage can be irreversible
Retroperitoneal fibrosis	Ergolinic dopamine agonists (cabergoline),	Idiopathic retroperitoneal fibrosis is more common

(ACE = angiotensin-converting enzyme; ANCA = antineutrophil cytoplasmic antibody; NSAIDs = non-steroidal anti-inflammatory drugs)

## Infections of the urinary tract

In health, bacterial colonisation is confined to the lower end of the urethra and the remainder of the urinary tract is sterile (see Ch. 6). The urinary tract can become infected with various bacteria but the most common is *E. coli* derived from the gastrointestinal tract. The most common presenting problem is cystitis with urethritis (generally referred to as urinary tract infection (UTI)).

### Urinary tract infection

UTI is a common disorder, accounting for 1%–3% of consultations in general medical practice. The prevalence of UTI in women is about 3%

at the age of 20, increasing by about 1% in each subsequent decade. In males, UTI is uncommon, except in the first year of life and in men over 60, when it may complicate bladder outflow obstruction.

### Pathophysiology

Urine is an excellent culture medium for bacteria; in addition, the urothelium of susceptible persons may have more receptors, to which virulent strains of *E. coli* become adherent. In women, the ascent of organisms into the bladder is easier than in men; the urethra is shorter and the absence of bactericidal prostatic secretions may be relevant. Sexual intercourse may cause minor urethral trauma and transfer bacteria from the perineum into the bladder. Instrumentation of the bladder may also introduce organisms. Multiplication of organisms then depends on a number of factors, including the size of the inoculum and

virulence of the bacteria. Conditions that predispose to UTI are shown in [Box 18.43](#).

### Clinical features

Typical features of cystitis and urethritis include:

- abrupt onset of frequency of micturition and urgency
- burning pain in the urethra during micturition (dysuria)
- suprapubic pain during and after voiding
- intense desire to pass more urine after micturition, due to spasm of the inflamed bladder wall (strangury)
- urine that may appear cloudy and have an unpleasant odour
- non-visible or visible haematuria.

Systemic symptoms are usually slight or absent. However, infection in the lower urinary tract can spread to cause acute pyelonephritis. This is suggested by prominent systemic symptoms with fever, rigors, vomiting, hypotension and loin pain, guarding or tenderness, and may be an indication for hospitalisation. Only about 30% of patients with acute pyelonephritis have associated symptoms of cystitis or urethritis. Prostatitis is suggested by perineal or suprapubic pain, pain on ejaculation and prostatic tenderness on rectal examination.

The differential diagnosis of lower urinary tract symptoms includes urethritis due to sexually transmitted disease, notably chlamydia (Ch. 15) and urethritis associated with reactive arthritis (Ch. 26). Some patients, usually female, have symptoms suggestive of urethritis and cystitis but no bacteria are cultured from the urine ('urethral syndrome'). Possible explanations include infection with organisms not readily cultured by ordinary methods (such as *Chlamydia* and certain anaerobes), intermittent or low-count bacteriuria, reaction to toiletries or disinfectants, symptoms related to sexual intercourse, or post-menopausal atrophic vaginitis.

The differential diagnosis of acute pyelonephritis includes pyonephrosis, acute appendicitis, diverticulitis, cholecystitis, salpingitis, ruptured ovarian cyst or ectopic pregnancy. In pyonephrosis due to an infected and obstructed upper urinary tract, patients may become extremely ill, with fever, leucocytosis and positive blood cultures. With a perinephric abscess, there is marked pain and tenderness, and often bulging of the loin on the affected side. Urinary symptoms may be absent in this situation and urine testing negative, containing neither pus cells nor organisms.

### Investigations

An approach to investigation is shown in [Box 18.44](#). In an otherwise healthy woman with a single lower urinary tract infection, urine culture

prior to treatment is not mandatory. Investigation is necessary, however, in patients with recurrent infection or after failure of initial treatment, during pregnancy, or in patients susceptible to serious infection, such as the immunocompromised, those with diabetes or an indwelling catheter, and older people ([Box 18.45](#)). The diagnosis can be made from the combination of typical clinical features and abnormalities on urinalysis. In symptomatic infections, urine dipstick tests may be positive for leucocyte esterase released from neutrophils and nitrites, due to conversion of nitrates to nitrites by urinary pathogens. The absence of both nitrites and leucocyte esterase in the urine makes UTI unlikely. Interpretation of bacterial counts in the urine, and of what is a 'significant' culture result, is based on probabilities. Urine taken by suprapubic aspiration should be sterile, so the presence of any organisms is significant. If the patient has symptoms and there are neutrophils in the urine, a small number of organisms is significant. In asymptomatic patients, more than  $10^5$  organisms/mL is usually regarded as significant (asymptomatic bacteriuria; see below).

Typical organisms causing UTI in the community include *E. coli* derived from the gastrointestinal tract (about 75% of infections), *Proteus* spp., *Pseudomonas* spp., streptococci and *Staphylococcus epidermidis*. In hospital, *E. coli* still predominates but *Klebsiella* and streptococci are becoming more common. Certain strains of *E. coli* have a particular propensity to invade the urinary tract.

Investigations to detect underlying predisposing factors for UTI are used selectively, most commonly in children, men or patients with recurrent infections (see [Box 18.44](#)).

### Management

Antibiotics are recommended in all cases of proven UTI ([Box 18.46](#)), but not asymptomatic bacteriuria (see below). If urine culture has been

18.43 Risk factors for urinary tract infection	
<b>Bladder outflow obstruction</b>	
• Benign prostatic enlargement	• Urethral stricture
• Prostate cancer	
<b>Anatomical abnormalities</b>	
• Vesico-ureteric reflux	• Bladder fistula
• Uterine prolapse	
<b>Neurological problems</b>	
• Multiple sclerosis	• Diabetic neuropathy
• Spina bifida	
<b>Foreign bodies</b>	
• Urethral or suprapubic catheter	• Nephrostomy tube
• Ureteric stent	• Urolithiasis
<b>Loss of host defences</b>	
• Atrophic urethritis and vaginitis in post-menopausal women	

18.44 Investigation of patients with urinary tract infection	
<b>All patients</b>	
<ul style="list-style-type: none"> <li>• Dipstick* estimation of nitrite, leucocyte esterase and glucose</li> <li>• Microscopy/cytometry of urine for white blood cells, organisms</li> <li>• Urine culture</li> </ul>	
<b>Infants, children, anyone with fever or complicated infection</b>	
<ul style="list-style-type: none"> <li>• Full blood count; creatinine, eGFR</li> <li>• Blood cultures</li> </ul>	
<b>Pyelonephritis: men, children, women with recurrent infections</b>

18.45 Urinary infection in old age	
<ul style="list-style-type: none"> <li>• <b>Prevalence of asymptomatic bacteriuria:</b> rises with age. Among the most frail in institutional care it rises to 40% in women and 30% in men.</li> <li>• <b>Decision to treat:</b> treating asymptomatic bacteriuria does not improve chronic incontinence or decrease mortality or morbidity from symptomatic urinary infection. It risks adverse effects from the antibiotic and the emergence of resistant organisms. Bacteriuria should not be treated in the absence of urinary symptoms.</li> <li>• <b>Source of infection:</b> the urinary tract is the most frequent source of bacteraemia in older patients admitted to hospital. It may present with an acute confusional state.</li> <li>• <b>Incontinence:</b> new or increased incontinence is a common presentation of UTI in older women.</li> <li>• <b>Treatment:</b> post-menopausal women with acute lower urinary tract symptoms may require longer than 3 days' therapy.</li> </ul>	

### 18.46 Antibiotic regimens for urinary tract infection in adults<sup>1</sup>

Scenario	Drug	Regimen	Duration	Comment
<b>Cystitis</b>				
First choices	Trimethoprim Nitrofurantoin	200 mg twice daily 50 mg 4 times daily	3 days	7–10 days in men
Second choices <sup>1</sup>	Cefalexin Ciprofloxacin Pivmecillinam	250 mg 4 times daily 250 mg twice daily 400 mg 3 times daily		
In pregnancy	Nitrofurantoin Cefalexin	50 mg 4 times daily 250 mg 4 times daily	7 days	Avoid trimethoprim and quinolones during pregnancy; avoid nitrofurantoin at term
<b>Prophylactic therapy</b>				
First choice Second choice <sup>1</sup>	Trimethoprim Nitrofurantoin	100 mg at night 50 mg at night	Continuous	
<b>Pyelonephritis</b>				
First choices	Cefalexin Ciprofloxacin	1 g 4 times daily 500 mg twice daily	14 days 7 days	Admit to hospital if no response within 24 hrs
Second choices	Gentamicin <sup>2</sup> Cefuroxime	Adjust dose according to renal function and serum levels 750–1500 mg 3 times daily	14 days	
<b>Epididymo-orchitis</b>				
Young men Older men	Ciprofloxacin Ciprofloxacin	100 mg twice daily 500 mg twice daily	14 days	Refer young men to genito-urinary department to check for <i>Chlamydia trichomatis</i> and <i>Neisseria gonorrhoeae</i> , which requires addition of a single dose of ceftriaxone 500 mg IM
<b>Acute prostatitis</b>				
First choice Second choice	Ciprofloxacin Trimethoprim	500 mg twice daily 200 mg twice daily	14 days	

<sup>1</sup>In all cases, the choice of drug should take locally determined antibiotic resistance patterns into account. <sup>2</sup>See Hartford nomogram (Fig. 6.18). (IM = intramuscular)

performed, treatment may be started while awaiting the result. For infection of the lower urinary tract, treatment for 3 days is the norm and is less likely to induce significant alterations in bowel flora, including *Clostridioides* (formerly *Clostridium*) *difficile*, than more prolonged therapy. Trimethoprim or nitrofurantoin is the usual first choice of drug for initial treatment; however, between 10% and 40% of organisms causing UTI are resistant to trimethoprim, the lower rates being seen in community-based practice. Trimethoprim and nitrofurantoin are not recommended if eGFR is <30 mL/min/1.73 m<sup>2</sup> due to reduced efficacy/increased risk of toxicity. In addition, trimethoprim may increase serum potassium and creatinine levels and lead to artefactual reductions in eGFR, which resolve once the drug is discontinued. Quinolone antibiotics such as ciprofloxacin and norfloxacin, and cephalosporins such as cefalexin are also generally effective. Co-amoxiclav and amoxicillin are no longer recommended as blind therapy, as up to 30% of organisms are resistant. They may be used once cultures confirm that the organism is sensitive. Penicillins and cephalosporins are safe to use in pregnancy but trimethoprim, sulphonamides, quinolones and tetracyclines should be avoided.

In more severe infection, antibiotics should be continued for 7–14 days. Seriously ill patients may require intravenous therapy with gentamicin for a few days (see Box 18.46), later switching to an oral agent.

A fluid intake of at least 2 L/day is usually recommended, although this is not based on evidence and may exacerbate symptoms of dysuria.

### Persistent or recurrent UTI

If the causative organism persists on repeat culture despite treatment, or if there is reinfection with any organism after an interval, then an underlying cause is more likely to be present (see Box 18.43) and more

### 18.47 Prophylactic measures to be adopted by women with recurrent urinary infections

- Fluid intake of at least 2 L/day
- Regular complete emptying of bladder
- Good personal hygiene
- Emptying of bladder before and after sexual intercourse
- Cranberry juice/tablets and/or D-mannose may be effective

detailed investigation is justified (see Box 18.44). In women, recurrent infections are common and investigation is justified only if infections are frequent (three or more per year) or unusually severe. Recurrent UTI, particularly in the presence of an underlying cause, may result in permanent renal damage, whereas uncomplicated infections rarely (if ever) do so (see chronic reflux nephropathy below).

If an underlying cause cannot be treated, suppressive antibiotic therapy (see Box 18.46) can be used to prevent recurrence and reduce the risk of sepsis and renal damage. Urine should be cultured at regular intervals; a regimen of two or three antibiotics in sequence, rotating every 6 months, is often used in an attempt to reduce the emergence of resistant organisms. Other simple measures may help to prevent recurrence (Box 18.47). Trimethoprim or nitrofurantoin is recommended for prophylaxis. Alternative antibiotics include cefalexin, co-amoxiclav and ciprofloxacin, but these should be avoided if possible because of adverse effects and the generation of resistance.

### Asymptomatic bacteriuria

This is defined as more than 10<sup>5</sup> organisms/mL in the urine of apparently healthy asymptomatic patients. Approximately 1% of children under the

age of 1 year, 1% of schoolgirls, 0.03% of schoolboys and men, 3% of non-pregnant adult women and 5% of pregnant women have asymptomatic bacteriuria. It is increasingly common in those aged over 65. There is no evidence that this condition causes renal scarring in adults who are not pregnant and have a normal urinary tract, and, in general, treatment is not indicated. Up to 30% will develop symptomatic infection within 1 year, however. Treatment is required in infants, pregnant women and those with urinary tract abnormalities.

### Catheter-related bacteriuria

In patients with a urinary catheter, bacteriuria increases the risk of Gram-negative bacteraemia fivefold. Bacteriuria is common, however, and almost universal during long-term catheterisation. Treatment is usually avoided in asymptomatic patients, as this may promote antibiotic resistance. Careful sterile insertion technique is important and the catheter should be removed as soon as it is not required.

### Acute pyelonephritis

The kidneys are infected in a minority of patients with UTI. Acute renal infection (pyelonephritis) presents as a classic triad of loin pain, fever and tenderness over the kidneys. The renal pelvis is inflamed and small abscesses are often evident in the renal parenchyma (see Fig. 18.13C).

Renal infection is almost always caused by organisms ascending from the bladder, and the bacterial profile is the same as for lower urinary tract infection (see above). Rarely, bacteraemia may give rise to renal or perinephric abscesses, most commonly due to staphylococci. Predisposing factors may facilitate infection, such as cysts or renal scarring.

Rarely, acute pyelonephritis is associated with papillary necrosis. Fragments of renal papillary tissue are passed per urethra and can be identified histologically. They may cause ureteric obstruction and, if this occurs bilaterally or in a single kidney, it may lead to AKI. Predisposing factors include diabetes mellitus, chronic urinary obstruction, analgesic nephropathy and sickle-cell disease. A necrotising form of pyelonephritis with gas formation, emphysematous pyelonephritis, is occasionally seen in patients with diabetes mellitus. Xanthogranulomatous pyelonephritis is a chronic infection that can resemble renal cell cancer. It is usually associated with obstruction, is characterised by accumulation of foamy macrophages and generally requires nephrectomy. Infection of cysts in polycystic kidney disease (p. 579) requires prolonged antibiotic treatment.

Appropriate investigations are shown in Box 18.44 and management is described above and in Box 18.46. Intravenous rehydration may be needed in severe cases. If complicated infection is suspected or response to treatment is not prompt, urine should be re-cultured and renal tract ultrasound performed to exclude urinary tract obstruction or a perinephric collection. If obstruction is present, drainage by a percutaneous nephrostomy or ureteric stent should be considered and the underlying cause treated.

### Tuberculosis

Tuberculosis of the kidney and renal tract is secondary to tuberculosis elsewhere and is the result of blood-borne infection. Initially, lesions develop in the renal cortex; these may ulcerate into the renal pelvis and involve the ureters, bladder, epididymis, seminal vesicles and prostate. Calcification in the kidney and stricture formation in the ureter are typical.

Clinical features may include symptoms of bladder involvement (frequency, dysuria); haematuria (sometimes macroscopic); malaise, fever, night sweats, lassitude and weight loss; loin pain; associated genital disease; and chronic renal failure as a result of urinary tract obstruction or destruction of kidney tissue.

Neutrophils are present in the urine but routine urine culture may be negative (sterile pyuria). Special techniques of microscopy and culture may be required to identify tubercle bacilli and are most usefully performed on early morning urine specimens. Bladder involvement should be assessed by cystoscopy. Radiology of the urinary tract and a chest X-ray to look for pulmonary tuberculosis are mandatory. Anti-tuberculous chemotherapy follows standard regimens (see Box 17.52). Surgery to relieve urinary tract obstruction or to remove a very severely infected kidney may be required.

### Urolithiasis

Renal stone disease is common, affecting people of all countries and ethnic groups. In the UK, the prevalence is about 1.2%, with a lifetime risk of developing a renal stone by age 60–70 of approximately 7% in men. In some regions, the risk is higher, most notably in Saudi Arabia, where the lifetime risk of developing a renal stone in men aged 60–70 is just over 20%.

#### Pathophysiology

Urinary calculi consist of aggregates of crystals, usually containing calcium or phosphate in combination with small amounts of proteins and glycoproteins. The most common types are summarised in Box 18.48. A number of risk factors have been identified for renal stone formation (Box 18.49), however in developed countries most calculi occur in healthy young men, in whom investigations reveal no clear predisposing cause. Renal stones vary greatly in size, from sand-like particles anywhere in the urinary tract to large, round stones in the bladder. In developing countries, bladder stones are common, particularly in children, whereas in developed countries, renal stones are more common. Staghorn calculi fill the whole renal pelvis and branch into the calyces (Fig. 18.28); they are usually associated with infection and composed largely of struvite. Deposits of calcium may be present throughout the renal parenchyma, giving rise to fine calcification within it (nephrocalcinosis), especially in patients with renal tubular acidosis, hyperparathyroidism, vitamin D intoxication and healed renal tuberculosis. Cortical nephrocalcinosis may occur in areas of cortical necrosis, typically after AKI in pregnancy or other severe AKI.

#### Clinical features

The clinical presentation is highly variable. Many patients with renal stone disease are asymptomatic, whereas others present with pain, haematuria, UTI or urinary tract obstruction. A common presentation is with acute loin pain together with haematuria: a symptom complex termed renal or ureteric colic. This is most commonly caused by ureteric obstruction by a calculus but the same symptoms can occur in association with a sloughed renal papilla, tumour or blood clot. The patient is suddenly aware of pain in the loin, which radiates round the flank to the groin and often into the testis or labium, in the sensory distribution of the first lumbar nerve. The pain steadily increases in intensity to reach a peak in a few minutes. The patient is restless and generally tries unsuccessfully to obtain relief by changing position or pacing the room. There is pallor, sweating and often vomiting.

#### 18.48 Composition of renal stones

Composition	Percentage
Calcium oxalate <sup>1</sup>	60%
Calcium phosphate	15%
Uric acid	10%
Magnesium ammonium phosphate (struvite) <sup>2</sup>	15%
Cystine and others	1%

<sup>1</sup>Stones often contain small amounts of calcium phosphate. <sup>2</sup>Associated with urine infection.

## 18.49 Predisposing factors for kidney stones

### General factors

- Early onset of urolithiasis (especially children and adolescents)
- Familial stone formation
- Uric acid and urate-containing stones
- Infection stones

### Diseases associated with stone formation

- Hyperparathyroidism
- Metabolic syndrome
- Nephrocalcinosis
- Ileal disease or resection (increases oxalate absorption and urinary excretion)
- Polycystic kidney disease (PKD)
- Increased levels of vitamin D
- Sarcoidosis
- Spinal cord injury, neurogenic bladder

### Environmental and dietary causes

- Low urine volumes: high ambient temperatures, low fluid intake
- Chronic lead and cadmium exposure

### Congenital and inherited causes

- Cystinuria (type A, B and AB)
- Renal tubular acidosis type I (distal)
- Primary hyperoxaluria
- Xanthinuria
- Lesch–Nyhan syndrome
- Cystic fibrosis

### Anatomical abnormalities associated with stone formation

- Medullary sponge kidney
- Pelvi-ureteric junction obstruction
- Calyceal diverticulum
- Ureteric stricture
- Ureteric reflux
- Horseshoe kidney
- Ureterocele

From EAU guidelines 2019. <https://uroweb.org/guideline/urolithiasis/>.

**Fig. 18.28** Non-contrast computed tomogram of the kidneys, ureters and bladder (CTKUB). Coronal view showing a staghorn calculus in the left kidney. Courtesy of Dr I. Mendichovszky, University of Cambridge.

Frequency, dysuria and haematuria may occur. The intense pain usually subsides within 2 hours but may continue unabated for hours or days. It is usually constant during attacks, although slight fluctuations in severity may be seen. Subsequent to an attack of renal colic, intermittent dull pain in the loin or back may persist for several hours.

### Investigations

Patients with symptoms of renal colic should be investigated to determine whether or not a stone is present, to identify its location and to assess whether it is causing obstruction. About 90% of stones contain calcium and these can be visualised on plain abdominal X-ray (radio-opaque stones) but non-contrast CTKUB (see Fig. 18.28) is the gold standard for diagnosing a stone within the kidney or ureter, as 99% of stones are visible using this method. Ultrasound can show stones within the kidney and dilatation of the renal pelvis and ureter if the stone is obstructing urine flow; it is useful in unstable patients or young women, in whom exposure to ionising radiation is particularly undesirable.

A minimum set of investigations (Box 18.50) should be performed in patients with a first renal stone. The yield of more detailed investigation is low, and hence is usually reserved for those at high risk for further stone formation (see Box 18.50). Chemical analysis of stones is often helpful in defining the underlying cause. Since most stones pass spontaneously through the urinary tract, ideally the urine should be sieved for a few days after an episode of colic in order to collect the calculus for analysis.

### Management

The immediate treatment of renal colic is with analgesia and antiemetics. Renal colic is often unbearably painful and demands powerful analgesia; a non-steroidal anti-inflammatory drug (NSAID), e.g. diclofenac, given by any route is first-line treatment and is often very effective. Intravenous paracetamol should be given if NSAIDs are contraindicated or are not giving sufficient pain relief. An opioid should then be considered, e.g. morphine (10–20 mg) or pethidine (100 mg) intramuscularly.

## 18.50 Investigations for renal stones

Sample	Test	First stone	High-risk stone formers
Stone	Chemical composition <sup>1</sup>	✓	✓

	Amino acids		✓
24-hr urine	Urea		✓
	Creatinine clearance		✓
	Sodium		✓
	Calcium		✓
	Oxalate		✓
	Uric acid		✓

<sup>1</sup>The most valuable test if a stone can be obtained. <sup>2</sup>Only if serum calcium or urinary calcium excretion is high.

Patients with renal or ureteric stones are at high risk of infection; if surgery is contemplated, the patient should be covered with appropriate antibiotics. Urgent drainage of the affected collecting system with a ureteric stent or percutaneous nephrostomy is required if infection occurs in the stagnant urine proximal to the stone (pyonephrosis), and in patients with a solitary kidney who develop anuria in association with a stone in the ureter.

Asymptomatic stones less than 5 mm in diameter can be observed as they are not likely to affect quality of life and up to 90% may pass spontaneously without intervention. Conversely, only 10% of stones >6 mm in diameter pass spontaneously through the urinary tract and hence these may need an intervention. Stones can be fragmented by extracorporeal shock wave lithotripsy (ESWL), in which shock waves generated outside the body are focused on the stone, breaking it into small pieces that can pass easily down the ureter (Fig. 18.29). Surgical options are ureteroscopy and stone fragmentation, usually with a laser, or percutaneous nephrolithotomy (PCNL) and fragmentation with an ultrasonic disaggregator. The recommended treatment depends on stone size, location and patient characteristics. Figure 18.29 details options by stone location.

Measures to prevent further stone formation are guided by the investigations in Box 18.50. Some general principles apply to almost every patient with calcium-containing stones (Box 18.51), while other measures apply to specific stone types. Urate stones can be prevented by allopurinol but its role in patients with calcium stones and high urate excretion is uncertain. Stones formed in cystinuria can be reduced by penicillamine therapy. It may also be helpful to attempt to alkalinise the urine with sodium bicarbonate, as a high pH discourages urate and cystine stone formation.

## Diseases of the collecting system and ureters

### Congenital abnormalities

Various congenital anomalies of the kidney and urinary tract (often abbreviated as CAKUT) can occur (Fig. 18.30); they affect more than 10% of

infants. If not immediately lethal, they can lead to complications in later life, including obstructive nephropathy and CKD.

### Single kidneys

About 1 in 500 infants is born with only one kidney. In isolation this is usually compatible with normal life, although it may be associated with other developmental abnormalities.

### Medullary sponge kidney disease

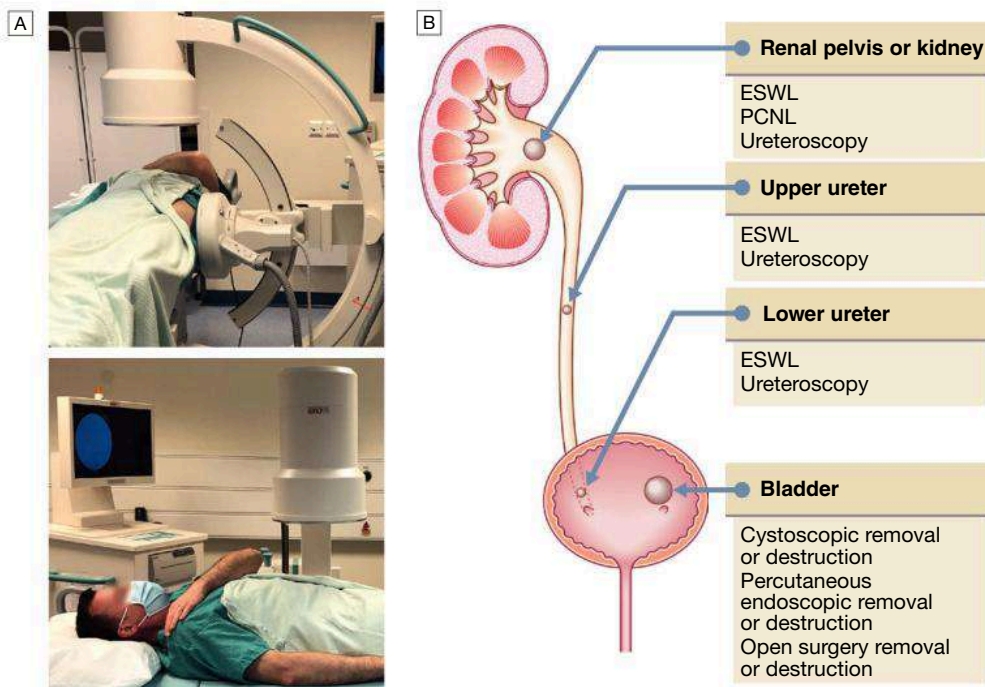

Medullary sponge kidney is a congenital disorder characterised by malformation of the papillary collecting ducts in the pericalyceal region of the renal pyramids. This leads to the formation of microscopic and large medullary cysts. Patients often present as adults with renal stones but the renal function usually remains adequate. The diagnosis is made by ultrasound, CT or intravenous urography, where contrast medium is seen to fill dilated or cystic tubules, which are sometimes calcified.

### Ureterocele

A ureterocele occurs behind a pin-hole ureteric orifice when the intramural part of the ureter dilates and bulges into the bladder. It can become very large and cause lower urinary tract obstruction. Incision of the pin-hole opening relieves the obstruction.

### Ectopic ureters and duplex kidneys

Ectopic ureters occur with congenital duplication of one or both kidneys (duplex kidneys). Developmentally, the ureter has two main branches and, if this arrangement persists, the two ureters of the duplex kidneys may drain separately into the bladder. The lower pole moiety enters the bladder superiorly and laterally, while the upper pole moiety enters the bladder inferomedially to the lower pole moiety ureter or, more rarely, enters the vagina or seminal vesicle. The lower pole moiety has an ineffective valve mechanism, so that urine passes up the ureter on voiding (vesico-ureteric reflux, see below), whereas the upper pole moiety is often associated with a ureterocele.

**Fig. 18.29** Options for removal of urinary stones. **A** A patient undergoing extracorporeal shock wave lithotripsy (ESWL). **B** The procedures that are used for removal of stones in the urinary tract, shown in relation to the site of the stone. **18.51 Measures to prevent calcium stone formation****Diet****Fluid**

- At least 2L output per day (intake 3–4L): check with 24-hr urine collections
- Intake distributed throughout the day (especially before bed)
- Add fresh lemon juice to drinking water (high in citrate, which may prevent calcium binding to other stone components and thus prevents stone formation)
- Avoid carbonated drinks

**Sodium**

- Restrict intake

**Protein**

- Moderate, not high

**Calcium**

- Maintain normal calcium intake (calcium forms an insoluble salt with dietary oxalate, lowering oxalate absorption and excretion)
- Avoid calcium supplements separate from meals (increase calcium excretion without reducing oxalate excretion)

**Oxalate**

- Avoid foods that are rich in oxalate (spinach, rhubarb)

**Drugs****Potassium citrate**

- Can reduce the recurrence of calcium oxalate and calcium oxalate/calcium phosphate stones in adults

**Thiazide diuretics**

- Reduce calcium excretion
- Valuable in recurrent stone formers and hypercalcaemia

**Allopurinol**

- If urate excretion high (unproven except for urate stones)

**Avoid**

- Vitamin D supplements (increase calcium absorption and excretion)
- Vitamin C supplementation (increases oxalate excretion)

**Megaureter**

A megaureter is a ureter dilated to more than 5mm in diameter. It may be obstructed or non-obstructed and refluxing or non-refluxing. Some 50% of cases are asymptomatic but patients may present with pain, haematuria or infection. Radiographic and pressure/flow studies may be needed to determine whether there is obstruction to urine flow. Patients with symptoms or reduced renal function are treated. Ideally, treatment is expectant with antibiotic prophylaxis. Surgery (narrowing of the ureter and/or reimplantation) may, however, be needed for recurrent symptoms, reduction of more than 10% in renal function or complications (i.e. stones).

**Pelvi-ureteric junction obstruction**

Pelvi-ureteric junction obstruction (PUJO) causes idiopathic hydronephrosis and results from a functional obstruction at the junction of the ureter and renal pelvis. The abnormality is likely to be congenital and is often bilateral. It can be seen in very young children but gross hydronephrosis may present at any age. The common presentation is ill-defined renal pain or ache, exacerbated by drinking large volumes of liquid (Dietl's crisis). Rarely, it is asymptomatic. The diagnosis is often suspected after ultrasound or CT scan, and can be confirmed with a <sup>99m</sup>Tc-MAG3 renogram followed by diuretic. In a PUJO, the MAG3 renogram shows a pathognomonic 'rising curve' as the radioisotope accumulates in the renal pelvis and still does not drain following the diuretic injection. Treatment is surgical excision of the pelvi-ureteric junction and reanastomosis (pyeloplasty), which can now be performed laparoscopically or

**Fig. 18.30** Congenital abnormalities of the urinary tract. (PUJ = pelvi-ureteric junction)

by robot-assisted surgery. Less invasive alternatives are also possible, including balloon dilatation and endoscopic pyelotomy, but are generally less effective.

**Reflux nephropathy**

This condition, which was previously known as chronic pyelonephritis, is a specific type of chronic interstitial nephritis associated with vesico-ureteric reflux (VUR) in early life and with the appearance of scars in the kidney, as demonstrated by various imaging techniques. About 12% of patients in Europe requiring treatment for ESRD may have this disorder but diagnostic criteria are imprecise.

**Pathophysiology**

Reflux nephropathy is thought to be due to chronic reflux of urine from the bladder into the ureters, in association with recurrent UTI in childhood. It was previously assumed that ascending infection was necessary for progressive renal damage in patients with VUR but there is evidence to suggest that renal scars can occur, even in the absence of infection. Furthermore, studies have found that efforts to surgically correct VUR or use prophylactic antibiotics to prevent the UTIs are ineffective in halting progression of the disease.

Susceptibility to VUR has a genetic component and may be associated with renal dysplasia and other congenital abnormalities of the urinary tract. It can be connected with outflow obstruction, usually caused by urethral valves, but usually occurs with an apparently normal bladder.

**Clinical features**

Usually, the renal scarring and dilatation are asymptomatic and the patient may present at any age with hypertension (sometimes severe), proteinuria or features of CKD. There may be no history of overt UTI. However, symptoms arising from the urinary tract may be present and include frequency of micturition, dysuria and aching lumbar pain. VUR may occur in children but diminishes as the child grows, and usually has disappeared by adulthood. Urinalysis often shows the presence of leucocytes and moderate proteinuria (usually <1 g/24 hrs) but these are not always present. The risk of renal stone formation is increased. A number of women first present with hypertension and/or proteinuria in pregnancy. Children and adults with small or unilateral renal scars have a

good prognosis, provided renal growth is normal. With significant unilateral scars there is usually compensatory hypertrophy of the contralateral kidney. In patients with more severe bilateral disease, prognosis is related to the severity of renal dysfunction, hypertension and proteinuria. If the serum creatinine is normal and hypertension and proteinuria are absent, then the long-term prognosis is usually good.

### Investigations

Renal scarring can be detected by ultrasound but it has poor sensitivity and is only capable of detecting major defects and excluding significant obstruction. Radionuclide DMSA scans are more sensitive (see Fig. 18.6), and serial imaging by MRI or CT may be useful in assessing progression. Abnormalities may be unilateral or bilateral and of any grade of severity. Gross scarring of the kidneys, commonly at the poles, is seen, with reduced kidney size and narrowing of the cortex and medulla. Renal scars may be juxtaposed to dilated calyces. In patients who develop heavy proteinuria and hypertension, renal biopsies show glomerulomegaly and focal glomerulosclerosis, probably as a secondary response to reduced nephron numbers. Radionuclide techniques can also be used to demonstrate VUR as a non-invasive alternative to micturating cystourethrography (MCUG; the bladder is filled with contrast media through a urinary catheter and images are taken during and after micturition; Fig. 18.31). As surgical intervention for VUR has declined in popularity (see below), however, this type of imaging is used less often.

### Management

Infection, if present, should be treated; if recurrent, it should be prevented with prophylactic therapy, as described above in this chapter for UTI, although as mentioned above this does not prevent CKD. If recurrent pyelonephritis occurs in an abnormal kidney with minimal function, nephrectomy may be indicated. Occasionally, hypertension is cured by the removal of a diseased kidney when the disease is predominantly or entirely unilateral.

As most childhood reflux tends to disappear spontaneously and trials have shown small or no benefits from anti-reflux surgery, such intervention is now less common. Severe reflux may be managed by ureteric reimplantation or subtrigonal injection of Teflon or polysaccharide (STING) beneath the ureteric orifice.

## Retroperitoneal fibrosis

Fibrosis of the retroperitoneal connective tissues may encircle and compress the ureter(s), causing obstruction. The fibrosis is most commonly idiopathic but can represent a reaction to infection, radiation or aortic aneurysm, or be caused by metastatic cancer. It is recognised as part of the spectrum of disorders associated with elevated IgG4 levels. Rarely, it can be associated with inflammatory bowel disease. Patients usually present with ill-defined symptoms of ureteric obstruction. Typically, there is an acute phase response (high CRP and ESR, and polyclonal hypergammaglobulinaemia). Imaging with CT or IVU shows ureteric obstruction with medial deviation of the ureters. Idiopathic retroperitoneal fibrosis may respond well to glucocorticoids (with a reduction in inflammatory marker levels) but ureteric stenting is often necessary to relieve obstruction and preserve renal function. Failure to improve indicates the need for surgery (ureterolysis), both to relieve obstruction and to exclude malignancy.

## Tumours of the kidney and urinary tract

Several malignant tumours can affect the kidney and urinary tract, including renal cell cancer, upper urinary tract urothelial cancers, bladder cancer, prostate cancer and cancers of the testis and penis. The urogenital tract can also be affected by benign tumours and secondary tumour deposits, which can cause obstructive uropathy. Renal cell cancer and bladder cancer are described here, while prostate cancer and testicular tumours are covered later in this chapter.

## Renal cell cancer

Renal cell cancer (RCC) is by far the most common malignant tumour of the kidney in adults, making up 2.5% of all adult cancers, with a prevalence of 16 cases per 100 000 population. It is twice as common in males. The peak incidence is between 65 and 75 years of age and it is uncommon before 40. RCCs of differing histological subtype arise from different parts of the nephron or collecting duct. Haemorrhage and necrosis give the cut surface a characteristic mixed golden-yellow and red appearance (Fig. 18.32B). Microscopically, clear cell RCCs are the most common histological subtype (85%), with papillary, chromophobe and collecting duct tumours comprising the majority of the remainder. In RCC, there is potentially spread along the renal vein and the inferior vena cava. Direct invasion of perinephric tissues is common. Lymphatic spread occurs to para-aortic nodes, while distant metastases (which may be solitary) most commonly develop in the lungs, bone and brain.

### Clinical features

In 50% of patients, asymptomatic renal tumours are identified as an incidental finding during imaging investigations carried out for other reasons. Among symptomatic patients, about 60% present with haematuria, 40% with loin pain and a few with a palpable mass. About 10% present with a triad of pain, haematuria and a mass; this usually represents advanced disease. RCC is one of the great mimics of medicine as patients may present with a remarkable range of systemic effects, including fever, raised ESR, polycythaemia, disorders of coagulation, hypercalcaemia, and abnormalities of plasma proteins and liver function tests. The patient may present with pyrexia of unknown origin (PUO) or, rarely, with neuropathy. Some of these systemic effects are caused by secretion of products by the tumour, such as renin, erythropoietin, parathyroid hormone-related protein (PTHrP) and gonadotrophins. The effects disappear when the tumour is removed but may reappear when metastases develop.

### Investigations

Ultrasound is often the initial investigation and allows differentiation between solid tumour and simple renal cysts. If the results are suggestive of a tumour, contrast-enhanced CT of the abdomen and chest should be

**Fig. 18.31 Vesico-ureteric reflux (grade IV) shown by micturating cystogram.** The bladder has been filled with contrast medium through a urinary catheter. After micturition, there was gross vesico-ureteric reflux into widely distended ureters and pelvicalyceal systems. Courtesy of Dr A.P. Bayliss and Dr P. Thorpe, Aberdeen Royal Infirmary.

**Fig. 18.32 Renal cell cancer.** **A** In this CT, the right kidney is expanded by a low-density tumour, which fails to take up contrast material. Tumour is shown extending into the renal vein and inferior vena cava (arrow). **B** Pathology specimen showing typical necrosis of a renal cell cancer. (A, B) Courtesy of Dr A.P. Bayliss and Dr P. Thorpe, Aberdeen Royal Infirmary.

performed for staging (Fig. 18.32A). For tumours with no evidence of metastatic spread and when the nature of the lesion is uncertain, ultrasound or CT-guided biopsy may be used to avoid nephrectomy for benign disease.

### Management

Radical nephrectomy that includes the perirenal fascial envelope is the treatment of choice. Nephrectomy is commonly performed laparoscopically, with equivalent outcomes to open surgery. Partial nephrectomy, which may be carried out by open but increasingly by minimally invasive robot-assisted or laparoscopic surgery, is recommended, where possible, for tumours of 7 cm or less, as there is a lower incidence of long-term cardiac- and renal-related morbidity. Patients at high operative risk who have small tumours may also be treated percutaneously by cryotherapy or radiofrequency ablation. Active surveillance with serial imaging in those with renal masses <4 cm is a management option that should also be discussed with patients. Surgery may also play a role in the treatment of solitary metastases, since these can remain single for long periods and excision may be curative.

RCC is resistant to most chemotherapeutic agents. Tyrosine kinase inhibitors (TKIs) such as sunitinib and pazopanib are the mainstay of treatment. Recently, T-cell checkpoint inhibitors such as PD-L1, PD-1 and CTLA-4 inhibitors have been licensed for use as single agents or in combination (PD-L1/PD-1 with CTLA-4 inhibitor or TKI) as first-line treatment options for metastatic RCC.

In previous years, patients who presented with distant metastases were treated with cytoreductive nephrectomy, in which nephrectomy was coupled with systemic cytokine treatment, since this was shown to improve survival as compared with either treatment in isolation. The benefit of cytoreductive nephrectomy is less clear with TKIs and hence is used sparingly; the benefit is unknown for T-cell checkpoint inhibitors.

Current survival data indicate that, if RCC is confined to the kidney, 5-year survival is 75%, but this falls to 12% when there are distant metastases.

### Urothelial tumours

Tumours arising from the transitional epithelium of the renal tract can affect the renal pelvis, ureter, bladder or urethra. They are rare under the age of 40, affect men 3–4 times more often than women, and account for about 3% of all malignant tumours. The bladder is by far the most frequently affected site. Although almost all tumours are urothelial cell cancer (previously known as transitional cell cancers), squamous cell cancer may occur in urothelium that has undergone metaplasia, usually following chronic inflammation due to stones or schistosomiasis. The

appearance of a urothelial cell cancer ranges from a delicate papillary structure with a relatively good prognosis to a solid ulcerating mass in more aggressive disease.

### Pathophysiology

Risk factors include cigarette smoking and exposure to industrial carcinogens such as aromatic amines, aniline dyes and aldehydes.

### Clinical features

More than 80% of patients present with painless, visible haematuria. It should be assumed that such bleeding is from a tumour until proven otherwise (p. 568). Tumours of the ureter or bladder may also cause symptoms of obstruction, depending on the site of involvement, and tumours of the bladder present with dysuria or storage symptoms. Physical examination is usually unremarkable, except in patients with very advanced disease, when bimanual examination may reveal a palpable mass.

### Investigations

Cystoscopy (usually flexible cystoscopy under a local anaesthetic) is used to evaluate the bladder in cases of haematuria or suspected bladder cancer. Imaging of the upper urinary tract (CT urogram is the gold standard but IVU combined with renal ultrasound is also acceptable) is also important to rule out abnormalities of the kidney, ureters and renal pelvis in patients with haematuria. If a suspicious defect is seen on CT urography or IVU in the ureter or renal pelvis, a retrograde ureteropyelogram, ureteroscopy and biopsy are required. If evidence of a solid invasive urothelial tumour is found, CT of the abdomen, pelvis and chest should be performed to define tumour stage.

### Management

Most bladder tumours are low-grade, non-muscle-invasive lesions that can be successfully treated endoscopically by transurethral resection of the tumour. Intravesical chemotherapy with mitomycin C is usually administered as a one-off treatment post resection to prevent tumour recurrence, or may be given as a prolonged course to treat multiple low-grade bladder tumours. Patients with carcinoma in situ have a high risk of progression to invasive cancer. These patients often respond well to intravesical bacille Calmette–Guérin (BCG) treatment but more radical treatment by cystectomy may be required if this is unsuccessful. Following initial treatment and endoscopic clearance of bladder tumours, regular check cystoscopies are required to look for evidence of recurrence. Patients with recurrences of non-muscle-invasive disease can usually be treated by further resection and diathermy, but if this is unsuccessful, a cystectomy may be needed.

The management of muscle-invasive bladder cancer involves radical cystectomy with urinary diversion into an incontinent ileal conduit or a continent catheterisable bowel pouch; the latter is usually reserved for patients under the age of 70 years.

The prognosis of bladder cancer depends on tumour stage and grade. In patients where the cancer has not invaded the bladder muscle at diagnosis, 5% of low-grade tumours and 50% of high-grade tumours progress to develop invasion of the bladder muscle. Overall, the 5-year survival for patients with muscle-invasive bladder cancer of either grade is 50%–70%.

Urothelial cell cancer of the renal pelvis and ureter is usually treated by laparoscopic or open nephro-ureterectomy, but if the tumour is solitary and low-grade, it may be treated endoscopically.

## Urinary incontinence

Urinary incontinence is defined as any involuntary leakage of urine. It may occur in patients with a normal urinary tract, as the result of dementia or poor mobility, or transiently during an acute illness or hospitalisation, especially in older people (Box 18.52). The prevalence of any form of incontinence in all females is 25%–45%, with a concomitant socio-economic burden. Childbirth, hysterectomy, obesity, recurrent UTI, smoking, caffeine and constipation are risk factors for incontinence.

### Pathophysiology

In the normal micturition cycle, urine accumulates in the bladder during the storage phase, the sphincter tone gradually increases, but there are no significant changes in vesical pressure, detrusor pressure or intra-abdominal pressure. During voiding, intravesical pressure increases as a result of detrusor contraction and the sphincter relaxes, allowing urine to flow from the bladder until it is empty. Clinical disorders associated with incontinence are connected with various abnormalities in this cycle and these are discussed in more detail below.

### Stress incontinence

This occurs because passive bladder pressure exceeds the urethral pressure, due either to poor pelvic floor support or a weak urethral sphincter. Usually there is an element of both these factors. Stress incontinence is very common in women and seen most frequently following childbirth. It is rare in men and usually follows surgery to the prostate. The presentation is with incontinence during coughing, sneezing or exertion. In women, perineal inspection may reveal leakage of urine when the patient coughs.

### Urge incontinence

This usually occurs because of detrusor over-activity, which produces an increased bladder pressure that overcomes the urethral sphincter. Urgency with or without incontinence may also be driven by a hypersensitive bladder resulting from UTI or a bladder stone. Detrusor over-activity is usually idiopathic, other than in patients with neurological conditions such as spina bifida or multiple sclerosis, in whom it is neurogenic. The incidence of urge incontinence increases with age, occurring in 10%–15% of the population aged over 65 years and in approximately 50% of patients requiring nursing home care. It is more common in women, but is also seen in men with lower urinary tract obstruction and most often remits after the obstruction is relieved.

### Continual incontinence

This is suggestive of a fistula, usually between the bladder and vagina (vesicovaginal), or the ureter and vagina (ureterovaginal). It is most common following gynaecological surgery but is also seen in patients with gynaecological malignancy or post radiotherapy. In parts of the world where obstetric services are scarce, prolonged obstructed labour can be a common cause of vesicovaginal fistulae. Continual incontinence may also be seen in infants with congenital ectopic ureters. Occasionally, stress incontinence is so severe that the patient leaks continuously.

### Overflow incontinence

This occurs when the bladder becomes chronically over-distended and may lead to AKI (high-pressure chronic urinary retention). It is most commonly seen in men with benign prostatic enlargement or bladder neck obstruction (see below) but may arise in either sex as a result of failure of the detrusor muscle (atonic bladder). The latter may be idiopathic but more commonly is the result of damage to the pelvic nerves, either from surgery (commonly, hysterectomy or rectal excision), trauma or infection, or from compression of the cauda equina by disc prolapse, trauma or tumour. Incontinence due to prostatic enlargement can be regarded as a type of overflow incontinence.

### Post-micturition dribble

This is very common in men, even in the relatively young. It is due to a small amount of urine becoming trapped in the U-bend of the bulbar urethra, which leaks out when the patient moves. Post-micturition dribble is more pronounced if associated with a urethral diverticulum or urethral stricture. It may occur in women with a urethral diverticulum and may mimic stress incontinence.

### Clinical assessment

Patients should be encouraged to keep a voiding diary, including the measured volume voided, frequency of voiding, a note of incontinence pad usage, precipitating factors and associated features, such as urgency, since this can be of diagnostic value. Structured questionnaires may help objectively quantify symptoms. The patient should be assessed for evidence of cognitive impairment and impaired mobility. A neurological assessment should be performed to detect disorders such as multiple sclerosis that may affect the nervous supply of the bladder, and the lumbar spine should be inspected for features of spina bifida occulta. Perineal sensation and anal sphincter tone should be assessed. Rectal examination is needed to assess the prostate in men and to exclude faecal impaction as a cause of incontinence. Genital examination should be done to identify phimosis or paraphimosis in men, and vaginal mucosal atrophy, cystoceles or rectoceles in women.

### Investigations

Urinalysis and culture should be performed in all patients. Ultrasound examination can be helpful in identifying patients with overflow incontinence who have incomplete bladder emptying, as it may reveal a significant amount of fluid in the bladder (>100 mL) post-micturition. Urine flow rates and full urodynamic assessment by cystometry may be required to diagnose the type of incontinence and are indicated in selected cases when the diagnosis is unclear on clinical grounds. A CT scan and cystoscopy should be performed in patients with continual incontinence who are suspected of having a fistula. Imaging with MRI is indicated when a urethral diverticulum is suspected.

### Management

Weight reduction in obese patients will aid resolution of incontinence. Women with stress incontinence respond well to physiotherapy. The

#### 18.52 Incontinence in old age

- **Prevalence:** urinary incontinence affects 15% of women and 10% of men aged over 65 years.
- **Cause:** incontinence may be transient and due to delirium, urinary infection, medication (such as diuretics), faecal impaction or restricted mobility, and these should be treated before embarking on further specific investigation. Routine urinalysis is rarely helpful and can be misleading.
- **Detrusor over-activity:** established incontinence in old age is most commonly due to detrusor over-activity, which may be caused by damage to central inhibitory centres or local detrusor muscle abnormalities.
- **Catheterisation:** poor manual dexterity or cognitive impairment may necessitate the help of a carer to assist with intermittent catheterisation.

mainstay of treatment for urge incontinence is bladder retraining, which involves teaching patients to hold more urine voluntarily in their bladder, assisted by anticholinergic medication.

Surgery may be required in patients who have severe daytime incontinence despite conservative treatment. In neurologically intact patients, stress urinary incontinence in males is treated surgically by artificial urinary sphincter and in females by returning the urethra and bladder neck to their normal position with a pubovaginal sling or colposuspension. For urge incontinence intravesical injection of botulinum neurotoxin type A has excellent results. Further surgical options are sacral nerve stimulation, detrusor myectomy or bladder augmentation.

The treatment of incontinence secondary to fistula formation is surgical. Patients with overflow incontinence due to bladder obstruction should be treated surgically or with long-term catheterisation (intermittent or continuous). Incontinence secondary to neurological diseases can be managed by intermittent self-catheterisation.

## Prostate disease

### Prostatitis

This results from inflammation of the prostate gland. Acute or chronic bacterial prostatitis can be caused by infection with the same bacteria that are associated with UTI (p. 599) but chronic prostatitis can also be 'non-bacterial', in which case no organism can be cultured from the urine. This is also known as chronic pelvic pain syndrome. Clinical features of prostatitis include frequency, dysuria, painful ejaculation, perineal or groin pain, difficulty passing urine and, in acute disease, considerable systemic disturbance. The prostate is enlarged and tender. Bacterial prostatitis is confirmed by a positive culture from urine or from urethral discharge obtained after prostatic massage, and the treatment of choice is a quinolone antibiotic. A 6-week course of antibiotics is required (see Box 18.46). Treatment of chronic pelvic pain syndrome is challenging but some patients respond to a combination of  $\alpha$ -adrenoceptor antagonists ( $\alpha$ -blockers), NSAIDs and amitriptyline.

### Benign prostatic enlargement

Benign prostatic enlargement (BPE) is extremely common. It has been estimated that about half of all men aged 80 years and over will have lower urinary tract symptoms associated with bladder outlet obstruction (BOO) due to BPE. Benign prostatic hyperplasia (BPH) is the histological abnormality that underlies BPE.

#### Pathophysiology

The prostate gland increases in volume by 2.4 cm<sup>3</sup> per year on average from 40 years of age. The process begins in the periurethral (transitional) zone and involves both glandular and stromal tissue to a variable degree. The cause is unknown, although BPE does not occur in patients with hypogonadism, suggesting that hormonal factors may be important.

#### Clinical features

The primary symptoms of BPE arise because of difficulty in voiding urine due to obstruction of the urethra by the prostate; these voiding symptoms consist of hesitancy, poor urinary flow and a sensation of incomplete emptying. Other storage symptoms include urinary frequency, urgency of micturition and urge incontinence, although these are not specific to BPE. Some patients present suddenly with acute urinary retention, when they are unable to micturate and develop a painful, distended bladder. This is often precipitated by excessive alcohol intake, constipation or prostatic infection. Severity of symptoms can be ascertained by using the International Prostate Symptom Score (IPSS) questionnaire (Box 18.53), which serves as a valuable starting point for assessment of the patient. Once a baseline value is established, any improvement or deterioration may be monitored on subsequent visits. The IPSS is combined with a quality-of-life score, in which patients are asked the following question:

18.53 The International Prostate Symptom Score (IPSS)		
Symptom	Question	Example score
Straining	How often have you had to push or strain to begin urination?	1
Urgency	How often have you found it difficult to postpone urination?	2
Intermittency	How often have you found that you stopped and started again several times when you urinated?	1
Emptying	How often have you had a sensation of not emptying your bladder completely after you finished urinating?	3
Frequency	How often have you had to urinate again less than 2 hours after you finished urinating?	1
Weak stream	How often have you had a weak urinary stream?	2
Nocturia	How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	1
<b>Total score</b>		<b>11</b>
0 = not at all; 1 = less than one-fifth of the time; 2 = less than half the time; 3 = about half of the time; 4 = more than half of the time; 5 = almost always. A score of 0–7 indicates mild symptoms, 8–19 moderate symptoms and 20–35 severe symptoms. In the example shown, the patient had moderate symptoms.		

'If you were to spend the rest of your life with your urinary condition the way it is now, how would you feel about that?' Responses range from 0 (delighted) to 6 (terrible).

Patients may also present with chronic urinary retention. Here, the bladder slowly distends due to inadequate emptying over a long period of time. Patients with chronic retention can also develop acute retention: so-called acute-on-chronic retention. This condition is characterised by pain-free bladder distension, which may result in hydronephrosis, hydronephrosis and renal failure (high-pressure chronic retention, of which nocturnal incontinence is a pathognomonic symptom). On digital rectal examination (DRE), patients with BPE have evidence of prostatic enlargement with a smooth prostate gland. Abdominal examination may also reveal evidence of bladder enlargement in patients with urinary retention.

#### Investigations

The diagnosis of BOO secondary to BPE is a clinical one but flow rates can be accurately measured with a flow meter, post-void residual volume of urine assessed with ultrasound, and prostate volume by transrectal ultrasound scan (TRUS). Objective assessment of obstruction is possible by urodynamics and should be undertaken if symptoms are mixed, with both voiding and storage making underlying pathophysiology uncertain and/or flow test equivocal for obstruction (<150 ml voided or >10 mL/s). If symptoms or signs, such as a palpable bladder, nocturnal enuresis, recurrent UTI or a history of renal stones, are present, renal function

should be assessed; if it is abnormal, screening should be conducted for evidence of obstructive uropathy by ultrasound examination.

### Management

Patients who present with acute retention require urgent treatment and should undergo immediate catheterisation to relieve the obstruction. Those with mild to moderate symptoms can be treated by medication (Box 18.54). The first-line treatments are  $\alpha_{1A}$ -adrenoceptor blockers such as tamsulosin, which reduce the tone of smooth muscle cells in the prostate and bladder neck, thereby reducing the obstruction. The 5 $\alpha$ -reductase inhibitors finasteride and dutasteride inhibit conversion of testosterone to the nine times more potent dihydrotestosterone in the prostate and so cause the prostate to reduce in size. This class of drugs is indicated in patients with an estimated prostate size of more than 30 g or a prostate-specific antigen (PSA) level of more than 1.4 ng/mL. Patients who fail to respond to a single drug may be treated with a combination of  $\alpha$ -blockers and 5 $\alpha$ -reductase inhibitors, since this is more efficacious than either agent alone. Symptoms that are resistant to medical therapy require surgical treatment to remove some of the prostate tissue that is causing urethral obstruction. This is usually achieved by transurethral resection of the prostate (TURP) but enucleation of the prostate by holmium laser or vapourisation by potassium-titanyl-phosphate (KTP) laser (Greenlight laser) is equally effective and has potentially fewer complications. Open surgery is very rarely needed, as very large glands can be treated with holmium laser treatment.

## Prostate cancer

Prostate cancer is the most common malignancy in men in the UK, with an incidence of ~170 per 100 000 population. It is also common in northern Europe and the United States (particularly in the African American population) but is rare in China and Japan. It is uncommon in India but the incidence is increasing. Prostate cancer rarely occurs before the age of 50 and has a mean age at presentation of 70 years.

### Pathophysiology

Prostate cancers tend to arise within the peripheral zone of the prostate and almost all are adenocarcinomas. Metastatic spread to pelvic lymph nodes occurs early and metastases to bone, mainly the lumbar spine and pelvis, are common. Genetic factors are known to play an important role in pathogenesis, and multiple genetic loci have been found to predispose to the disease in genome-wide association studies. A family history of prostate cancer greatly increases a man's chances of developing the disease.

### Clinical features

Most patients either are asymptomatic or present with lower urinary tract symptoms indistinguishable from BPE. On DRE the prostate may feel nodular and stony-hard, and the median sulcus may be lost, but up to 45% of cancers are impalpable. Symptoms and signs due to metastases are much less common at the initial presentation but may include back pain, weight loss, anaemia and obstruction of the ureters.

### Investigations

Measurement of PSA levels in a peripheral blood sample, together with DRE, is the cornerstone of diagnosis. Prior to a PSA test, men should be given careful counselling about the limitations of the test: namely, a normal level does not exclude prostate cancer, while a high value does not confirm the diagnosis but will open a discussion about biopsy and possible future treatments with potential side-effects (Box 18.55). The need for radical treatment of localised prostate cancer is still not established; radical treatments have significant potential morbidity and mortality, yet early identification and treatment of prostate cancer may save lives. Current evidence suggests that population-based screening for prostate cancer with PSA is of limited value, due in part to the fact that over 700 patients would need to be screened to cure 1 man of prostate cancer. Individuals suspected of having prostate cancer, based on an elevated PSA and/or abnormal DRE,

## 18.54 Treatment for benign prostatic enlargement

### Medical

- Prostate <30 g:  $\alpha$ -blockers
- Prostate > 30 g: 5 $\alpha$ -reductase inhibitors  $\pm$   $\alpha$ -blockers

### Surgical

- Transurethral resection of the prostate (TURP)
- Laser enucleation
- Laser vapourisation
- Open prostatectomy

## 18.55 Advantages and disadvantages of prostate-specific antigen (PSA) testing in order to identify men with prostate cancer

### Advantages

- Identification of prostate cancer at a treatable stage, which otherwise may not have been identified\*

### Disadvantages

- High false-positive rate: 50%–60% of men with an elevated PSA will not have prostate cancer
- High false-negative rate: 25% of men with a normal PSA have prostate cancer
- Leads to further invasive tests (biopsy) with morbidity (e.g. sepsis or bleeding)
- May lead to diagnosis of prostate cancer, which is often over-treated by surgery or radiotherapy with associated side-effects (e.g. impotence or incontinence)
- If PSA is elevated but biopsy is normal, there is a potential need for further testing and associated anxiety

\*The advantages of identifying prostate cancer earlier than would be the case if the man developed symptomatic disease must be considered against the limitations of PSA testing.

should undergo transrectal or transperineal ultrasound-guided prostate biopsies. About 40% of patients with a serum PSA of 4.0–10 ng/mL or more will have prostate cancer on biopsy, although 25% of patients with a PSA of less than 4 ng/mL may also have prostate cancer. Occasionally, a small focus of tumour is found incidentally in patients undergoing TURP for benign hyperplasia. If the diagnosis of prostate cancer is confirmed, staging should be performed by pelvic MRI to assess the presence and extent of local involvement. An isotope bone scan should be carried out if distant metastases are suspected (rare if the PSA is below 20 ng/mL); very high levels of serum PSA (>100 ng/mL) almost always indicate distant bone metastases. Following diagnosis, serial assessment of PSA levels is useful for monitoring response to treatment and disease progression.

### Management

Tumour confined to the prostate is potentially curable by radical prostatectomy, radical radiotherapy or brachytherapy (implantation of small radioactive particles into the prostate). These options should be considered only in patients with more than 10 years' life expectancy. Patients who are found to have small-volume, low-grade disease do not appear to require specific treatment but should be followed up periodically with PSA testing, DRE and a schedule of biopsies; this is known as active surveillance. Prostate cancer, like breast cancer, is sensitive to steroid hormones; metastatic prostate cancer is treated by androgen depletion, involving either surgery (orchidectomy) or, more commonly, androgen-suppressing drugs. Androgen receptor blockers, such as bicalutamide or cyproterone acetate, may also prevent tumour cell growth. Gonadotrophin-releasing hormone (GnRH) analogues, such as goserelin, continuously occupy pituitary receptors, preventing them from responding to the GnRH pulses that normally stimulate luteinising hormone (LH) and follicle-stimulating hormone (FSH) release. This initially causes an increase in testosterone before producing a prolonged reduction, and for this reason the initial dose must be covered with an androgen receptor blocker to prevent a tumour flare.

A small proportion of patients fail to respond to endocrine treatment. A larger number respond for a year or two but then the disease progresses.

Chemotherapy with docetaxel can then be effective and provide a modest (around 3 months) survival advantage. Newer hormonal agents such as enzalutamide and abiraterone acetate also provide some survival benefit. There is also a role for initial prostate radiotherapy in those with low volume metastatic prostate cancer. Radiotherapy is useful for localised bone pain but the basis of treatment remains pain control by analgesia (p. 145). Provided that patients do not die of another cause, the 10-year survival rate of patients with tumours localised to the prostate is 95%, but if metastases are present, this falls to 10%. Life expectancy is not reduced in patients with small foci of tumour.

## Testicular tumours

Testicular tumours are uncommon, with a prevalence of 5 cases per 100 000 population. They occur mainly in young men aged between 20 and 40 years. They often secrete  $\alpha$ -fetoprotein (AFP) and  $\beta$ -human chorionic gonadotrophin ( $\beta$ -hCG), which are useful biochemical markers for both diagnosis and prognosis. Seminoma and non-seminomatous germ cell tumours (NSGCT) account for ~85% of all tumours of the testis. Leydig cell tumours are less common.

Seminomas arise from seminiferous tubules and represent a relatively low-grade malignancy. Metastases can occur through lymphatic spread, however, and typically involve the lungs.

NSGCTs arise from primitive germinal cells and tend to occur at a younger age than seminomas. They may contain cartilage, bone, muscle, fat and a variety of other tissues, and are classified according to the degree of differentiation. Well-differentiated tumours are the least aggressive; at the other extreme, trophoblastic teratoma is highly malignant. Occasionally, teratoma and seminoma occur together.

Leydig cell tumours are usually small and benign but secrete oestrogens, leading to presentation with gynaecomastia.

### Clinical features and investigations

The common presentation is incidental discovery of a painless testicular lump, although some patients complain of a testicular ache.

All suspicious scrotal lumps should be imaged by ultrasound. Serum levels of AFP and  $\beta$ -hCG are elevated in extensive disease. Oestradiol may be elevated, suppressing LH, FSH and testosterone. Accurate staging is based on CT of the lungs, liver and retroperitoneal area.

### Management and prognosis

The primary treatment is surgical inguinal orchidectomy. Subsequent adjuvant treatment depends on the histological type and stage. Adjuvant chemotherapy with carboplatin is the treatment of choice for early-stage but high-risk seminoma. NSGCTs confined to the testes may be managed conservatively, but more advanced cancers are treated with chemotherapy, usually the combination of bleomycin, etoposide and cisplatin. Follow-up is by CT and assessment of LDH, AFP and  $\beta$ -hCG. Retroperitoneal lymph node dissection is performed for residual or recurrent nodal masses.

The 5-year survival rate for patients with seminoma is 90%–95%. For NSGCT, the 5-year survival varies between 60% and 95%, depending on tumour type, stage and volume.

## Erectile dysfunction

Causes of erectile failure are shown in [Box 18.56](#). Vascular, neuropathic and psychological causes are most common. Exclusion of previously unrecognised cardiovascular disease is important in men presenting with erectile dysfunction. With the exception of diabetes mellitus, endocrine causes are relatively uncommon and are characterised by loss of libido,

### 18.56 Causes of erectile dysfunction

#### With reduced libido

- Hypogonadism
- Depression

#### With intact libido

- Psychological problems, including anxiety
- Vascular insufficiency (atheroma)
- Neuropathic causes (diabetes mellitus, alcohol excess, multiple sclerosis)
- Drugs ( $\beta$ -blockers, thiazide diuretics)

as well as erectile dysfunction. Erectile dysfunction and reduced libido occur in over 50% of men with advanced CKD or those on dialysis, and is a markedly under-diagnosed problem. It is important to discuss matters frankly with the patient, and to establish whether there are associated features of hypogonadism and if erections occur at any other time. If the patient has erections on waking, vascular and neuropathic causes are much less likely and a psychological cause should be suspected.

### Investigations

Blood should be taken for glucose, lipids, prolactin, testosterone, LH and FSH. A number of further tests are available but are rarely employed because they do not usually influence management. These include nocturnal tumescence monitoring (using a plethysmograph placed around the shaft of the penis overnight) to establish whether blood supply and nerve function are sufficient to allow erections to occur during sleep; intracavernosal injection of prostaglandin E<sub>1</sub> to test the adequacy of blood supply; and internal pudendal artery angiography.

### Management

First-line therapy is usually with oral phosphodiesterase type 5 inhibitors, such as sildenafil, which elevate cyclic guanosine monophosphate (cGMP) levels in vascular smooth muscle cells of the corpus cavernosum, causing vasodilatation and penile erection. Co-administration of these drugs with nitric oxide donors, such as glycerol trinitrate, is contraindicated because of the risk of severe hypotension. Other treatments for impotence include self-administered intracavernosal injection or urethral administration of prostaglandin E<sub>1</sub>; vacuum devices that achieve an erection maintained by a tourniquet around the base of the penis; and prosthetic implants, either of a fixed rod or an inflatable reservoir. Psychotherapy involving the patient and sexual partner may be helpful for psychological problems. Erectile dysfunction associated with peripheral neuropathy and vascular disease is difficult to treat. If hypogonadism is detected, it should be managed as described on page 670.

## Multiple Choice Questions

18.1. A previously well 5-year-old girl presents with leg and periorbital oedema and is found to have 4+ proteinuria on urine dipstick testing. Her renal function is normal. She has no family history of note. Her initial management should involve:

- A. A kidney biopsy
- B. No kidney biopsy but treat initially with corticosteroids
- C. Prophylactic antibiotics
- D. No kidney biopsy but treat initially with cyclophosphamide
- E. An ACE inhibitor

Answer: B.

This child has nephrotic syndrome so this is very likely to be Minimal Change Disease, such that a biopsy is usually not performed but treatment is commenced with corticosteroids. A biopsy is only considered in a child with nephrotic syndrome if they fail to respond adequately to corticosteroids. Prophylactic antibiotics are sometime used in children with reflux nephropathy and recurrent UTIs but are not indicated in nephrotic syndrome. The proteinuria should resolve, often very quickly, with corticosteroids so ACE inhibition is not warranted.

18.2. The following are valid therapeutic interventions for renal bone disease except:

- A. Activated vitamin D supplementation
- B. Parathyroidectomy
- C. Injections of recombinant human parathyroid hormone (PTH)
- D. Dietary phosphate restriction
- E. Calcimimetic drugs (e.g. cinacalcet) which bind the calcium-sensing receptor on the parathyroid gland.

Answer: C.

Renal bone disease is caused by decreased excretion of phosphate and decreased activation of vitamin D (i.e. impaired conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitaminD in the kidney). These events, as well as low calcium levels caused by low vitamin D activation, directly stimulate the parathyroid glands to produce PTH in an effort to correct the low calcium and high phosphate. Therefore, interventions such as activated vitamin D supplementation and dietary phosphate restriction will help. Reducing PTH levels either medically (calcimimetics) or surgically may be needed in resistant cases. Administering PTH will obviously not help.

18.3. A 64-year-old man presents with fever and shortness of breath. He has a history of type 2 diabetes, hypertension and chronic kidney disease and is prescribed lisinopril, amlodipine, metformin and simvastatin. Observations show:  $\text{SaO}_2$  86% on  $\text{FiO}_2$  35%, pulse 130 beats/min, BP 142/68 mmHg. He tests positive for SARS-CoV-2 and his condition deteriorates, and his increasing oxygen requirements necessitate his transfer to ICU for ventilation. He develops anuria and requires dialysis. What is the most likely cause of his acute decline in kidney function?

- A. Acute tubular necrosis
- B. Metformin
- C. Obstructive nephropathy
- D. Post-infectious glomerulonephritis
- E. Pre-renal failure

Answer: A.

The tubular region of the kidneys are most susceptible to injury due to the relative hypoxia at baseline in the medulla and the high oxygen demand of the tubules. Intercurrent illness may cause AKI by promoting systemic hypoxia or reduced renal perfusion. SARS-CoV-2 can cause a number of kidney problems, including proteinuria, microthrombi and ATN through hypoxia or direct viral infection.

Metformin should be discontinued in AKI, however this is due to the risk of accumulation of metformin leading to a lactic acidosis and metformin per se does not cause kidney injury.

Obstructive nephropathy is a possibility given this man's age and the fact that he has developed anuria, but is much less likely in this context.

Post-infectious glomerulonephritis typically occurs after the infection and is less common with viral infections.

While there may have been an element of pre-renal failure earlier in his illness, his blood pressure is now adequate and the anuria implies that he has developed ATN. Hence, further fluid resuscitation is unlikely to result in recovery of renal function, and he will need dialysis support until his condition improves and his necrotic tubules regenerate. Unfortunately, the severity of his disease is consistent with a poor prognosis.

18.4. A 62-year-old man presents with shortness of breath which came on suddenly during the night. He has noticed a wheeze, but no cough or sputum. He has end-stage kidney disease due to diabetic nephropathy, he is anuric and has been on haemodialysis for 2 years and is due his regular dialysis session the next day. His observations are: temp 37.6°C,  $\text{SaO}_2$  88% on  $\text{FiO}_2$  35%, pulse 120 bpm, BP 178/100 mmHg. What is the most likely cause of his shortness of breath?

- A. Acidosis due to renal failure
- B. Exacerbation of obstructive airways disease
- C. Pulmonary embolus
- D. Pulmonary oedema
- E. Renal anaemia

Answer: D.

This is a classical presentation, where a patient with anuric end-stage kidney disease on haemodialysis accumulates fluid between dialysis sessions and develops pulmonary oedema, with paroxysmal nocturnal dyspnoea prior to their next haemodialysis session.

While renal anaemia and acidosis can cause shortness of breath, they do not typically cause hypoxia. An exacerbation of obstructive airways disease is possible, given the wheeze, but there is no history of obstructive airways disease and a wheeze can also be present in pulmonary oedema.

Pulmonary embolus is also a cause of acute shortness of breath, but would be less likely than pulmonary oedema in this context.

18.5. A 66-year-old woman who smokes 15 cigarettes per day presents with painful visible haematuria which persists despite treatment with two courses of oral antibiotics. What is the optimal next management step?

- A. A course of intravenous antibiotics
- B. Rigid cystoscopy under general anaesthetic
- C. Flexible cystoscopy and upper tract imaging
- D. Urine culture and CT urogram
- E. Ureteroscopy

Answer: C.

Visible haematuria is a red flag symptom and should be investigated. Although the symptom may be due to a urinary tract infection, repeated courses of antibiotics should not be given, rather urgent referral to a urologist should occur. The urology department will likely have a haematuria clinic where the patient can be investigated urgently with flexible

cystoscopy (under local anaesthetic) to evaluate for intravesical lesions and upper tract imaging (ultrasound or CT urogram) to evaluate the upper urinary tracts.

18.6. An otherwise fit and well 69-year-old man with a 6cm biopsy proven clear cell renal cell cancer and associated bilateral lung (largest lesion 4cm diameter), bone and pancreatic metastases is best treated with which of the following treatments?

- A. Tyrosine kinase inhibitor
- B. Immediate cytoreductive nephrectomy
- C. Nephrectomy and metastatectomies
- D. Platinum based chemotherapy
- E. Anti-androgen therapy

Answer: A.

This is a case of widespread metastatic clear cell renal cell cancer. Recommended treatment is with systemic therapy, of which there are many options: tyrosine kinase inhibitors (TKIs), T-cell checkpoint inhibitors, mTOR inhibitors or combination of TKIs with T-cell checkpoint inhibitors. Immediate cytoreductive nephrectomy is not recommended as there is no survival advantage over systemic therapy and may never be recommended unless there is a dramatic response to the metastatic disease burden. Multiple metastatectomies would be very morbid and very unlikely to be curative. Anti-androgen therapy is used in prostate cancer and platinum-based chemotherapy in urothelial cancers.

## Clinical examination in biochemical and metabolic disorders

Many biochemical and metabolic disorders are clinically silent or present with non-specific manifestations, and are first detected by laboratory testing. Several abnormalities can be picked up by history and physical examination, however, as summarised below.

**Hyperlipidaemia**

**H** Xanthelasma

**G** Corneal arcus

**Acute hypernatraemia**

**I** Dizziness  
Delirium  
Weakness

**Acute hyponatraemia**

**I** Cerebral oedema  
Vomiting  
Somnolence  
Seizures  
Coma

**Gangliosidosis**

**J** Cherry-red spot fundus

**Glycogen storage disease**

**K** Hepatomegaly

**Porphyria**

**L** Abdominal pain

**M** Photosensitive rash

**Hyperlipidaemia**

**N** Tendon xanthoma

**O** Eruptive xanthoma

**Hypervolaemia**

**F** Raised jugular venous pressure

**E** Extra heart sounds

**D** Lung crepitations

**C** Ankle oedema

**Hypovolaemia**

**B** Low blood pressure

**A** Rapid pulse

**Observation**

- General appearance
- Skin turgor
- Oedema
- Rash
- Eyes

*Insets: (ankle oedema) From Huang H-W, Wong L-S, Lee C-H. Sarcoidosis with bilateral leg lymphedema as the initial presentation: a review of the literature. **Assessment of volume status and electrolyte disturbances**

Check blood pressure, pulse and jugular venous pressure

Check skin turgor

Check for dry mouth

Check for sacral and ankle oedema

Examine chest for pleural effusion

Examine abdomen for hepatomegaly and ascites

Check bloods

Review results

Check ECG

Hypokalaemia

Hyperkalaemia

**Check for signs of hyperlipidaemia**

Check skin and tendons for xanthomas

Check eyes for arcus and xanthelasma

**Examine for signs of multi-system disease**

Check for peripheral neuropathy and for muscle tenderness or weakness

Check for hepato-splenomegaly

Check for cardiomegaly and arrhythmias

Check bloods and urine for metabolic biochemistry

There is a worldwide trend towards increased use of laboratory-based diagnostic investigations, and biochemical investigations in particular. In the health-care systems of higher-income countries, it has been estimated that 60%–70% of all critical decisions taken in regard to patients, and over 90% of data stored in electronic medical records systems, involve a laboratory service or result.

This chapter covers a diverse group of disorders affecting adults that are not considered elsewhere in this book, whose primary manifestation is in abnormalities of biochemistry laboratory results, or whose underlying pathophysiology involves disturbance in specific biochemical pathways.

## Biochemical investigations

There are three broad reasons why a clinician may request a biochemical laboratory investigation:

- to screen an asymptomatic subject for the presence of disease
- to assist in diagnosis of a patient's presenting complaint
- to monitor changes in test results, as a marker of disease progression or response to treatment.

Contemporary medical practice has become increasingly reliant on laboratory investigation and, in particular, on biochemical investigation. This has been associated with extraordinary improvements in the analytical capacity and speed of laboratory instrumentation and the following operational trends:

- Large central biochemistry laboratories feature extensive use of automation and information technology. Specimens are transported from clinical areas to the laboratory using high-speed transport systems (such as pneumatic tubes) and identified with

machine-readable labels (such as bar codes). Laboratory instruments have been miniaturised and integrated with robot transport systems to enable multiple rapid analyses of a single sample. Statistical process control techniques are used to assure the quality of analytical results, and increasingly to monitor other aspects of the laboratory, such as the time taken to complete the analysis ('turn-around time').

- Point-of-care testing (POCT) brings selected laboratory analytical systems into clinical areas, to the patient's bedside or even connected to an individual patient. These systems allow the clinician to receive results almost instantaneously for immediate treatment of the patient, although often with lesser precision or at greater cost than using a central laboratory.
- The diversity of analyses has widened considerably with the introduction of many techniques borrowed from the chemical or other industries (Box 19.1).

Good medical practice involves the appropriate ordering of laboratory investigations and correct interpretation of test results (Box 19.2). The key principles, including the concepts of sensitivity and specificity, are described in Chapter 1. Reference intervals for laboratory results are provided in Chapter 35. Many laboratory investigations can be subject to variability arising from whether the sample is being taken in the fed or fasted state; the timing of sample collection, in relation to diurnal variation of analytes; dosage intervals for therapeutic drug monitoring; sample type, such as serum, plasma; use of anticoagulants, such as EDTA, which can interfere with some assays; or artefacts, such as taking a venous sample proximal to the site of an intravenous infusion. It is therefore important for clinical and laboratory staff to communicate effectively and for clinicians to follow local recommendations concerning collection and transport of samples in the appropriate container and with appropriate labelling.

### 19.1 Range of analytical modalities used in the clinical biochemistry laboratory

Analytical modality	Analyte	Typical applications
<b>Ion-selective electrodes</b>	Blood gases, electrolytes (Na, K, Cl)	Point-of-care testing (POCT) High-throughput analysers
<b>Colorimetric chemical reaction or coupled enzymatic reaction</b>	Simple mass or concentration measurement (creatinine, phosphate) Simple enzyme activity	High-throughput analysers
<b>Ligand assay (usually immunoassay)</b>	Specific proteins Hormones Drugs	Increasingly available for POCT or high-throughput analysers
<b>Chromatography: gas chromatography (GC), high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC)</b>	Organic compounds	Therapeutic drug monitoring (TDM)
<b>Mass spectroscopy (MS)</b>	Drugs Vitamins Organic compounds	Screening for drugs of misuse Vitamins Biochemical metabolites
<b>Spectrophotometry, turbidimetry, nephelometry, fluorimetry</b>	Haemoglobin derivatives Specific proteins Immunoglobulins	Xanthochromia Lipoproteins Paraproteins
<b>Electrophoresis</b>	Proteins Some enzymes	Paraproteins Isoenzyme analysis
<b>Atomic absorption (AA) Inductively coupled plasma/mass spectroscopy (ICP-MS)</b>	Trace elements and metals	Quantitation of heavy metals
<b>Molecular diagnostics</b>	Nucleic acid quantification and/or sequence	Inherited and somatic cell variants (Ch. 3) Genetic polymorphisms (Ch. 3) Variations in rates of drug metabolism (Ch. 2) Microbial diagnosis (Ch. 6)

19.2 How to interpret urea and electrolytes results*	
<b>Sodium</b>	
<ul style="list-style-type: none"> <li>• Largely reflects changes in water balance</li> <li>• See 'Hypernatraemia' and 'Hyponatraemia'</li> </ul>	
<b>Potassium</b>	
<ul style="list-style-type: none"> <li>• May reflect K shifts in and out of cells</li> <li>• Low levels usually mean excessive losses (gastrointestinal or renal)</li> <li>• High levels usually mean renal dysfunction</li> <li>• See 'Hypokalaemia' and 'Hyperkalaemia'</li> </ul>	
<b>Chloride</b>	
<ul style="list-style-type: none"> <li>• Generally changes in parallel with plasma Na</li> <li>• Low in metabolic alkalosis</li> <li>• High in some forms of metabolic acidosis</li> </ul>	
<b>Bicarbonate</b>	
<ul style="list-style-type: none"> <li>• Abnormal in acid–base disorders</li> <li>• See <a href="#">Box 19.18</a></li> </ul>	
<b>Urea</b>	
<ul style="list-style-type: none"> <li>• Increased with a fall in glomerular filtration rate (GFR), reduced renal perfusion or urine flow rate, and in high protein intake or catabolic states</li> </ul>	
<b>Creatinine</b>	
<ul style="list-style-type: none"> <li>• Increased with a fall in GFR, in individuals with high muscle mass, and with some drugs</li> <li>• See <a href="#">Figure 18.2</a></li> </ul>	
*The term urea and electrolytes (UEs) refers to urea, electrolytes and creatinine. In some countries this is abbreviated to EUC (electrolytes/urea/creatinine).	

## Water and electrolyte homeostasis

Total body water (TBW) is approximately 60% of body weight in an adult male, although the proportion is somewhat more for infants and less for women. In a 70 kg man TBW is therefore about 40 L. Approximately 25 L is located inside cells (the intracellular fluid or ICF), while the remaining 15 L is in the extracellular fluid (ECF) compartment (see [Fig. 19.1](#)). Most of the ECF (approximately 12 L) is interstitial fluid, which is within the tissues but outside cells, whereas the remainder (about 3 L) is in the plasma compartment.

The ion composition between the main body fluid compartments intracellularly and extracellularly is illustrated in [Figure 19.1](#). The dominant positively charged ion (cation) within cells is potassium, whereas phosphates and negatively charged proteins constitute the major intracellular negatively charged ions (anions). In the ECF the dominant cation is sodium, while chloride and, to a lesser extent, bicarbonate are the most important ECF anions. An important difference between the intravascular (plasma) and interstitial compartments of the ECF is that only plasma contains significant concentrations of protein.

The major force maintaining the difference in cation concentrations between the ICF and ECF is the sodium–potassium pump (Na,K-activated adenosine triphosphatase – ATPase), which is present in all cell membranes. Maintenance of these gradients is essential for many cell processes, including the excitability of conducting tissues such as nerve and muscle. The difference in protein content between the plasma and the interstitial fluid compartment is maintained by the impermeability of the capillary wall to protein. This protein concentration gradient (the colloid osmotic, or oncotic, pressure of the plasma) contributes to the balance of forces across the capillary wall that favour fluid retention within the plasma compartment.

The concentration of sodium in the ECF plays a pivotal role in determining plasma osmolality and thereby controlling intracellular volume through changes in water balance between the intracellular and extracellular space. In contrast, plasma volume is largely controlled by total body sodium, which determines volume change. Therefore, disturbances in

**Fig. 19.1** Normal distribution of body water and electrolytes. Schematic representation of volume (L = litres) and composition (dominant ionic species only shown) of the intracellular fluid (ICF) and extracellular fluid (ECF) in a 70 kg male. The main difference in composition between the plasma and interstitial fluid (ISF) is the presence of appreciable concentrations of protein in the plasma but not the ISF. The Na/K differential is maintained by the Na,K-adenosine triphosphatase (ATPase) pump.

water homeostasis typically present with biochemical abnormalities such as hyponatraemia or hypernatraemia, whereas disturbances in sodium homeostasis present with hypervolaemia or hypovolaemia as the result of expansion or contraction of ECF volume, respectively.

## Sodium homeostasis

Most of the body's sodium is located in the ECF, where it is by far the most abundant cation. Accordingly, total body sodium is the principal determinant of ECF volume. Sodium intake varies widely between individuals, ranging between 50 and 250 mmol/24 hr. The kidneys can compensate for these wide variations in sodium intake by increasing excretion of sodium when there is sodium overload, and retaining sodium in the presence of sodium depletion, to maintain normal ECF volume and plasma volume.

## Functional anatomy and physiology

The functional unit for renal excretion is the nephron, which is illustrated in [Figure 19.2](#). Blood undergoes ultrafiltration in the glomerulus, generating a fluid that is free from cells and protein and which resembles plasma in its electrolyte composition. This is delivered into the renal tubules, where reabsorption of water and various electrolytes occurs. (More detail on the structure and function of the glomerulus is given in [Ch. 18](#).) The glomerular filtration rate (GFR) is approximately 125 mL/min (equivalent to 180 L/24 hr) in a normal adult. Over 99% of the filtered fluid is reabsorbed into the blood in the peritubular capillaries during its passage through successive segments of the nephron, mainly as a result of tubular reabsorption of sodium. The processes mediating sodium reabsorption, and the factors that regulate it, are key to understanding clinical disturbances and pharmacological interventions of sodium and fluid balance.

The nephron can be divided into four different functional segments in terms of sodium and water reabsorption (see [Fig. 19.2](#)).

### Proximal renal tubule

About 65% of the filtered sodium load is reabsorbed in the proximal renal tubule. The cellular mechanisms are complex but some of the key features are shown in panel (A) of [Figure 19.2](#). The key to sodium reabsorption from the luminal fluid rests on the basolateral (blood-side) of the cell where large numbers of Na,K-ATPase pumps are present (black circle)

**Fig. 19.2 Anatomy of the nephron and principal transport mechanisms in different parts of the renal tubule.** The apical membrane of tubular cells is the side facing the lumen and the basolateral membrane is the side facing the blood. Black circles indicate active transport pumps linked to ATP hydrolysis and other symbols indicate ion channels and transporter molecules (see text for more details). Details of the proportion of sodium reabsorbed, water permeability and sites of action for different classes of diuretics are shown. The SGLT2 inhibitors are primarily used for the treatment of diabetes but have diuretic properties by blocking SGLT2 (yellow circle) in the proximal tubule [A]. At the same site, acetazolamide inhibits carbonic anhydrase (CA), which, by reducing production of hydrogen ions by proximal tubular cells, inhibits sodium–hydrogen exchange through the NHE-3 transporter (pink circle). Loop diuretics block the NKCC2 transporter (white cylinder) in the loop of Henle [B], whereas thiazide diuretics block the NCCT channel (orange cylinder) in the early distal tubule [C]. Amiloride and spironolactone block the ENaC channel (blue doughnut) in the late distal tubule and collecting ducts [D]. See text for further details and abbreviations. (aa = afferent arteriole; ea = efferent arteriole; md = macula densa)

which transport sodium from the cells into the blood. This creates a low concentration of sodium within the cell that drives the passive reabsorption of sodium from the lumen into the epithelial cell. Transporters in the apical membrane are then able to couple sodium transport to the entry of various organic molecules, including glucose, amino acids, phosphate and others. An example of this is shown in Figure 19.2 where the reabsorption of Na is coupled to the reabsorption of glucose via the SGLT2 transport protein (yellow circle). Entry of sodium into the tubular cells at this site is also linked to secretion of H<sup>+</sup> ions, through the sodium–hydrogen exchanger (NHE-3) (pink circle). This relates to a complicated system responsible for bicarbonate reabsorption where HCO<sub>3</sub> ions in the lumen are combined with H<sup>+</sup> ions to form carbonic acid (H<sub>2</sub>CO<sub>3</sub>). The H<sub>2</sub>CO<sub>3</sub> is broken down to form H<sub>2</sub>O and CO<sub>2</sub> in a reaction catalysed by carbonic anhydrase (CA) present on the luminal membrane of the tubular cell. The CO<sub>2</sub> and H<sub>2</sub>O are then freely able to diffuse into the tubular cell. Within the tubular cell, H<sub>2</sub>CO<sub>3</sub> is generated from H<sub>2</sub>O and CO<sub>2</sub> by intracellular CA. The H<sub>2</sub>CO<sub>3</sub> then dissociates spontaneously to produce H<sup>+</sup> ions which are transported into the lumen by the NHE-3 transporter and

HCO<sub>3</sub><sup>-</sup> ions which are transported into the blood. This allows for almost complete reabsorption of bicarbonate in the proximal tubule. In addition, a large component of the transepithelial flux of sodium, water and other dissolved solutes occurs through gaps *between* the cells (the ‘shunt’ pathway). Overall, fluid and electrolyte reabsorption is almost isotonic in this segment, as water reabsorption is matched very closely to sodium fluxes, such that the osmolality of fluid passing into the loop of Henle is very similar to that of plasma. A component of this water flow also passes *through* the cells, via aquaporin-1 (AQP-1) water channels (see Fig. 19.5), which are not sensitive to hormonal regulation. Acetazolamide and SGLT2 inhibitors both act on this segment to promote sodium excretion by their effects on carbonic anhydrase and the SGLT2 protein, respectively.

### Loop of Henle

The thick ascending limb of the loop of Henle reabsorbs a further 25% of the filtered sodium but is impermeable to water, resulting in dilution of the luminal fluid as illustrated in panel (B) in Figure 19.2. Again, the primary driving

force is the Na,K-ATPase on the basolateral cell membrane (black circle) which creates a low intracellular concentration of sodium, but in this segment, sodium entry through the Na,K,2Cl (NKCC2, white cylinder) allows electroneutral entry of these ions into the renal tubular cell by balancing transport of cations (Na<sup>+</sup>/K<sup>+</sup>) with anions (Cl<sup>-</sup>). Some of the potassium accumulated inside the cell recirculates across the apical membrane back into the lumen through the ROMK potassium channel (white circle), providing a continuing supply of potassium to match the high concentrations of sodium and chloride in the lumen. Due to this, a small positive transepithelial potential difference exists in the lumen of this segment relative to the interstitium, and this serves to drive cations such as sodium, potassium, calcium and magnesium between the cells, forming a reabsorptive shunt pathway. Loop diuretics like furosemide inhibit sodium reabsorption in this segment by inhibiting the NKCC2 transporter.

### Early distal renal tubule

The early distal tubule (also called distal convoluted tubule) is responsible for reabsorption of about 7% of the filtered sodium load, as shown in panel (C) in Figure 19.2. This is again primarily driven by the activity of the basolateral Na,K-ATPase (black circle). In this segment, entry of sodium into the cell from the luminal fluid occurs via the NCCT sodium–chloride co-transport carrier (orange cylinder). This segment is also impermeable to water, resulting in further dilution of the luminal fluid. There is no significant transepithelial flux of potassium in this segment, but calcium is reabsorbed in exchange for sodium, where a basolateral sodium–calcium exchanger (blue cylinder) leads to low intracellular concentrations of calcium, promoting calcium entry from the luminal fluid through a calcium channel (blue ellipse). Thiazide diuretics inhibit sodium reabsorption in this segment by inhibiting the NCCT transporter.

### Late distal renal tubule and collecting ducts

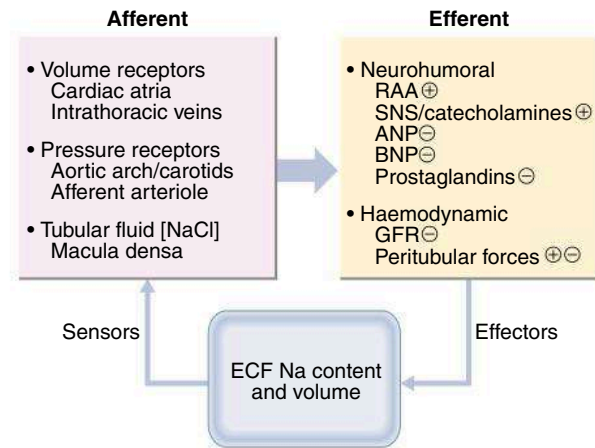

The late distal tubule and cortical collecting duct are anatomically and functionally continuous (panel (D) in Fig. 19.2). Here, sodium entry from the luminal fluid into principal cells occurs through the epithelial sodium channel (ENaC), generating a substantial lumen-negative transepithelial potential difference. This sodium flux into the tubular cells is balanced by secretion of potassium and hydrogen ions into the lumen and by reabsorption of chloride ions. Potassium passes into the luminal fluid down its electrochemical gradient, through an apical potassium channel (ROMK) in the principal cells (white circle). Hydrogen ion secretion is mediated by an H<sup>+</sup>-ATPase (black triangle) located on the luminal membrane of the alpha intercalated cells. Beta intercalated cells secrete bicarbonate and both cell types participate in the excretion of ammonia and ammonium. The distal tubule and collecting duct have a variable permeability to water, depending on circulating levels of vasopressin (antidiuretic hormone, ADH). All ion transport processes in this segment are stimulated by the steroid hormone aldosterone, which can increase sodium reabsorption to a maximum of 2%–3% of the filtered sodium load. Amiloride and spironolactone both reduce sodium reabsorption in this segment by inhibiting the activity of the ENaC transporter (blue doughnut), either directly, as in the case of amiloride, or by inhibiting the effects of aldosterone, as is the case with spironolactone.

Less than 1% of sodium reabsorption occurs in the medullary collecting duct, where it is inhibited by atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP).

### Regulation of sodium transport

The amount of sodium excreted by the kidney is dependent on the filtered load of sodium (which is principally determined by GFR) and the control of tubular sodium reabsorption. A number of interrelated mechanisms serve to maintain whole-body sodium balance, and hence ECF volume, by matching urinary sodium excretion to sodium intake (Fig. 19.3), and controlling those two processes.

Important sensing mechanisms include volume receptors in the cardiac atria and the intrathoracic veins, as well as pressure receptors

**Fig. 19.3 Mechanisms involved in the regulation of sodium transport.** ANP = atrial natriuretic peptide; BNP = brain natriuretic peptide; ECF = extracellular fluid; GFR = glomerular filtration rate; RAA = renin–angiotensin–aldosterone system; SNS = sympathetic nervous system. ⊕ indicates an effect to stimulate Na reabsorption and hence reduce Na excretion, while ⊖ indicates an effect to inhibit Na reabsorption and hence increase Na excretion.

located in the central arterial tree (aortic arch and carotid sinus) and the afferent arterioles within the kidney. A further afferent signal is generated within the kidney itself: the enzyme renin is released from specialised smooth muscle cells in the walls of the afferent and efferent arterioles, at the point where they make contact with the early distal tubular cells of the macula densa to form the juxtaglomerular apparatus (see Fig. 19.2). Renin release is stimulated by:

- reduced perfusion pressure in the afferent arteriole
- increased sympathetic nerve activity
- decreased sodium chloride concentration in the distal tubular fluid.

Renin acts on the peptide substrate, angiotensinogen (which is produced by the liver), to produce angiotensin I, which is cleaved by angiotensin-converting enzyme (ACE), largely in the pulmonary capillary bed, to produce angiotensin II (see Fig. 20.19). Angiotensin II has multiple actions: it stimulates proximal tubular sodium reabsorption and release of aldosterone from the zona glomerulosa of the adrenal cortex, and causes vasoconstriction of small arterioles. Aldosterone amplifies sodium retention by its action on the cortical collecting duct. The net effect of activation of the renin–angiotensin system is to raise blood pressure and cause sodium and water retention, thereby correcting hypovolaemia.

Changes in GFR alter peritubular hydrostatic pressure and oncotic pressure in opposite directions, resulting in a change in sodium reabsorption. In particular, with hypovolaemia, and a reduction in hydrostatic pressure and an increase in oncotic pressure, there is an increase in sodium reabsorption.

The sympathetic nervous system also acts to increase sodium retention, both through haemodynamic mechanisms (afferent arteriolar vasoconstriction and GFR reduction) and by direct stimulation of proximal tubular sodium reabsorption. In contrast, other humoral mediators, such as the natriuretic peptides, which inhibit sodium reabsorption, contribute to natriuresis during periods of sodium and volume excess.

Increases in sodium intake cause hypervolaemia, which increases renal perfusion and GFR and suppresses renin production through increased delivery of sodium into the macula densa. This sets in motion a train of events opposite to those that occur in hypovolaemia, to cause an increase in sodium excretion.

### Presenting problems in sodium balance

When the balance of sodium intake and excretion is disturbed, any tendency for plasma sodium concentration to change is usually corrected

by the osmotic mechanisms controlling water balance. As a result, disorders in sodium balance present chiefly as alterations in the ECF volume, resulting in hypovolaemia or hypervolaemia, rather than as an alteration in plasma sodium concentration. Clinical manifestations of altered ECF volume are illustrated in [Box 19.3](#).

## Hypovolaemia

Hypovolaemia is defined as a reduction in circulating blood volume. The most common causes are loss or sequestration of sodium-containing fluids or acute blood loss, as summarised in [Box 19.4](#).

### Pathogenesis

Loss of sodium-containing fluid triggers the changes in renal sodium handling and activation of the renin–angiotensin system that were described earlier in this chapter. Loss of whole blood, as in acute haemorrhage, is another cause of hypovolaemia, and elicits the same mechanisms for the conservation of sodium and water as loss of sodium-containing fluid.

### Clinical features

Hypovolaemia is primarily a clinical diagnosis, based on characteristic symptoms such as thirst, dizziness and weakness along with characteristic clinical signs (see [Box 19.3](#)) in the context of a relevant precipitating illness.

### Investigations

Serum sodium concentrations do not reflect total body sodium and are therefore not helpful in making the diagnosis of hypovolaemia. The GFR is usually maintained unless the hypovolaemia is very severe or prolonged, but urinary flow rate is reduced as a consequence of activation of

sodium- and water-retaining mechanisms in the nephron. Serum creatinine, which reflects GFR, is usually normal, but serum urea concentration is typically elevated due to a low urine flow rate, which is accompanied by increased tubular reabsorption of urea. Similarly, serum uric acid may also rise, reflecting increased reabsorption in the proximal renal tubule. The urine sodium concentration appropriately falls and sodium excretion may reduce to less than 0.1% of the filtered sodium load.

### Management

Management of sodium and volume depletion has two main components:

- treat the cause where possible, to stop ongoing salt and volume losses
- replace the salt and water deficits, and provide ongoing maintenance requirements, usually by intravenous fluid replacement when depletion is severe.

### Intravenous fluid therapy

Intravenous fluid therapy can be used to maintain water, sodium and potassium intake when the patient is fasting, such as during an acute illness or post-operatively. If any deficits or continuing pathological losses are identified, additional fluid and electrolytes will be required. In prolonged periods of fasting (more than a few days), attention also needs to be given to providing sufficient caloric and nutritional intake to prevent excessive catabolism of body energy stores. The daily maintenance requirements for water and electrolytes in a typical adult are shown in [Box 19.5](#) and the composition of some widely available intravenous fluids are given in [Box 19.6](#). The choice of fluid and the rate of administration depend on the clinical circumstances, as assessed at the bedside and from laboratory data, as described in [Box 19.7](#).

The choice of intravenous fluid therapy in the treatment of significant hypovolaemia relates to the concepts in [Figure 19.1](#). If fluid containing neither sodium nor protein is given, it will distribute in the body fluid compartments in proportion to the normal distribution of total body water. For example, administration of 1 L of 5% dextrose contributes little (approximately 3/40 of the infused volume) towards expansion of the plasma volume, which makes this fluid unsuitable for restoring the circulation and perfusion of vital organs. Intravenous infusion of an isotonic (normal) saline solution, on the other hand, is more effective at expanding the ECF, although only a small proportion (about 3/15) of the infused volume actually contributes to plasma volume.

Whilst it would appear that solutions containing plasma proteins (colloids) would be better retained within the vascular space and be more effective at correcting hypovolaemia than protein-free fluids (crystalloids), clinical studies have not shown any advantage of giving albumin-containing infusions in the treatment of acute hypovolaemia and indeed have demonstrated increased morbidity related to their use. Therefore, crystalloids are the fluid of choice for resuscitation in acute hypovolaemia. More studies, however, are required to clarify the most appropriate crystalloid in this situation, given that normal saline can cause a mild metabolic acidosis, perhaps related to excessive chloride loading, whereas ‘balanced solutions’, such as Hartmann’s, may cause a mild hyponatraemia, as their composition is slightly hypotonic.

## Hypervolaemia

Hypervolaemia is the result of sodium and water excess and is rare in patients with normal cardiac and renal function, since the kidney has a

19.3 Clinical features of hypovolaemia and hypervolaemia		
	Hypovolaemia	Hypervolaemia
<b>Symptoms</b>	Thirst Dizziness on standing Weakness	Ankle swelling Abdominal swelling Breathlessness
<b>Signs</b>	Postural hypotension Tachycardia Dry mouth Reduced skin turgor Reduced urine output Weight loss Delirium, stupor	Peripheral oedema Raised JVP Pulmonary crepitations Pleural effusion Ascites Weight gain Hypertension (sometimes)

(JVP = jugular venous pressure)

19.4 Causes of hypovolaemia	
Mechanism	Examples
<b>Inadequate sodium intake</b>	Environmental deprivation, inadequate therapeutic replacement
<b>Gastrointestinal sodium loss</b>	Vomiting, diarrhoea, nasogastric suction, external fistula
<b>Skin sodium loss</b>	Excessive sweating, burns
<b>Renal sodium loss</b>	Diuretic therapy, mineralocorticoid deficiency, tubulointerstitial disease
<b>Internal sequestration*</b>	Bowel obstruction, peritonitis, pancreatitis, crush injury
<b>Reduced blood volume</b>	Acute blood loss

\*A cause of circulatory volume depletion, although total body sodium and water may be normal or increased.

19.5 Basic daily water and electrolyte requirements		
	Requirement per kg	Typical 70 kg adult
<b>Water</b>	35–45 mL/kg	2.45–3.15 L/24 hrs
<b>Sodium</b>	1.5–2 mmol/kg	105–140 mmol/24 hrs
<b>Potassium</b>	1.0–1.5 mmol/kg	70–105 mmol/24 hrs

## 19.6 Composition of some isotonic intravenous fluids

Fluid	D-glucose	Calories	Na <sup>+</sup> (mmol/L)	Cl <sup>-</sup> (mmol/L)	Other (mmol/L)
5% dextrose	50 g	200	0	0	0
Normal (0.9%) saline	0	0	154	154	0
Hartmann's solution	0	0	131	111	K <sup>+</sup> 5 Ca <sup>2+</sup> 2 Lactate <sup>-</sup> 29

## 19.7 How to assess fluid and electrolyte balance in hospitalised patients

### Step 1: assess clinical volume status

- Examine patient for signs of hypovolaemia or hypervolaemia (see Box 19.3)
- Check daily weight change

### Step 2: review fluid balance chart

- Check total volumes IN and OUT on previous day (IN–OUT is positive by ~400 mL in normal balance, reflecting insensible fluid losses of ~800 mL and metabolic water generation of ~400 mL)
- Check cumulative change in daily fluid balance over previous 3–5 days
- Correlate chart figures with weight change and clinical volume status to estimate net fluid balance

### Step 3: assess ongoing fluid losses

- Check losses from gastrointestinal tract and surgical drains
- Estimate increased insensible losses (e.g. in fever) and internal sequestration ('third space')

### Step 4: check plasma U&Es (see Box 19.2)

- Check plasma Na as marker of relative water balance
- Check plasma K as a guide to extracellular K balance
- Check HCO<sub>3</sub><sup>-</sup> as a clue to acid–base disorder
- Check urea and creatinine to monitor renal function

### Step 5: prescribe appropriate intravenous fluid replacement therapy

- Replace basic water and electrolytes each day (see Box 19.5)
- Allow for anticipated oral intake and pathological fluid loss
- Adjust amounts of water (if IV, usually given as isotonic 5% dextrose), sodium and potassium according to plasma electrolyte results

(IV = intravenous; U&Es = urea and electrolytes)

large capacity to increase renal excretion of sodium and water via the homeostatic mechanisms described earlier in the chapter.

### Pathogenesis

The most common systemic disorders responsible for hypervolaemia are outlined in Box 19.8. In cardiac failure, cirrhosis and nephrotic syndrome, sodium retention occurs in response to circulatory insufficiency caused by the primary disorder, as illustrated in Figure 19.4. The pathophysiology is different in kidney failure, when the primary cause of volume expansion is the profound reduction in GFR impairing sodium and water excretion, while secondary tubular mechanisms are of lesser importance. In primary hyperaldosteronism (Conn syndrome) the pathophysiology also differs, in that increased secretion of aldosterone directly stimulates sodium reabsorption.

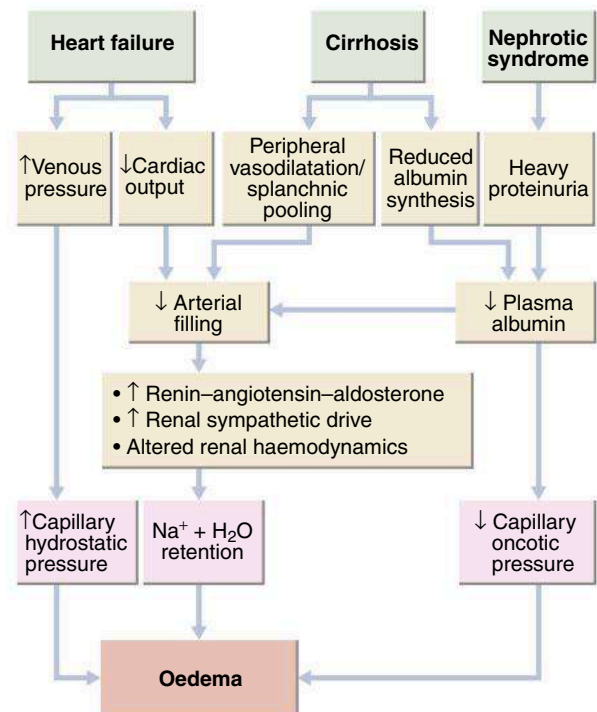

### Clinical features

Peripheral oedema is the most common physical sign of hypervolaemia since the excess fluid leaks out of the capillaries to expand the interstitial compartment of the ECF. This is particularly the case in nephrotic syndrome and chronic liver disease, in which hypoalbuminaemia is a prominent feature. The main exception is Conn syndrome, which presents with hypertension and often hypokalaemia, but in which peripheral oedema is unusual.

## 19.8 Causes of sodium and water excess

Mechanism	Examples
Impaired renal function	Primary renal disease
Primary hyperaldosteronism*	Conn syndrome
Secondary hyperaldosteronism (see Fig. 19.5)	Congestive cardiac failure Cirrhotic liver disease Nephrotic syndrome Protein-losing enteropathy Malnutrition Idiopathic/cyclical oedema Renal artery stenosis*

\*Conditions in this box other than primary hyperaldosteronism and renal artery stenosis are typically associated with generalised oedema.

**Fig. 19.4** Secondary mechanisms causing sodium excess and oedema in cardiac failure, cirrhosis and nephrotic syndrome. Primary renal retention of Na and water may also contribute to oedema formation when glomerular filtration rate is significantly reduced (see Box 19.8).

### Investigations

Although hypervolaemia is accompanied by an excess of total body sodium, serum sodium concentrations tend to be normal due to the accompanying water retention. Serum concentrations of potassium are normal except in

Conn syndrome, where there is hypokalaemia due to the increased aldosterone production. Creatinine, GFR and urea are usually normal, unless the underlying cause of hypervolaemia is renal failure. General investigations may reveal evidence of cardiac, renal or liver disease.

### Management

The management of hypervolaemia involves a number of components:

- specific treatment directed at the underlying cause, such as ACE inhibitors in heart failure and glucocorticoids in minimal change nephropathy
- restriction of dietary sodium (to 50–80 mmol/24 hr) to match the diminished excretory capacity
- fluid restriction

### Diuretic therapy

Diuretics play a pivotal role in the treatment of hypervolaemia due to salt and water retention and in hypertension. They act by inhibiting sodium reabsorption at various locations along the nephron (see Fig. 19.2). Their potency and adverse effects relate to their mechanism and site of action.

**Carbonic anhydrase inhibitors** Acetazolamide is a carbonic anhydrase inhibitor that inhibits intracellular production of H<sup>+</sup> ions in the proximal tubule, reducing the fraction of sodium reabsorption that is exchanged for H<sup>+</sup> by the apical membrane sodium–hydrogen exchanger. It is a weak diuretic but is seldom used clinically for this purpose, since only a small fraction of proximal sodium reabsorption uses this mechanism, and much of the sodium that is not reabsorbed in the proximal tubule can be reabsorbed by downstream segments of the nephron. Its use is also complicated by metabolic acidosis due to reduction in proximal bicarbonate reabsorption.

**Sodium-dependent glucose transporter inhibitors** Inhibitors of the sodium-dependent glucose transporter 2 (SGLT2), such as dapagliflozin and canagliflozin, simultaneously block glucose and sodium reabsorption in the proximal tubule. They have mild diuretic properties but are principally used to lower blood glucose in the treatment of diabetes. However, they have been found to have renoprotective effects beyond their ability to improve diabetic control, probably related to a reduction in glomerular hyperfiltration. This occurs due to their ability to reduce sodium reabsorption and thereby a reduction in tubuloglomerular feedback.

**Loop diuretics** Loop diuretics, such as furosemide, inhibit sodium reabsorption in the thick ascending limb of the loop of Henle, by blocking the action of the apical membrane NKCC2 co-transporter. Because this segment reabsorbs a large fraction of the filtered sodium, these drugs are potent diuretics, and are commonly used in diseases associated with significant oedema. Loop diuretics cause excretion not only of sodium (and with it water) but also of potassium. This occurs chiefly as a result of delivery of increased amounts of sodium to the late distal tubule and cortical collecting ducts, where sodium reabsorption is associated with secretion of potassium, and is amplified if circulating aldosterone levels are high.

**Thiazide diuretics** Thiazide diuretics inhibit sodium reabsorption in the early distal tubule, by blocking the NCCT co-transporter in the apical membrane. Since this segment reabsorbs a much smaller fraction of the filtered sodium, these are less potent than loop diuretics, but are widely used in the treatment of hypertension and less severe oedema. Like loop diuretics, thiazides increase excretion of potassium through delivery of increased amounts of sodium to the late distal tubule and collecting duct. They are the diuretics that are most likely to be complicated by the development of hyponatraemia.

**Potassium-sparing diuretics** Potassium-sparing diuretics act on the late distal renal tubule and cortical collecting duct segment to inhibit sodium reabsorption. Since sodium reabsorption and potassium secretion are linked at this site, the reduced sodium reabsorption is accompanied by reduced potassium secretion. The apical sodium channel ENaC (see Fig. 19.2) is

blocked by amiloride and triamterene, while spironolactone and eplerenone also act at this site by blocking binding of aldosterone to mineralocorticoid receptors thereby blocking ENaC activity.

**Osmotic diuretics** These act independently of a specific transport mechanism. As they are freely filtered at the glomerulus but not reabsorbed by any part of the tubular system, they retain fluid osmotically within the tubular lumen and limit the extent of sodium reabsorption in multiple segments. Mannitol is the most commonly used osmotic diuretic. It is given by intravenous infusion to achieve short-term diuresis in conditions such as cerebral oedema.

### Clinical use of diuretics

The following principles should be observed when using diuretics:

- Use the minimum effective dose.
- Use for as short a period of time as necessary.
- Monitor regularly for adverse effects.

The choice of diuretic is determined by the potency required, the presence of coexistent conditions and the side-effect profile.

Adverse effects encountered with the most frequently used classes of diuretic (loop drugs and thiazide drugs) are summarised in Box 19.9. Volume depletion and electrolyte disorders are the most common, as predicted from their mechanism of action. The metabolic side-effects listed are rarely of clinical significance and may reflect effects on K<sup>+</sup> channels that influence insulin secretion. Since most drugs from these classes are sulphonamides, there is a relatively high incidence of hypersensitivity reactions, and occasional idiosyncratic side-effects in a variety of organ systems.

The side-effect profile of the potassium-sparing diuretics differs in a number of important respects from that of other diuretics. The disturbances in potassium, magnesium and acid–base balance are in the opposite direction, so that normal or increased levels of potassium and magnesium are found in the blood, and there is a tendency to metabolic acidosis, especially when renal function is impaired.

An important feature of the most commonly used diuretic drugs (furosemide, thiazides and amiloride) is that they act on their target molecules from the luminal side of the tubular epithelium. Since they are highly protein-bound in the plasma, very little reaches the urinary fluid by glomerular filtration, but there are active transport mechanisms for secreting organic acids and bases, including these drugs, across the proximal tubular wall into the lumen, resulting in adequate drug concentrations being delivered to later tubular segments. This secretory process may be impaired by certain other drugs, and also by accumulated organic anions as occurs in chronic kidney disease and chronic liver failure, leading to resistance to diuretics. The transport protein is also responsible for the secretion of uric acid so the use of these diuretics can competitively inhibit this process and result in gout.

Diuretic resistance is encountered under a variety of circumstances, including impaired renal function, activation of sodium-retaining mechanisms, impaired oral bioavailability (such as in patients with gastrointestinal disease) and decreased renal blood flow. In these circumstances,

## 19.9 Adverse effects of loop-acting and thiazide diuretics

### Renal side-effects

- Hypovolaemia
- Hyponatraemia
- Hypokalaemia
- Metabolic alkalosis
- Hyperuricaemia
- Hypomagnesaemia
- Hypercalciuria (loop)
- Hypocalciuria (thiazide)

### Metabolic side-effects

- Glucose intolerance/hyperglycaemia
- Hyperlipidaemia

### Miscellaneous side-effects

- Hypersensitivity reactions
- Acute pancreatitis/cholecystitis (thiazide)
- Erectile dysfunction

short-term intravenous therapy with a loop-acting agent such as furosemide may be useful. Combinations of diuretics administered orally may also increase potency. Either a loop or a thiazide drug can be combined with a potassium-sparing drug, and all three classes can be used together for short periods, with carefully supervised clinical and laboratory monitoring.

## Water homeostasis

Daily water intake can vary from about 500 mL to several litres a day. About 800 mL of water is lost daily through the stool, sweat and the respiratory tract (insensible losses) and about 400 mL is generated daily through oxidative metabolism (metabolic water). The kidneys are chiefly responsible for adjusting water excretion to balance intake, endogenous production and losses so as to maintain total body water content and serum osmolality within the reference range of 280–296 mOsmol/kg.

## Functional anatomy and physiology

While regulation of total ECF volume is principally achieved through renal control of sodium excretion, mechanisms exist to allow for the excretion of urine that is hypertonic or hypotonic in relation to plasma to maintain constant plasma osmolality.

These functions are largely achieved by the loop of Henle and the collecting ducts (see Fig. 19.2). The countercurrent configuration of flow in adjacent limbs of the loop (Fig. 19.5) involves osmotic movement of water from the descending limbs and reabsorption of solute from neighbouring ascending limbs, to set up a gradient of osmolality from isotonic (like plasma) in the renal cortex to hypertonic (around 1200 mOsmol/kg) in the inner part of the medulla. At the same time, the fluid emerging from the thick ascending limb is hypotonic compared to plasma because it

has been diluted by the reabsorption of sodium, but not water, from the thick ascending limb and is further diluted in the early distal tubule. As this dilute fluid passes from the cortex through the collecting duct system to the renal pelvis, it traverses the medullary interstitial gradient of osmolality set up by the operation of the loop of Henle, and water is able to be reabsorbed. Whether water is reabsorbed at this point to concentrate the urine or whether the duct becomes impermeable to water allowing for dilute urine to be excreted depends on the presence or absence of the circulating level of vasopressin respectively. Vasopressin is released by the posterior pituitary gland under conditions of increased plasma osmolality or hypovolaemia.

- When water intake is high and plasma osmolality is normal or low-normal (Fig. 19.5B), vasopressin levels are suppressed and the collecting ducts remain impermeable to water. The luminal fluid osmolality remains low, resulting in the excretion of a dilute urine (minimum osmolality approximately 50 mOsmol/kg in a healthy young person).
- When water intake is restricted and plasma osmolality is high (Fig. 19.5A), or in the presence of significant plasma volume depletion, vasopressin levels rise. This causes water permeability of the collecting ducts to increase through binding of vasopressin to the V2 receptor, which enhances collecting duct water permeability through the insertion of AQP-2 channels into the luminal cell membrane. This results in osmotic reabsorption of water along the entire length of the collecting duct, with maximum urine osmolality approaching that in the medullary tip (up to 1200 mOsmol/kg).

Parallel to these changes in vasopressin release are changes in water-seeking behaviour triggered by the sensation of thirst, which also becomes activated as plasma osmolality rises.

In summary, for adequate dilution of the urine there must be:

- adequate solute delivery to the loop of Henle and early distal tubule
- normal function of the loop of Henle and early distal tubule

**Fig. 19.5 Mechanisms of renal water handling.** (1) Filtrate from the proximal tubule is isotonic to plasma and cortical interstitial fluid. (2) Water moves down its osmotic gradient, concentrating the filtrate but not diluting the interstitium, as the vasa recta carries away the water. (3) The filtrate is at its highest concentration at the bend of the loop and therefore the surrounding medulla is also concentrated. (4) NaCl is pumped out of the filtrate in the thick ascending limb and early distal tubule, increasing the interstitial fluid osmolality. (5) The filtrate has a concentration of 100 mOsmol/kg as it leaves the early distal tubule. **A** In the face of water deficit, vasopressin levels rise, causing AQP2 channels to migrate to the luminal side of the cell membrane increasing water permeability of the collecting ducts, resulting in osmotic reabsorption of water. **B** In the situation of water overload, vasopressin secretion is suppressed, AQP2 channels are held intracellularly, rendering the collecting ducts impermeable to water, resulting in production of a dilute urine.

- absence of vasopressin in the circulation.

If any of these processes is faulty, water retention and hyponatraemia may result.

Conversely, to achieve concentration of the urine there must be:

- adequate solute delivery to the loop of Henle
- normal function of the loop of Henle
- vasopressin release into the circulation
- vasopressin action on the collecting ducts.

Failure of any of these steps may result in inappropriate water loss and hypernatraemia.

## Presenting problems in regulation of osmolality

Changes in plasma osmolality are mainly determined by changes in serum sodium concentration and its associated anions. As outlined above, changes in sodium concentration usually occur because of disturbances in water balance, either because there is a relative excess of body water compared to total body sodium (hyponatraemia) or a relative lack of body water compared to total body sodium (hypernatraemia). Abnormalities of water balance can result from disturbances in urinary concentration or dilution.

If extracellular osmolality falls, water flows across cell membranes, causing cell swelling, whereas cell shrinkage occurs when osmolality rises. Brain cells and therefore cerebral function are particularly sensitive to such volume changes and can result in increased intracerebral pressure and reduced cerebral perfusion.

## Hyponatraemia

Hyponatraemia is defined as a serum Na  $<135$  mmol/L. It is a common electrolyte abnormality with many potential underlying causes, as summarised in [Box 19.10](#).

### Pathophysiology

In all cases, hyponatraemia is caused by greater retention of water relative to sodium. The causes are best categorised according to associated changes in the ECF volume (see [Box 19.10](#)).

### Hyponatraemia with hypovolaemia

In this situation there is depletion of sodium and water but the sodium deficit exceeds the water deficit, causing hypovolaemia and hyponatraemia (see [Box 19.3](#)). The cause of sodium loss is usually apparent and common examples are shown in [Box 19.10](#).

19.10 Causes of hyponatraemia	
Volume status	Examples
<b>Hypovolaemic</b>	Renal sodium losses: Diuretic therapy (especially thiazides) Adrenocortical failure Gastrointestinal sodium losses: Vomiting Diarrhoea Skin sodium losses: Burns
<b>Euvolaemic</b>	Primary polydipsia Excessive electrolyte-free water infusion SIADH Hypothyroidism
<b>Hypervolaemic</b>	Congestive cardiac failure Cirrhosis Nephrotic syndrome Chronic kidney disease (during free water intake)

(SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion; see [Box 19.11](#)).

### Hyponatraemia with euvolaemia

In this situation there are no major disturbances of body sodium content and the patient is clinically euvolaemic. Excess body water may be the result of abnormally high intake, either orally (primary polydipsia) or as a result of medically infused fluids (as intravenous dextrose solutions, or by absorption of sodium-free bladder irrigation fluid after prostatectomy).

Water retention also occurs in the syndrome of inappropriate secretion of antidiuretic hormone, or vasopressin (SIADH). In this condition, an endogenous source of vasopressin (either cerebral or tumour-derived) promotes water retention by the kidney in the absence of an appropriate physiological stimulus ([Box 19.11](#)). The clinical diagnosis requires the patient to be euvolaemic, with no evidence of cardiac, renal or hepatic disease potentially associated with hyponatraemia. Other non-osmotic stimuli that cause release of vasopressin (pain, stress, nausea) should also be excluded. Supportive laboratory findings are shown in [Box 19.11](#).

### Hyponatraemia with hypervolaemia

In this situation, excess water retention is associated with sodium retention and volume expansion, as in heart failure, liver disease or kidney disease.

### Clinical features

Hyponatraemia is often asymptomatic but can also be associated with profound disturbances of cerebral function, manifesting as anorexia, nausea, vomiting, delirium, lethargy, seizures and coma. The likelihood of symptoms occurring is related to the speed at which hyponatraemia develops rather than the severity of hyponatraemia. This is because water rapidly flows into cerebral cells when plasma osmolality falls acutely, causing them to become swollen and ischaemic. However, when hyponatraemia develops gradually, cerebral neurons have time to respond by reducing intracellular osmolality, through excreting potassium and reducing synthesis of intracellular organic osmolytes ([Fig. 19.6](#)). The osmotic gradient favouring water movement into the cells is thus reduced and symptoms are avoided. This process takes about 24–48 hours and hyponatraemia is therefore classified as acute ( $<48$  hrs) and chronic ( $>48$  hrs). Hyponatraemia can also be defined as mild (130–135 mmol/L), moderate (125–129 mmol/L) or severe ( $<124$  mmol/L), based on biochemical findings or on the degree of severity of symptoms ([Box 19.12](#)).

### Investigations

An algorithm for the clinical assessment of patients with hyponatraemia is shown in [Figure 19.7](#). Artefactual causes of hyponatraemia should be considered in all cases. These include severe hyperlipidaemia or hyperproteinaemia, when the aqueous fraction of the serum specimen

19.11 Causes and diagnosis of syndrome of inappropriate antidiuretic hormone secretion (SIADH)	
<b>Causes</b>	
<ul style="list-style-type: none"> <li>• Tumours</li> <li>• Central nervous system disorders: stroke, trauma, infection, psychosis, porphyria</li> <li>• Pulmonary disorders: pneumonia, tuberculosis, obstructive lung disease</li> <li>• Drugs: anticonvulsants, psychotropics, antidepressants, cytotoxics, oral hypoglycaemic agents, opiates</li> <li>• Idiopathic</li> </ul>

**Fig. 19.6 Hyponatraemia and the brain.** Numbers represent osmolality (osmo) in mOsm/kg.

### 19.12 Symptoms and severity of hyponatraemia

Severity	Serum sodium	Symptoms
Mild	130–135 mmol/L	None
Moderate	125–129 mmol/L	Nausea Delirium Headache
Severe	<124 mmol/L	Vomiting Somnolence Seizures Coma Cardiorespiratory arrest

is reduced because of the volume occupied by the macromolecules (although this artefact is dependent on the assay technology). Transient hyponatraemia may also occur due to osmotic shifts of water out of cells during hyperosmolar states caused by acute hyperglycaemia or by mannitol infusion, but in these cases plasma osmolality is normal.

When these conditions have been excluded, serum and urine electrolytes and osmolality (Fig. 19.7) are usually the only tests required to clarify the underlying cause. Hypovolaemic hyponatraemia is characterised by a low urinary sodium concentration (<30 mmol/L) when there are extrarenal causes of sodium loss and high urinary sodium concentration (>30 mmol/L) in patients with excessive renal sodium loss.

Measurement of vasopressin is not generally helpful in distinguishing between different categories of hyponatraemia. This is because

concentrations of vasopressin are raised both in hypovolaemic states and in most chronic hypervolaemic states, as the impaired circulation in those disorders activates vasopressin release through non-osmotic mechanisms. Indeed, patients with these disorders may have higher circulating vasopressin (ADH) levels than patients with SIADH. The only disorders listed in Box 19.10 in which vasopressin is suppressed are primary polydipsia and iatrogenic water intoxication, where the hypo-osmolar state inhibits vasopressin release from the pituitary. Plasma vasopressin measurements are no longer used in routine practice since it is unstable and have been replaced by measurements of copeptin. This is a peptide derived from the carboxyl terminal of the vasopressin precursor and acts as a surrogate for vasopressin. Copeptin measurements can be useful in the differential diagnosis of patients with the combination of hyponatraemia and polyuria.

### Management

The treatment of hyponatraemia is critically dependent on its rate of development, severity, presence of symptoms and underlying cause. If hyponatraemia has developed rapidly (<48 hrs) and there are signs of cerebral oedema, such as obtundation or convulsions, sodium levels should be restored rapidly to normal by infusion of hypertonic (3%) sodium chloride. A common approach is to give an initial bolus of 150 mL over 20 minutes, which may be repeated once or twice over the initial hours of observation, depending on the neurological response and rise in plasma sodium.

Rapid correction of hyponatraemia that has developed more slowly (>48 hrs) can be hazardous, since brain cells adapt to slowly developing hypo-osmolality by reducing the intracellular osmolality, thus maintaining normal cell volume (see Fig. 19.6). Under these conditions, an abrupt increase in extracellular osmolality can lead to water shifting out of neurons, abruptly reducing their volume and causing them to detach from their myelin sheaths. The resulting 'myelinolysis' can produce permanent structural and functional damage to mid-brain structures, and is generally fatal. The rate of correction of the plasma Na concentration in chronic asymptomatic hyponatraemia should not exceed 10 mmol/L/24 hrs, and an even slower rate is generally safer.

The underlying cause should also be treated. For hypovolaemic patients, this involves controlling the source of sodium loss, and administering intravenous saline if clinically warranted. Patients with euvolaemic hyponatraemia generally respond to fluid restriction in the range of 600–1000 mL/24 hrs, accompanied where possible by withdrawal of the precipitating stimulus (such as drugs causing SIADH). In patients with persistent hyponatraemia due to prolonged SIADH, oral urea therapy (30–45 g/day) can be used, which provides a solute load to promote water excretion. Oral vasopressin receptor antagonists such as tolvaptan may also be used to block the vasopressin-mediated component of water retention in a range of hyponatraemic conditions, but concerns exist with regard to the risk of overly rapid correction of hyponatraemia with these agents. Hypervolaemic patients with hyponatraemia need treatment of the underlying condition, accompanied by cautious use of diuretics in conjunction with strict fluid restriction. Potassium-sparing diuretics may be particularly useful in this context when there is significant secondary hyperaldosteronism.

### Hypernatraemia

Hypernatraemia is defined to exist when the serum Na is >145 mmol/L. The causes are summarised in Box 19.13, grouped according to any associated disturbance in total body sodium content.

#### Pathophysiology

Hypernatraemia occurs due to inadequate concentration of the urine in the face of restricted water intake. This can arise because of failure to generate an adequate medullary concentration gradient in the kidney due to low GFR or loop diuretic therapy, but more commonly is caused by failure of the vasopressin system. This can occur because of pituitary damage (cranial diabetes insipidus) or because the collecting duct cells are

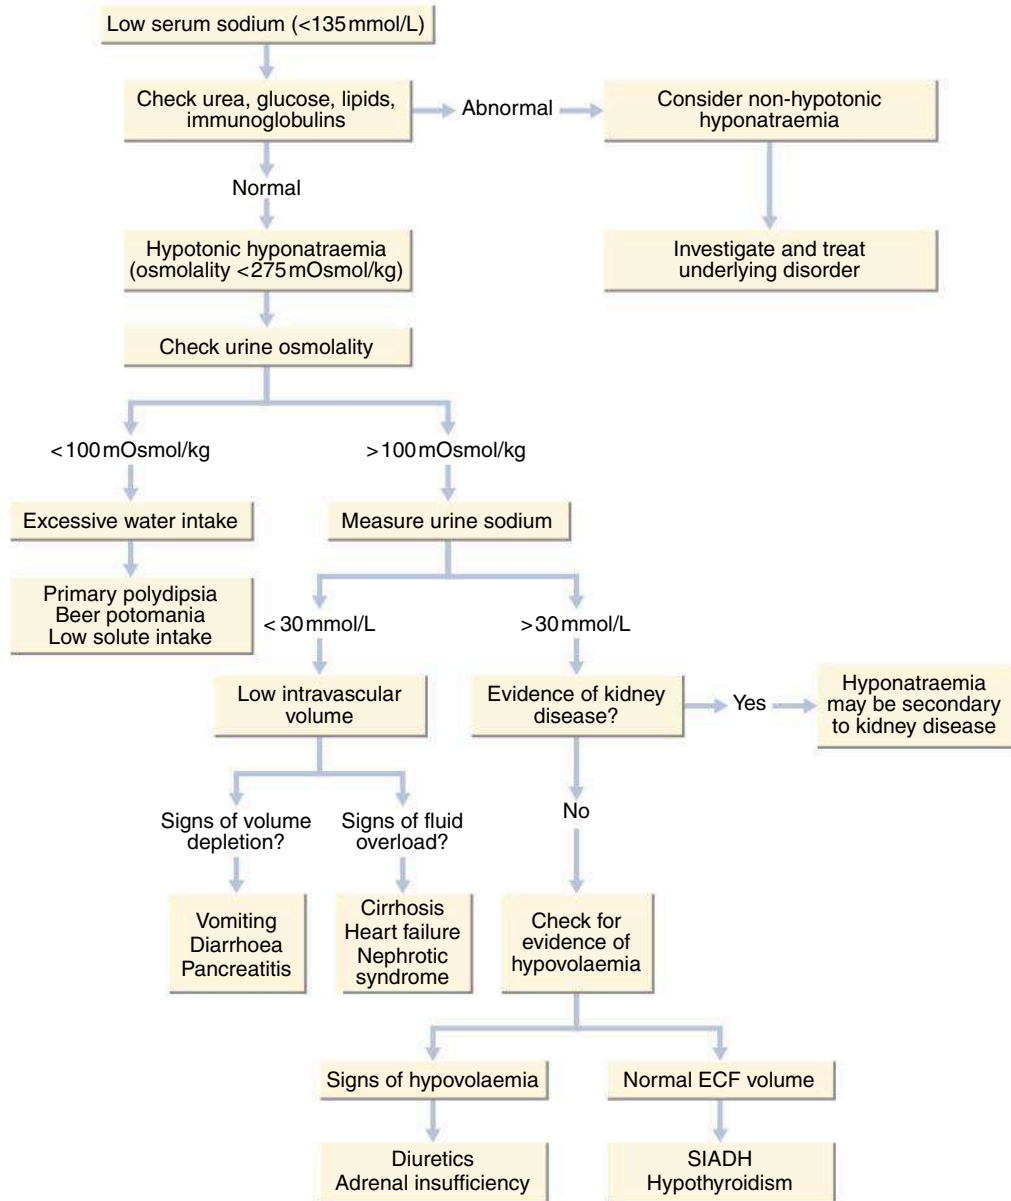

Fig. 19.7 Algorithm for the diagnosis of hyponatraemia. (ECF = extracellular fluid; SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion)

19.13 Causes of hypernatraemia	
Volume status	Examples
<b>Hypovolaemic</b>	Renal sodium losses: Diuretic therapy (especially osmotic diuretic, or loop diuretic during water restriction) Glycosuria (hyperglycaemic hyperosmolar state) Gastrointestinal sodium losses: Colonic diarrhoea Skin sodium losses: Excessive sweating
<b>Euvolaemic</b>	Diabetes insipidus (central or nephrogenic)
<b>Hypervolaemic</b>	Enteral or parenteral feeding Intravenous or oral salt administration Chronic kidney disease (during water restriction)

unable to respond to circulating vasopressin concentrations in the face of restricted water intake (nephrogenic diabetes insipidus). Whatever the underlying cause, sustained or severe hypernatraemia generally reflects an impaired thirst mechanism or responsiveness to thirst.

### Clinical features

Patients with hypernatraemia generally have reduced cerebral function, either as a primary problem or as a consequence of the hypernatraemia itself, which results in dehydration of neurons and brain shrinkage. In the presence of an intact thirst mechanism and preserved capacity to obtain and ingest water, hypernatraemia may not progress very far. If adequate water is not obtained, dizziness, delirium, weakness and, ultimately, coma and death can result.

As outlined above, copeptin can be used in the diagnosis of water regulation disorders as a surrogate marker of vasopressin release. It is used in this regard to distinguish between central and nephrogenic diabetes insipidus.

### Management

Treatment of hypernatraemia depends on both the rate of development and the underlying cause. If there is reason to think that the condition has developed rapidly, neuronal shrinkage may be acute and relatively rapid correction may be attempted. This can be achieved by infusing an appropriate volume of intravenous fluid (isotonic 5% dextrose or hypotonic 0.45% saline) at an initial rate of 50–70 mL/hr. In older, institutionalised patients, however, it is more likely that the disorder has developed slowly, and extreme caution should be exercised in lowering plasma sodium to

### 19.14 Hyponatraemia and hypernatraemia in old age

- **Decline in GFR:** older patients are predisposed to both hyponatraemia and hypernatraemia, mainly because, as glomerular filtration rate declines with age, the capacity of the kidney to dilute or concentrate the urine is impaired.
- **Hyponatraemia:** occurs when free water intake continues in the presence of a low dietary salt intake and/or diuretic drugs (particularly thiazides).
- **Vasopressin release:** water retention is aggravated by any condition that stimulates vasopressin release, especially heart failure. Moreover, the vasopressin response to non-osmotic stimuli may be brisker in older subjects. Appropriate water restriction may be a key part of management.
- **Hypernatraemia:** occurs when water intake is inadequate, due to physical restrictions preventing access to drinks and/or blunted thirst. Both are frequently present in patients with advanced dementia or following a severe stroke.
- **Dietary salt:** hypernatraemia is aggravated if dietary supplements or medications with a high sodium content (especially effervescent preparations) are administered. Appropriate prescription of fluids is a key part of management.

avoid the risk of cerebral oedema. Where possible, the underlying cause should also be addressed (see [Box 19.13](#)).

Older adult patients are predisposed, in different circumstances, to both hyponatraemia and hypernatraemia, and a high index of suspicion of these electrolyte disturbances is appropriate in older patients with recent alterations in behaviour ([Box 19.14](#)).

## Potassium homeostasis

Potassium is the major intracellular cation (see [Fig. 19.1](#)), and the steep concentration gradient for potassium across the cell membrane of excitable cells plays an important part in generating the resting membrane potential and allowing the propagation of the action potential that is crucial to normal functioning of nerve, muscle and cardiac tissues. Control of body potassium balance is described below.

### Functional anatomy and physiology

The kidneys normally excrete some 90% of the daily intake of potassium, typically 80–100mmol/24 hrs. Potassium is freely filtered at the glomerulus; around 65% is reabsorbed in the proximal tubule and a further 25% in the thick ascending limb of the loop of Henle. Little potassium is transported in the early distal tubule but a significant secretory flux of potassium into the urine occurs in the late distal tubule and cortical collecting duct to ensure that the amount removed from the blood is proportional to the ingested load.

The mechanism for potassium secretion in the distal parts of the nephron is shown in panel (D) of [Figure 19.2](#). Movement of potassium from blood to lumen is dependent on active uptake across the basal cell membrane by the Na,K-ATPase, followed by diffusion of potassium through the ROMK channel into the tubular fluid. The electrochemical gradient for potassium movement into the lumen is contributed to both by the high intracellular potassium concentration and by the negative luminal potential difference relative to the blood.

A number of factors influence the rate of potassium secretion. Luminal influences include the rate of sodium delivery and fluid flow through the late distal tubule and cortical collecting ducts. This is a major factor responsible for the increased potassium loss that accompanies diuretic treatment. Agents interfering with the generation of the negative luminal potential also impair potassium secretion, and this is the basis of reduced potassium secretion associated with potassium-sparing diuretics such as amiloride. Factors acting on the blood side of this tubular segment include plasma potassium and pH, such that hyperkalaemia and alkalosis both enhance potassium secretion directly. However, the most important factor in the acute and chronic adjustment of potassium secretion to match metabolic potassium load is aldosterone.

**Fig. 19.8** Feedback control of plasma potassium concentration.

As shown in [Figure 19.8](#), a negative feedback relationship exists between the plasma potassium concentration and aldosterone. In addition to its regulation by the renin–angiotensin system (see [Fig. 20.19](#)), aldosterone is released from the adrenal cortex in direct response to an elevated plasma potassium. Aldosterone then acts on the kidney to enhance potassium secretion, hydrogen secretion and sodium reabsorption, in the late distal tubule and cortical collecting ducts. The resulting increase in excretion of potassium maintains plasma potassium within a narrow range (3.5–5.0 mmol/L). Factors that reduce angiotensin II levels may indirectly affect potassium balance by blunting the rise in aldosterone that would otherwise be provoked by hyperkalaemia. This accounts for the increased risk of hyperkalaemia during therapy with ACE inhibitors and related drugs.

### Presenting problems in potassium homeostasis

Changes in the distribution of potassium between the ICF and ECF compartments can alter plasma potassium concentration, without any overall change in total body potassium content. Potassium is driven into the cells by extracellular alkalosis and by a number of hormones, including insulin, catecholamines (through the  $\beta_2$ -receptor) and aldosterone. Any of these factors can produce hypokalaemia, whereas extracellular acidosis, lack of insulin and insufficiency or blockade of catecholamines or aldosterone can cause hyperkalaemia due to efflux of potassium from the intracellular compartment.

### Hypokalaemia

Hypokalaemia is a common electrolyte disturbance and is defined as existing when serum K<sup>+</sup> falls below 3.5mmol/L. The main causes of hypokalaemia are shown in [Box 19.15](#).

#### Pathophysiology

Hypokalaemia is generally indicative of abnormal potassium loss from the body, through either the kidney or the gastrointestinal tract. Renal causes of hypokalaemia can be divided into those with and those without hypertension. Hypokalaemia in the presence of hypertension may be due to increased aldosterone secretion in Conn syndrome or a genetic defect affecting sodium channels in the distal nephron (Liddle syndrome). Excessive intake of liquorice or treatment with carbenoxolone may result in a similar clinical picture, due to inhibition of the renal 11 $\beta$ HSD2 enzyme, which inactivates cortisol in peripheral tissues.

If blood pressure is normal or low, hypokalaemia can be classified according to the associated change in acid–base balance. Inherited

19.15 Causes of hypokalaemia	
Cause	Other features and comment
<b>Reduced intake</b> Dietary deficiency Potassium-free intravenous fluids	Urine K <sup>+</sup> <20–30 mmol/24 hrs
<b>Redistribution into cells</b> Alkalosis Insulin Catecholamines β-adrenergic agonists Hypokalaemic periodic paralysis	Caused by flux of K <sup>+</sup> into cells
<b>Increased urinary excretion</b> Activation of mineralocorticoid receptor: Conn syndrome Cushing's syndrome Glucocorticoid excess Carbenoxolone/liquorice	Urine K <sup>+</sup> > 20–30 mmol/24 hrs  Associated with hypertension with alkalosis
Genetic disorders: Liddle syndrome	Associated with hypertension with alkalosis
Bartter syndrome Gitelman syndrome	Associated with alkalosis and hypomagnesaemia
Renal tubular acidosis Type 1 (distal) Type 2 (proximal)	Inherited and acquired forms; associated with high serum chloride. Type 2 associated with glycosuria, aminoaciduria and phosphaturia
Acetazolamide	Associated with acidosis
Diuresis: Loop diuretics Thiazides Recovery from acute tubular necrosis Recovery from renal obstruction	Increased sodium delivery to distal tubule
<b>Increased gastrointestinal loss</b> Upper gastrointestinal tract: Vomiting Nasogastric aspiration	Urine K <sup>+</sup> <20–30 mmol/L  Loss of gastric acid Associated with metabolic alkalosis
Lower gastrointestinal tract: Diarrhoea Laxative abuse Villous adenoma Bowel obstruction/fistula Ureterosigmoidostomy	Associated with metabolic acidosis

defects in tubular transport should be suspected when hypokalaemia occurs in association with hypotension and alkalosis, provided that diuretic use has been excluded. One such disease is Bartter syndrome, in which sodium reabsorption in the thick ascending limb of Henle is defective, usually due to a loss-of-function variant of the *NKCC2* transporter. The clinical and biochemical features are similar to those in chronic treatment with furosemide. In Gitelman syndrome there is a loss-of-function variant affecting the *NCCT* transporter in the early distal tubule. The clinical and biochemical features are similar to chronic thiazide treatment. Note that while both Bartter and Gitelman syndromes are characterised by hypokalaemia and hypomagnesaemia, urinary calcium excretion is increased in Bartter syndrome but decreased in Gitelman syndrome, analogous to the effects of the loop and thiazide diuretics, respectively, on calcium transport (see [Box 19.9](#)).

If hypokalaemia occurs in the presence of a normal blood pressure and metabolic acidosis, renal tubular acidosis (proximal or 'classical' distal) should be suspected.

When hypokalaemia is due to potassium wasting through the gastrointestinal tract, the cause is usually obvious clinically. In some cases, when there is occult induction of vomiting, hypokalaemia is characteristically associated with metabolic alkalosis, due to loss of gastric acid. If, however, potassium loss has occurred through the surreptitious use of aperients, the hypokalaemia is generally associated with metabolic acidosis. In both cases, urinary potassium excretion is low unless there is significant extracellular volume depletion, which can raise urinary potassium levels by stimulating aldosterone production.

Hypokalaemia can also be caused by redistribution of potassium into cells as outlined above or as the result of K<sup>+</sup> flux into muscle in hypokalaemic periodic paralysis, which is associated with variants in several genes that regulate transmembrane ion flow into muscle cells. Finally, reduced dietary intake of potassium can contribute to hypokalaemia but is seldom the only cause, except in extreme cases.

### Clinical features

Patients with mild hypokalaemia (plasma K<sup>+</sup> 3.0–3.5 mmol/L) are generally asymptomatic, but more profound reductions in plasma potassium often lead to muscular weakness and associated tiredness. Ventricular ectopic beats or more serious arrhythmias may occur and the arrhythmogenic effects of digoxin may be potentiated. Typical electrocardiogram (ECG) changes occur, affecting the T wave in particular. Functional bowel obstruction may occur due to paralytic ileus. Long-standing hypokalaemia may cause renal tubular damage (hypokalaemic nephropathy) and can interfere with the tubular response to vasopressin (acquired nephrogenic diabetes insipidus), resulting in polyuria and polydipsia.

### Investigations

Measurement of plasma electrolytes, bicarbonate, urine potassium and sometimes of plasma calcium and magnesium is usually sufficient to establish the diagnosis. If the diagnosis remains unclear, plasma renin should be measured. Levels are low in patients with primary hyperaldosteronism and other forms of mineralocorticoid excess, but raised in other causes of hypokalaemia. Measurement of urinary potassium may also be helpful; if the kidney is the route of potassium loss, the urine potassium is high (>30 mmol/24 hrs), whereas if potassium is being lost through the gastrointestinal tract, the kidney retains potassium, resulting in a lower urinary potassium (generally <20 mmol/24 hrs). It should be noted, however, that if gastrointestinal fluid loss is also associated with hypovolaemia, activation of the renin–angiotensin–aldosterone system may occur, causing increased loss of potassium in the urine.

The cause of hypokalaemia may remain unclear despite the above investigations when urinary potassium measurements are inconclusive and the history is incomplete or unreliable. Many such cases are associated with metabolic alkalosis, and in this setting the measurement of urine chloride concentration can be helpful. A low urine chloride (<30 mmol/L) is characteristic of vomiting (spontaneous or self-induced, in which chloride is lost in HCl in the vomit), while a urine chloride >40 mmol/L suggests diuretic therapy (acute phase) or a tubular disorder such as Bartter or Gitelman syndromes. Differentiation between occult diuretic use and primary tubular disorders can be achieved by performing a screen of urine for diuretic drugs.

### Management

Treatment of hypokalaemia involves first determining the cause and correcting this where possible. If the problem is mainly one of redistribution of potassium into cells, reversal of the process responsible may be sufficient to restore plasma potassium without providing supplements. In most cases, however, some form of potassium replacement will be required. This can generally be achieved with slow-release potassium chloride tablets, but in more acute circumstances intravenous potassium chloride may be necessary. The rate of administration depends on the severity of hypokalaemia and the presence of cardiac or neuromuscular

complications, but should generally not exceed 10mmol of potassium per hour. In patients with severe, life-threatening hypokalaemia, infusion rates of up to 20mmol/hr can be used with continuous cardiac monitoring.

In the less common situation where hypokalaemia occurs in the presence of metabolic acidosis, alkaline salts of potassium, such as potassium bicarbonate, can be given by mouth. If magnesium depletion is also present, replacement of magnesium may also be required, since low cellular magnesium can promote tubular potassium secretion, causing ongoing urinary losses. In some circumstances, potassium-sparing diuretics, such as amiloride, can assist in the correction of hypokalaemia, hypomagnesaemia and metabolic alkalosis, especially when renal loss of potassium is the underlying cause.

## Hyperkalaemia

Hyperkalaemia is a common electrolyte disorder, which is defined as existing when serum  $K^+$  is  $>5$ mmol/L. The causes of hyperkalaemia are summarised in [Box 19.16](#).

### Pathophysiology

It is important to remember that hyperkalaemia can be artefactual due to haemolysis of blood specimens during collection or in vitro, or due to release of potassium from platelets in patients with thrombocytosis.

True hyperkalaemia, however, can occur either because of redistribution of potassium between the ICF and ECF, or because potassium intake exceeds excretion. Redistribution of potassium from the ICF to the ECF may take place in the presence of systemic acidosis, or when the circulating levels of insulin, catecholamines and aldosterone are reduced, or when the effects of these hormones are blocked.

High dietary potassium intake may contribute to hyperkalaemia, but is seldom the only explanation unless renal excretion mechanisms are impaired. The mechanism of hyperkalaemia in acute kidney injury and chronic kidney disease is impaired excretion of potassium into the urine as the result of a reduced GFR. In addition, acute kidney injury can be associated with severe hyperkalaemia when there is an increased potassium load, such as in rhabdomyolysis or in sepsis, particularly when acidosis is present. In chronic kidney disease, adaptation to moderately elevated plasma potassium levels commonly occurs. However, acute rises in potassium triggered by excessive dietary intake, hypovolaemia or drugs (see below) may occur and destabilise the situation.

Hyperkalaemia can also develop when tubular potassium secretory processes are impaired, even if the GFR is normal. This can arise in association with low levels of aldosterone, as is found in Addison's disease, hyporeninaemic hypoaldosteronism or inherited disorders such as congenital isolated hypoaldosteronism, in which there is a defect in aldosterone biosynthesis, and pseudohypoaldosteronism type 2 (Gordon syndrome), caused by variants in the *WNK2* and *WNK4* genes, which causes decreased potassium secretion in the renal tubules.

Drug-induced causes include ACE inhibitors, angiotensin-receptor blockers (ARBs), non-steroidal anti-inflammatory drugs (NSAIDs) and  $\beta$ -adrenoceptor antagonists ( $\beta$ -blockers). In aldosterone deficiency or aldosterone resistance, hyperkalaemia may be associated with acid retention, giving rise to the pattern of hyperkalaemic distal ('type 4') renal tubular acidosis.

In another group of conditions, tubular potassium secretion is impaired as the result of aldosterone resistance. This can occur in a variety of diseases in which there is inflammation of the tubulointerstitium, such as systemic lupus erythematosus; following renal transplantation; during treatment with potassium-sparing diuretics; and in a number of inherited disorders of tubular transport.

### Clinical features

Mild to moderate hyperkalaemia ( $<6.5$ mmol/L) is usually asymptomatic. More severe hyperkalaemia can present with progressive muscular weakness, but sometimes there are no symptoms until cardiac arrest

19.16 Causes of hyperkalaemia	
Cause	Other features and comment
<b>Artefactual</b> Haemolysis during venepuncture Haemolysis in vitro Thrombocytosis/leucocytosis	Release of intracellular $K^+$ during sample collection, transit or clotting
<b>Increased intake</b> Dietary potassium Potassium-containing intravenous fluids	
<b>Redistribution from cells</b> Acidosis Insulin deficiency Severe hyperglycaemia $\beta$ -blockers Hyperkalaemic periodic paralysis Rhabdomyolysis Severe haemolysis Tumour lysis syndrome	Caused by flux of intracellular $K^+$ into plasma
<b>Reduced urinary excretion</b> Reduced glomerular filtration: Acute kidney injury Chronic kidney disease Reduced mineralocorticoid receptor activation: Addison's disease Congenital adrenal hyperplasia Isolated aldosterone deficiency ACE inhibitors Angiotensin-receptor blockers Calcineurin inhibitors Spironolactone Eplerenone Heparin Inhibitors of renin production: Non-steroidal anti-inflammatory drugs $\beta$ -blockers Tubulointerstitial disease: Interstitial nephritis Diabetic nephropathy Obstructive uropathy Other: Amiloride Gordon syndrome	Plasma creatinine typically $>500$ $\mu\text{mol/L}$ (5.67 mg/dL) Both reduce aldosterone levels All block the mineralocorticoid receptor Inhibits aldosterone production Blocks $K^+$ exchange in distal tubule Direct effect on $K^+$ transport in renal tubule

occurs. The typical ECG changes are shown on page 615. Peaking of the T wave is an early ECG sign but widening of the QRS complex presages a dangerous cardiac arrhythmia. However, these characteristic ECG findings are not always present, even in severe hyperkalaemia.

### Investigations

Measurement of electrolytes, creatinine and bicarbonate, when combined with clinical assessment, usually provides the explanation for hyperkalaemia. In aldosterone deficiency, plasma sodium concentration is characteristically low, although this can occur with many causes of hyperkalaemia. Addison's disease should be excluded unless there is an obvious alternative diagnosis

### Management

Treatment of hyperkalaemia depends on its severity and the rate of development, but opinions vary as to what level of serum potassium constitutes severe hyperkalaemia and requires urgent treatment.

19.17 Treatment of severe hyperkalaemia	
Objective	Therapy
Stabilise cell membrane potential <sup>1</sup>	IV calcium gluconate (10 mL of 10% solution)
Shift K <sup>+</sup> into cells	Inhaled $\beta_2$ -adrenoceptor agonist IV glucose (50 mL of 50% solution) and 5–10 IU rapidly acting insulin IV sodium bicarbonate <sup>2</sup>
Remove K <sup>+</sup> from body	IV furosemide and normal saline <sup>3</sup> Ion-exchange resin orally or rectally Dialysis

<sup>1</sup>If severe hyperkalaemia (K<sup>+</sup> typically > 6.5 mmol/L). <sup>2</sup>If acidosis present. <sup>3</sup>If adequate residual renal function.  
(IV = intravenous)

Patients who have potassium concentrations <6.5 mmol/L in the absence of neuromuscular symptoms or ECG changes can be treated with a reduction of potassium intake and correction of predisposing factors. However, in acute and/or severe hyperkalaemia (plasma potassium >6.5–7.0 mmol/L), more urgent measures must be taken (Box 19.17). The first step should be infusion of 10 mL 10% calcium gluconate to stabilise conductive tissue membranes (calcium has the opposite effect to potassium on conduction of an action potential). Measures to shift potassium from the ECF to the ICF should also be applied, as they generally have a rapid effect and may avert arrhythmias. Ultimately, a means of removing potassium from the body is generally necessary. When renal function is reasonably preserved, loop diuretics (accompanied by intravenous saline if hypovolaemia is present) may be effective. In renal failure, dialysis may be required. Ion exchange resins, such as calcium resonium (which can be given orally or rectally) and oral sodium polystyrene sulfonate (SPS), have traditionally been used to bind and excrete gastrointestinal potassium. There are concerns, however, with regard to SPS's lack of proven efficacy and safety, with a number of reports of intestinal necrosis associated with its use. Newer cation exchange resins, which include sodium zirconium cyclosilicate and patiomer sorbitex calcium, have been developed. These are safe and effective treatments for hyperkalaemia and are preferred to SPS. However, they are not yet available in all countries for this indication.

## Acid–base homeostasis

The pH of arterial plasma is normally 7.40, corresponding to an H<sup>+</sup> concentration of 40 nmol/L, and under normal circumstances H<sup>+</sup> concentrations do not vary outside the range of 37–45 nmol/L (pH 7.35–7.43). Abnormalities of acid–base balance can occur in a wide range of diseases. Increases in H<sup>+</sup> concentration cause acidosis with a decrease in pH, whereas decreases in H<sup>+</sup> concentration cause alkalosis with a rise in pH.

## Functional anatomy and physiology

A variety of physiological mechanisms maintain pH of the ECF within narrow limits. The first is the action of blood and tissue buffers, of which the most important involves reaction of H<sup>+</sup> ions with bicarbonate to form carbonic acid, which, under the influence of the enzyme carbonic anhydrase (CA), dissociates to form CO<sub>2</sub> and water:

This buffer system is important because bicarbonate is present at a relatively high concentration in ECF (21–29 mmol/L), and two of its key components are under physiological control: CO<sub>2</sub> by the lungs, and bicarbonate by the kidneys. These relationships are illustrated in Figure 19.9 (a form of the Henderson–Hasselbalch equation).

Respiratory compensation for acid–base disturbances can occur quickly. In response to acid accumulation, pH changes in the brainstem stimulate ventilatory drive which reduces PCO<sub>2</sub> and subsequently increases pH. Conversely, systemic alkalosis leads to inhibition of ventilation, causing a rise in PCO<sub>2</sub> and reduction in pH, although it should be noted that this mechanism has limited capacity to change pH because hypoxia provides an alternative stimulus to drive ventilation.

The kidneys provide a third line of defence against disturbances of arterial pH. When acid accumulates due to chronic respiratory or metabolic (non-renal) causes, the kidneys have the capacity to enhance urinary excretion of acid, effectively increasing the plasma bicarbonate.

## Renal control of acid–base balance

Regulation of acid–base balance occurs at several sites in the kidney. The proximal tubule reabsorbs about 85% of the filtered bicarbonate ions, through the mechanism illustrated in panel (A) in Figure 19.2. This is dependent on the enzyme carbonic anhydrase, which is present both in the cytoplasm of the proximal tubular cells and on the luminal surface of the brush border membranes. The system has a high capacity for reabsorption of filtered bicarbonate but does not lead to significant acidification of the luminal fluid.

Distal nephron segments also have an important role in bicarbonate reabsorption and acid excretion. Dissociation of H<sub>2</sub>CO<sub>3</sub> occurs in the distal tubular cells, under the influence of carbonic anhydrase generating H<sup>+</sup> ions and HCO<sub>3</sub><sup>-</sup> ions. The H<sup>+</sup> ions are secreted into the lumen by an H<sup>+</sup>-ATPase in the alpha intercalated cells of the cortical collecting duct and the outer medullary collecting duct cells and the HCO<sub>3</sub><sup>-</sup> passes across the basolateral membrane into the blood. Within the tubular lumen, H<sup>+</sup> combines with hydrogen phosphate (HPO<sub>4</sub><sup>2-</sup>) in the distal tubular lumen to form dihydrogen phosphate (H<sub>2</sub>PO<sub>4</sub><sup>-</sup>), which is excreted in the urine with sodium. Similarly, H<sup>+</sup> combines with NH<sub>3</sub> in the luminal fluid to form ammonium (NH<sub>4</sub><sup>+</sup>) ions, which are trapped and excreted in the urine combined with chloride ions. The NH<sub>3</sub> necessary for this reaction is generated in tubular cells by the enzyme glutaminase which acts on the amino acid glutamine. Both of these buffers help to prevent the urinary pH falling below 5, which would create an unfavourable gradient that would stop further secretion of H<sup>+</sup> ions into the urine.

Titrateable acid and ammonium excretion removes approximately 1 mmol/kg of hydrogen ions from the body per day, which equates to the non-volatile acid load arising from the metabolism of dietary protein. The slightly alkaline plasma pH of 7.4 (H<sup>+</sup> 40 nmol/L) that is maintained

**Fig. 19.9** Relationship between pH, PCO<sub>2</sub> (in mmHg) and plasma bicarbonate concentration (in mmol/L). \*Note that changes in HCO<sub>3</sub><sup>-</sup> concentration are also part of the renal correction for sustained metabolic acid–base disturbances as long as the kidney itself is not the cause of the primary disturbance.

during health can be accounted for by the kidney's ability to generate an acidic urine (typically pH 5–6 ( $H^+$  1000–10 000 nmol/L), in which the net daily excess of metabolic acid produced by the body can be excreted.

## Presenting problems in acid–base balance

Patients with disturbances of acid–base balance may present clinically either with the effects of tissue malfunction due to disturbed pH (such as altered cardiac and central nervous system function), or with secondary changes in respiration that occur as a response to the underlying metabolic change (such as Kussmaul respiration during metabolic acidosis). The clinical picture is often dominated by the underlying cause rather than the acid–base abnormality itself. Frequently, acid–base disturbances only become evident when the venous plasma bicarbonate concentration is measured and found to be abnormal, or when blood gas analysis shows abnormalities in pH,  $PCO_2$  or bicarbonate.

The most common patterns of abnormality in blood gas parameters are shown in Box 19.18. Interpretation of arterial blood gases in respiratory failure is described in Box 17.16.

In metabolic disturbances, respiratory compensation is almost immediate, so that the predicted compensatory change in  $PCO_2$  is achieved soon after the onset of the metabolic disturbance. In respiratory disorders, on the other hand, a small initial change in bicarbonate occurs as a result of chemical buffering of  $CO_2$ , chiefly within red blood cells, but over days and weeks the kidney achieves further compensatory changes in bicarbonate concentration as a result of chronic adjustments in acid secretory capacity. When the clinically obtained acid–base parameters do not accord with the predicted compensation shown, a mixed acid–base disturbance should be suspected.

## Metabolic acidosis

Metabolic acidosis occurs when an acid other than carbonic acid (due to  $CO_2$  retention) accumulates in the body, resulting in a fall in the plasma bicarbonate. The causes of metabolic acidosis are summarised in Box 19.19, subdivided into two categories, depending on whether the anion gap is normal or raised. When plasma bicarbonate falls, another anion needs to take its place. This is either chloride (normal anion gap) or an unmeasured anion (raised anion gap). The causes are discussed in more detail below.

### Pathophysiology

Metabolic acidosis with a normal anion gap occurs when there is poisoning with or therapeutic infusion of a chloride-containing acid such as hydrochloric acid or ammonium chloride or when there is a primary loss of bicarbonate from the ECF (via the GI tract or from the kidneys). Renal tubular acidosis (RTA) can be caused by a defect in one of three processes:

- impaired bicarbonate reabsorption in the proximal tubule (proximal RTA)
- impaired acid secretion in the late distal tubule or cortical collecting duct intercalated cells (classical distal RTA)

- impaired sodium reabsorption in the late distal tubule or cortical collecting duct, which is associated with reduced secretion of both potassium and  $H^+$  ions (hyperkalaemic distal RTA).

Various subtypes of RTA are recognised and the most common causes are shown in Box 19.20. The inherited forms of RTA are due to variants in the genes that regulate acid or bicarbonate transport in the renal tubules (see Fig. 19.2).

Acidosis with an increased anion gap is most commonly seen in ketoacidosis, lactic acidosis and late kidney failure, where there is endogenous production of anions distinct from  $Cl^-$  and  $HCO_3^-$ . Ketoacidosis is caused by insulin deficiency and is exacerbated by catecholamine and stress hormone excess, which combine to cause lipolysis and the formation of acidic ketones (acetoacetate, 3-hydroxybutyrate and acetone). The most common cause of ketoacidosis is diabetic ketoacidosis (DKA); its aetiology and management are discussed in Chapter 21. Starvation ketoacidosis occurs when there is reduced food intake in situations of high glucose demand, such as in neonates, and in pregnant or breast-feeding women. In alcoholic ketoacidosis, there is usually a background of chronic malnutrition and a recent alcohol binge. Two subtypes of lactic acidosis have been defined:

19.19 Causes of metabolic acidosis	
Disorder	Mechanism
<b>Normal anion gap</b>	
Ingestion or infusion of inorganic acid	Therapeutic infusion of or poisoning with $NH_4Cl$ , HCl
Gastrointestinal $HCO_3^-$ loss	Loss of $HCO_3^-$ in diarrhoea, small bowel fistula, urinary diversion procedure
Renal tubular acidosis (RTA)	Urinary loss of $HCO_3^-$ in proximal RTA; impaired tubular acid secretion in distal RTA
<b>Increased anion gap</b>	
<b>Endogenous acid load</b>	
Diabetic ketoacidosis	Accumulation of ketones <sup>1</sup> with hyperglycaemia
Starvation ketosis	} Accumulation of ketones without hyperglycaemia
Alcoholic ketoacidosis	
Lactic acidosis	
Kidney disease	Shock, liver disease, drugs Accumulation of organic acids
<b>Exogenous acid load</b>	
Aspirin poisoning	Accumulation of salicylate <sup>2</sup>
Methanol poisoning	Accumulation of formate
Ethylene glycol poisoning	Accumulation of glycolate, oxalate

<sup>1</sup>Ketones include acid anions acetoacetate and  $\beta$ -hydroxybutyrate. <sup>2</sup>Salicylate poisoning is also associated with respiratory alkalosis due to direct ventilatory stimulation.

## 19.18 Principal patterns of acid–base disturbance

Disturbance	Blood $H^+$	Primary change	Compensatory response	Predicted compensation
Metabolic acidosis	$>40^1$	$HCO_3^- < 24$ mmol/L	$PCO_2 < 5.33$ kPa <sup>2</sup>	$PCO_2$ fall in kPa = $0.16 \times HCO_3^-$ fall in mmol/L
Metabolic alkalosis	$<40^1$	$HCO_3^- > 24$ mmol/L	$PCO_2 > 5.33$ kPa <sup>2,3</sup>	$PCO_2$ rise in kPa = $0.08 \times HCO_3^-$ rise in mmol/L
Respiratory acidosis	$>40^1$	$PCO_2 > 5.33$ kPa <sup>2</sup>	$HCO_3^- > 24$ mmol/L	Acute: $HCO_3^-$ rise in mmol/L = $0.75 \times PCO_2$ rise in kPa Chronic: $HCO_3^-$ rise in mmol/L = $2.62 \times PCO_2$ rise in kPa
Respiratory alkalosis	$<40^1$	$PCO_2 < 5.33$ kPa <sup>2</sup>	$HCO_3^- < 24$ mmol/L	Acute: $HCO_3^-$ fall in mmol/L = $1.50 \times PCO_2$ fall in kPa Chronic: $HCO_3^-$ fall in mmol/L = $3.75 \times PCO_2$ fall in kPa

<sup>1</sup> $H^+$  of 40 nmol/L = pH of 7.40. <sup>2</sup> $PCO_2$  of 5.33 kPa = 40 mmHg. <sup>3</sup> $PCO_2$  does not rise above 7.33 kPa (55 mmHg) because hypoxia then intervenes to drive respiration.

## 19.20 Causes of renal tubular acidosis

### Proximal renal tubular acidosis (type II RTA)

- Inherited:
  - Fanconi syndrome
  - Cystinosis
  - Wilson's disease
- Paraproteinaemia:
  - Myeloma
  - Amyloidosis
- Heavy metal toxicity:
  - Lead, cadmium and mercury poisoning
- Drugs:
  - Carbonic anhydrase inhibitors
  - Ifosfamide
- Primary hyperparathyroidism

### Classical distal renal tubular acidosis (type I RTA)

- Inherited
- Autoimmune diseases:
  - Systemic lupus erythematosus
  - Sjögren syndrome
- Hyperglobulinaemia
- Primary hyperparathyroidism
- Toxins and drugs:
  - Toluene
  - Lithium
  - Amphotericin

### Hyperkalaemic distal renal tubular acidosis (type IV RTA)

- Hypoaldosteronism (primary or secondary)
- Obstructive nephropathy
- Renal transplant rejection
- Drugs:
  - Amiloride
  - Spironolactone

- *type I*, due to tissue hypoxia and peripheral generation of lactate, as in patients with circulatory failure and shock
- *type II*, due to impaired metabolism of lactate, as in liver disease or by a number of drugs and toxins, including metformin, which inhibit lactate metabolism.

Metabolic acidosis with an increased anion gap may also be a consequence of exogenous acid loads from poisoning with aspirin, methanol or ethylene glycol. Typically, metabolic acidosis in chronic kidney disease is associated with a normal anion gap until late in the disease process when the gap widens due to the lack of excretion of anions such as phosphate, sulphate and urate.

### Clinical features

Normal anion gap metabolic acidosis is usually due either to bicarbonate loss in diarrhoea, where the clinical diagnosis is generally obvious, or to RTA. Although some forms of RTA are inherited, it may also be an acquired disorder, and in these circumstances the discovery of metabolic acidosis may serve as an early clue to the underlying diagnosis. The presentation of increased anion gap acidosis is usually dominated by clinical features of the underlying disease, such as uncontrolled diabetes mellitus, kidney failure or shock, or may be suggested by the clinical history of starvation, alcoholism or associated symptoms, such as visual complaints in methanol poisoning.

### Investigations

The different types of metabolic acidosis can be distinguished by blood gas measurements, along with measurements of creatinine, electrolytes and bicarbonate. Under normal circumstances, the anion gap, defined as the numerical difference between the main measured cations ( $\text{Na}^+ + \text{K}^+$ ) and the anions ( $\text{Cl}^- + \text{HCO}_3^-$ ) is about 5–11 mmol/L. This gap is normally made up of various unmeasured anions, such as phosphate and sulphate, as well as albumin. RTA should be suspected when there is a hyperchloraemic acidosis with a normal anion gap in the absence of gastrointestinal disturbance. The diagnosis can be confirmed by finding an inappropriately high urine pH (>5.5) in the presence of systemic acidosis. Sometimes, distal RTA may be incomplete, such that the plasma bicarbonate concentration may be normal. In this case, an acid challenge test can be performed by administration of an acid load in the form of ammonium chloride to reduce plasma bicarbonate. The diagnosis of incomplete distal RTA can be confirmed if the urine pH fails to fall below 5.3 in the presence of a low bicarbonate.

The different subtypes of RTA can be differentiated by various biochemical features. Patients with proximal and distal RTA often present with features of profound hypokalaemia, while type IV RTA is associated with hyperkalaemia. Proximal RTA is frequently associated with urinary wasting of amino acids, phosphate and glucose (Fanconi syndrome), as well as bicarbonate and potassium. Patients with this disorder can lower the urine pH when the acidosis is severe and plasma bicarbonate levels have fallen below 16 mmol/L, since distal  $\text{H}^+$  secretion mechanisms are intact. In the classical form of distal RTA, however, acid accumulation is relentless and progressive, resulting in mobilisation of calcium from bone and osteomalacia with hypercalciuria, renal stone formation and nephrocalcinosis. Potassium is also lost in classical distal RTA, while it is retained in hyperkalaemic distal RTA.

Investigations in patients with raised anion gap metabolic acidosis show features of the underlying cause, such as reduced GFR in kidney failure and raised urine or blood ketones in ketoacidosis. In DKA, blood glucose is raised, while in starvation and alcoholic acidosis blood glucose is not elevated and may be low. Measurement of plasma lactate is helpful in the diagnosis of lactic acidosis when values are increased over the normal maximal level of 2 mmol/L.

### Management

The first step in management of metabolic acidosis is to identify and correct the underlying cause when possible (see [Box 19.19](#)). This may involve controlling diarrhoea, treating diabetes mellitus, correcting shock, stopping drugs that might cause the condition, or using dialysis to remove toxins. Since metabolic acidosis is frequently associated with sodium and water depletion, resuscitation with intravenous fluids is often needed. In alcoholism and starvation ketosis, intravenous glucose is indicated. By stimulating endogenous insulin secretion, this will reverse hepatic ketone production. Malnourished patients may also require thiamin, potassium, magnesium and phosphate supplements. Use of intravenous bicarbonate in metabolic acidosis is controversial. Because rapid correction of acidosis can induce hypokalaemia or a fall in plasma ionised calcium, the use of bicarbonate infusions is best reserved for situations where the underlying disorder cannot be readily corrected and acidosis is severe ( $\text{H}^+ > 100 \text{ nmol/L}$ ,  $\text{pH} < 7.00$ ) or associated with evidence of tissue dysfunction.

The acidosis in RTA can sometimes be controlled by treating the underlying cause (see [Box 19.20](#)), but usually supplements of sodium and potassium bicarbonate are also necessary in types I and II RTA to achieve a target plasma bicarbonate level of >18 mmol/L and normokalaemia. In type IV RTA, loop diuretics, thiazides or fludrocortisone (as appropriate to the underlying diagnosis) may be effective in correcting the acidosis and the hyperkalaemia.

## Metabolic alkalosis

Metabolic alkalosis is characterised by an increase in the plasma bicarbonate concentration and the plasma pH (see [Box 19.18](#)). There is a compensatory rise in  $\text{PCO}_2$  due to hypoventilation but this is limited by the need to avoid hypoxia. Classical causes include Conn syndrome, Cushing's syndrome and glucocorticoid therapy. Occasionally, overuse of antacid salts for treatment of dyspepsia produces a similar pattern.

### Pathophysiology

Metabolic alkalosis is best classified according to the accompanying changes in ECF volume. Hypovolaemic metabolic alkalosis is the most common pattern. This can be caused by sustained vomiting, in which acid-rich fluid is lost directly from the body, or by treatment with loop diuretics or thiazides. In the case of sustained vomiting, loss of gastric acid is the immediate cause of the alkalosis, but several factors act to sustain or amplify this in the context of volume depletion ([Fig. 19.10](#)). Loss of sodium and fluid leads to hypovolaemia and secondary hyperaldosteronism, triggering proximal sodium bicarbonate reabsorption and additional acid secretion by the distal tubule. Hypokalaemia occurs due to potassium loss in the vomitus and by the kidney as the result of

secondary hyperaldosteronism, and itself is a stimulus to acid secretion. Additionally, the compensatory rise in  $PCO_2$  further enhances tubular acid secretion. The net result is sustained metabolic alkalosis with an inappropriately acid urine, which cannot be corrected until the deficit in circulating volume has been replaced.

Normovolaemic (or hypervolaemic) metabolic alkalosis occurs when bicarbonate retention and volume expansion occur simultaneously.

### Clinical features

Clinically, apart from manifestations of the underlying cause, there may be few symptoms or signs related to alkalosis itself. When the rise in systemic pH is abrupt, however, plasma ionised calcium falls and signs of increased neuromuscular irritability, such as tetany, may develop.

### Investigations

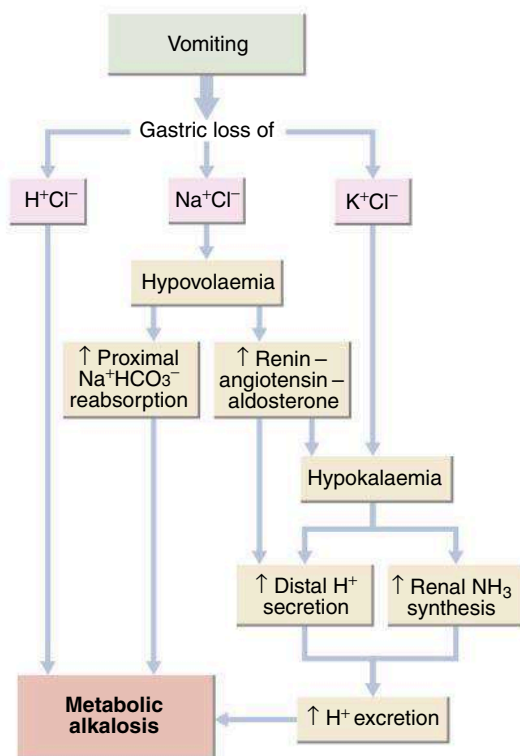

The diagnosis can be confirmed by measurement of electrolytes and arterial blood gases.

### Management

Metabolic alkalosis with hypovolaemia can be corrected by intravenous infusions of 0.9% saline with potassium supplements. This reverses the secondary hyperaldosteronism and allows the kidney to excrete the excess alkali in the urine. Management of metabolic alkalosis in the absence of hypovolaemia should focus on management of the underlying endocrine cause such as Conn syndrome, Cushing's syndrome or corticosteroid excess.

## Respiratory acidosis

Respiratory acidosis occurs when there is accumulation of  $CO_2$  due to type II respiratory failure. This results in a rise in the  $PCO_2$ , with a compensatory increase in plasma bicarbonate concentration, particularly when the disorder is of long duration and the kidney has fully developed its capacity for increased acid excretion.

**Fig. 19.10** Generation and maintenance of metabolic alkalosis during prolonged vomiting. Loss of  $H^+Cl^-$  generates metabolic alkalosis, which is maintained by renal changes.

This acid–base disturbance can arise from lesions anywhere along the neuromuscular pathways from the brain to the respiratory muscles that result in impaired ventilation. It can also arise during intrinsic lung disease if there is significant mismatching of ventilation and perfusion.

Clinical features are primarily those of the underlying cause of the respiratory disorder, such as paralysis, chest wall injury or chronic obstructive lung disease, but the  $CO_2$  accumulation may itself lead to drowsiness that further depresses respiratory drive.

Management involves correction of causative factors where possible, but ultimately ventilatory support may be necessary.

## Respiratory alkalosis

Respiratory alkalosis develops when there is a period of sustained hyperventilation, resulting in a reduction of  $PCO_2$  and increase in plasma pH. If the condition is sustained, renal compensation occurs, such that tubular acid secretion is reduced and the plasma bicarbonate falls.

Respiratory alkalosis is usually of short duration, occurring in anxiety states or as the result of over-vigorous assisted ventilation. It can be prolonged in the context of pregnancy, pulmonary embolism, chronic liver disease and ingestion of certain drugs such as salicylates that directly stimulate the respiratory centre in the brainstem.

Clinical features are those of the underlying cause but agitation associated with perioral and digital tingling may also occur, as alkalosis promotes the binding of calcium to albumin, resulting in a reduction in ionised calcium concentrations. In severe cases, Trousseau's sign and Chvostek's sign may be positive, and tetany or seizures can occur.

Management involves correction of identifiable causes, reduction of anxiety, and a period of rebreathing into a closed bag to allow  $CO_2$  levels to rise.

## Mixed acid–base disorders

It is not uncommon for more than one disturbance of acid–base metabolism to be present at the same time in the same patient: for example, a respiratory acidosis due to narcotic overdose with metabolic alkalosis due to vomiting. In these situations, the arterial pH will represent the net effect of all primary and compensatory changes. Indeed, the pH may be normal, but the presence of underlying acid–base disturbances can be gauged from concomitant abnormalities in the  $PCO_2$  and bicarbonate concentration.

In assessing these disorders, all clinical influences on the patient's acid–base status should be identified, and reference should be made to the table of predicted compensation given in [Box 19.18](#). If the compensatory change is discrepant from the rules of thumb provided, more than one disturbance of acid–base metabolism may be suspected.

## Calcium homeostasis

Disorders of calcium homeostasis are discussed in [Chapter 20](#) and bone disease is discussed in [Chapter 26](#).

## Magnesium homeostasis

Magnesium is mainly an intracellular cation. It is important to the function of many enzymes, including the Na,K-ATPase, and can regulate both potassium and calcium channels. Its overall effect is to stabilise excitable cell membranes.

## Functional anatomy and physiology

Renal handling of magnesium involves filtration of free plasma magnesium at the glomerulus (about 70% of the total), with extensive reabsorption (50%–70%) in the loop of Henle and other parts of the proximal and distal renal tubule. Magnesium reabsorption is also enhanced by parathyroid hormone (PTH).

## Presenting problems in magnesium homeostasis

Disturbances in magnesium homeostasis usually occur because of increased loss of magnesium through the gut or kidney or inability to excrete magnesium normally in patients with renal impairment.

### Hypomagnesaemia

Hypomagnesaemia is defined as existing when plasma magnesium concentrations are below the reference range of 0.75–1.0 mmol/L (1.5–2.0 mEq/L).

#### Pathophysiology

Hypomagnesaemia usually is a reflection of magnesium depletion (Box 19.21), which can be caused by excessive magnesium loss from the gastrointestinal tract (notably in chronic diarrhoea) or the kidney (during prolonged use of loop diuretics). Excessive alcohol ingestion can cause magnesium depletion through both gut and renal losses. Some inherited tubular transport disorders, such as Gitelman and Bartter syndromes, can also result in urinary magnesium wasting. Magnesium depletion has important effects on calcium homeostasis because magnesium is required for the normal secretion of PTH in response to a fall in serum calcium, and because hypomagnesaemia causes end-organ resistance to PTH.

#### Clinical features

Mild degrees of hypomagnesaemia may be asymptomatic but more severe hypomagnesaemia may be associated with symptoms of hypocalcaemia, such as tetany, cardiac arrhythmias (notably torsades de pointes), central nervous excitation and seizures, vasoconstriction and hypertension. Hypomagnesaemia and magnesium depletion are also associated (through uncertain mechanisms) with hyponatraemia and hypokalaemia, which may contribute to some of the clinical manifestations.

19.21 Causes of hypomagnesaemia	
Mechanism	Examples
Inadequate intake	Starvation Malnutrition Alcoholism Parenteral nutrition
Excessive losses	
Gastrointestinal	Prolonged vomiting/nasogastric aspiration Chronic diarrhoea/laxative abuse Malabsorption Small bowel bypass surgery Fistulae Proton pump inhibitors
Urinary	Diuretic therapy Alcohol Tubulotoxic drugs: Gentamicin Cisplatin Herceptin Volume expansion Diabetic ketoacidosis Post-obstructive diuresis Recovery from acute tubular necrosis Inherited tubular transport defect: Bartter syndrome Gitelman syndrome Primary renal magnesium wasting
Miscellaneous	Acute pancreatitis Foscarnet therapy Proton pump inhibitor therapy Hungry bone syndrome Diabetes mellitus

### Management

The underlying cause should be identified and treated where possible. When symptoms are present, the treatment of choice is intravenous magnesium chloride at a rate not exceeding 0.5 mmol/kg in the first 24 hours. If intravenous access is not feasible, magnesium sulphate can be given intramuscularly. Oral magnesium salts have limited effectiveness due to poor absorption and may cause diarrhoea. If hypomagnesaemia is caused by diuretic treatment, adjunctive use of a potassium-sparing agent can also help by reducing magnesium loss into the urine.

### Hypermagnesaemia

This is a much less common abnormality than hypomagnesaemia. Predisposing conditions include acute kidney injury, chronic kidney disease and adrenocortical insufficiency. The condition is generally precipitated in patients at risk from an increased intake of magnesium, or from the use of magnesium-containing medications, such as antacids, laxatives and enemas.

Clinical features include bradycardia, hypotension, reduced consciousness and respiratory depression.

Management involves ceasing all magnesium-containing drugs and reducing dietary magnesium intake, improving renal function if possible, and promoting urinary magnesium excretion using a loop diuretic with intravenous hydration, if residual renal function allows. Calcium gluconate may be given intravenously to ameliorate cardiac effects. Dialysis may be necessary in patients with poor renal function.

## Phosphate homeostasis

Inorganic phosphate (mainly present as  $\text{HPO}_4^{2-}$ ) is intimately involved in cell energy metabolism, intracellular signalling and bone and mineral homeostasis (Ch. 26). The normal plasma concentration is 0.8–1.4 mmol/L (2.48–4.34 mg/dL).

### Functional anatomy and physiology

Phosphate is freely filtered at the glomerulus and approximately 65% is reabsorbed by the proximal tubule, through an apical sodium–phosphate co-transport carrier. A further 10%–20% is reabsorbed in the distal tubules, leaving a fractional excretion of some 10% to pass into the urine, usually as  $\text{H}_2\text{PO}_4^-$ . Proximal reabsorption is decreased by PTH, fibroblast growth factor 23 (FGF23), volume expansion, osmotic diuretics and glucose infusion.

### Presenting problems in phosphate homeostasis

The following section deals primarily with conditions that cause acute disturbances in serum phosphate concentrations. Chronic disorders that are accompanied by phosphate depletion, such as osteomalacia and hypophosphataemic rickets, are discussed in Chapter 26. Acute kidney injury and chronic kidney disease, which are associated with hyperphosphataemia, are discussed below and also in Chapter 18.

### Hypophosphataemia

Hypophosphataemia is defined as existing when serum phosphate values fall below 0.8 mmol/L (2.48 mg/dL). The causes are shown in Box 19.22, subdivided into the underlying pathogenic mechanisms.

#### Pathophysiology

Phosphate may redistribute into cells during periods of increased energy utilisation (such as refeeding after a period of starvation) and during systemic alkalosis. However, severe hypophosphataemia usually represents an overall body deficit due to either inadequate intake or absorption through the gut, or excessive renal losses, most notably in primary

hyperparathyroidism or as the result of acute plasma volume expansion, osmotic diuresis and diuretics acting on the proximal renal tubule. Less common causes include inherited defects of proximal sodium–phosphate co-transport and tumour-induced osteomalacia due to ectopic production of the hormone FGF23.

### Clinical features

The clinical features of phosphate depletion are wide-ranging, reflecting the involvement of phosphate in many aspects of metabolism. Defects appear in the blood (impaired function and survival of all cell lineages), skeletal muscle (weakness, respiratory failure), cardiac muscle (congestive cardiac failure), smooth muscle (ileus), central nervous system (decreased consciousness, seizures and coma) and bone (osteomalacia and rickets in severe prolonged hypophosphataemia).

### Investigations

Measurement of creatinine, electrolytes, phosphate, albumin, calcium and alkaline phosphatase should be performed. In selected cases, measurement of PTH and 25(OH)D and FGF23 may be helpful. The combination of hypophosphataemia and hypercalcaemia suggests primary hyperparathyroidism, which should be further investigated by measurements of PTH. The combination of hypophosphataemia with raised FGF23 levels and normal levels of 25(OH)D suggests either hereditary hypophosphataemic rickets or tumour-induced osteomalacia.

### Management

Management of hypophosphataemia due to decreased dietary intake or excessive losses involves administering oral phosphate supplements and high-protein/high-dairy dietary supplements that are rich in naturally occurring phosphate. Intravenous treatment with sodium or potassium phosphate salts can be used in critical situations, but there is a risk of precipitating hypocalcaemia and metastatic calcification. Management of primary hyperparathyroidism is discussed in [Chapter 18](#) and of hypophosphataemic rickets in [Chapter 26](#).

## Hyperphosphataemia

Hyperphosphataemia is most commonly caused by acute kidney injury or chronic kidney disease. Rarely, hyperphosphataemia can occur in association with hypercalcaemia in the inherited disorder tumoral calcinosis due to loss-of-function variants in *FGF23* or *GALTN3*.

### Pathophysiology

In acute kidney injury and chronic kidney disease, the primary cause is reduced phosphate excretion as the result of a low GFR. In contrast, the hyperphosphataemia in hypoparathyroidism and pseudohypoparathyroidism is due to increased tubular phosphate reabsorption.

19.22 Causes of hypophosphataemia	
Mechanism	Examples
Redistribution into cells	Refeeding after starvation Respiratory alkalosis Treatment for diabetic ketoacidosis
Inadequate intake or absorption	Malnutrition Malabsorption Chronic diarrhoea Phosphate binders Antacids Vitamin D deficiency or resistance
Increased renal excretion	Hyperparathyroidism Extracellular fluid volume expansion with diuresis Osmotic diuretics Fanconi syndrome Familial hypophosphataemic rickets Tumour-induced hypophosphataemic rickets

Redistribution of phosphate from cells into the plasma can also be a contributing factor in the tumour lysis syndromes and other catabolic states. Phosphate accumulation can be aggravated in any of these conditions if the patient takes phosphate-containing preparations or inappropriate vitamin D therapy.

### Clinical features

The clinical features relate to hypocalcaemia and metastatic calcification, particularly in chronic kidney disease with tertiary hyperparathyroidism (when a high calcium–phosphate product occurs). Tumoral calcinosis is characterised by musculoskeletal pain due to deposition of calcium and phosphate in the joints and soft tissues.

### Management

Hyperphosphataemia in patients with kidney disease should be treated with dietary phosphate restriction and the use of oral phosphate binders. Hyperphosphataemia in hypoparathyroidism and pseudohypoparathyroidism does not usually require treatment. Hyperphosphataemia associated with tumour lysis syndromes and catabolic states can be treated with intravenous normal saline, which is given to promote phosphate excretion.

## Lipids and lipoprotein metabolism

The three main biological classes of lipid are:

- cholesterol, which is composed of hydrocarbon rings
- triglycerides (TGs), which are esters composed of glycerol linked to three long-chain fatty acids
- phospholipids, which are composed of a hydrophobic ‘tail’ consisting of two long-chain fatty acids linked through glycerol to a hydrophilic head containing a phosphate group.

Phospholipids are present in cell membranes and are important signalling molecules.

Despite their poor water solubility, lipids need to be absorbed from the gastrointestinal tract and transported throughout the body. This is achieved by incorporating lipids within lipoproteins. Plasma cholesterol and TGs are clinically important because they are major treatable risk factors for cardiovascular disease, while severe hypertriglyceridaemia also predisposes to acute pancreatitis.

## Functional anatomy and physiology

Lipids are transported and metabolised by apolipoproteins, which combine with lipids to form spherical or disc-shaped lipoproteins, consisting of a hydrophobic core and a less hydrophobic coat ([Fig. 19.11](#)). The structure of some apolipoproteins also enables them to act as enzyme co-factors or cell receptor ligands. Variations in lipid and apolipoprotein composition result in distinct classes of lipoprotein that perform specific metabolic functions.

### Processing of dietary lipid

The mechanisms responsible for intestinal absorption of dietary lipid are described in [Chapter 23](#) but the most salient features relevant to lipid metabolism are summarised in [Figure 19.12](#). Enterocytes lining the gut extract mono and diglycerides and free fatty acids from micelles. These are re-esterified into TGs, which are combined with a truncated form of apolipoprotein B (Apo B48) as it is synthesised. Intestinal cholesterol derived from dietary and biliary sources is also absorbed through a specific intestinal membrane transporter termed NPC1L1. This produces chylomicrons containing TG and cholesterol ester that are secreted basolaterally into lymphatic lacteals and carried to the circulation through the thoracic duct. On entering the blood stream, nascent chylomicrons are modified by further exchange of apolipoproteins. Chylomicron TGs are hydrolysed by lipoprotein lipase located on the endothelium of tissue capillary beds. This releases fatty acids that are used locally for energy production or stored as TG in muscle or fat. The residual ‘remnant’ chylomicron particle is avidly

cleared by low-density lipoprotein receptors (LDLRs) and other receptors in the liver, which recognise Apo E on the remnant lipoproteins. Complete absorption of dietary lipids takes about 6–10 hours, so chylomicrons are usually undetectable in the plasma after a 12-hour fast.

The main dietary determinants of plasma cholesterol concentrations are the intake of saturated and *trans*-unsaturated fatty acids, which reduce LDLR activity (see below), whereas dietary cholesterol has surprisingly little effect on plasma cholesterol levels. Plant sterols and drugs that inhibit cholesterol absorption are effective because they also reduce the re-utilisation of biliary cholesterol. The dietary determinants of plasma TG concentrations are complex since excessive intake of carbohydrate, fat or alcohol may all contribute to increased plasma TG by different mechanisms.

## Endogenous lipid synthesis

In the fasting state, the liver is the major source of plasma lipids (see Fig. 19.12). The liver may acquire lipids by uptake, synthesis or conversion from other macronutrients. These lipids are transported to other tissues by secretion of very low-density lipoproteins (VLDLs), which are rich in

Fig. 19.11 Structure of lipoproteins.

Fig. 19.12 Absorption, transport and storage of lipids. Pathways of lipid transport are shown; in addition, cholesterol ester transfer protein exchanges triglyceride and cholesterol ester between very low-density lipoprotein/chylomicrons and high-/low-density lipoprotein, and free fatty acids released from peripheral lipolysis can be taken up in the liver. (ABCA1/ABCG1 = adenosine triphosphate-binding cassette A1/G1; Apo = apolipoprotein; BA = bile acids; C = cholesterol; CE = cholesterol ester; FFA = free fatty acids; HDL = mature high-density lipoprotein; HL = hepatic lipase; HMGCoAR = hydroxy-methyl-glutaryl-co-enzyme A reductase; IDL = intermediate-density lipoprotein; iHDL = immature high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor (Apo B100 receptor); LPL = lipoprotein lipase; PCSK9 = proprotein convertase subtilisin kexin 9; SRB1 = scavenger receptor B1; TG = triglyceride; VLDL = very low-density lipoprotein)

TG but differ from chylomicrons in that they are less massive and contain full-length Apo B100. Following secretion into the circulation, VLDLs undergo metabolic processing similar to that of chylomicrons. Hydrolysis of VLDL TG releases fatty acids to tissues and converts VLDLs into 'remnant' particles, referred to as intermediate-density lipoproteins (IDLs). Most IDLs are rapidly cleared by LDLRs in the liver but some are processed by hepatic lipase, which converts the particle to an LDL by removing TG and most materials other than Apo B100, and free and esterified cholesterol. The catabolism of TG-rich chylomicrons and VLDL by lipoprotein lipase is modulated by Apos C2 and C3 on the surface of these particles.

## Cholesterol transport

The LDL particles act as a source of cholesterol for cells and tissues (see Fig. 19.12). LDL cholesterol is internalised by receptor-mediated endocytosis via the LDLR. Delivery of cholesterol by this mechanism contributes to the homeostatic control of intracellular cholesterol levels via sterol regulatory element binding protein (SREBP), which coordinates intracellular cholesterol metabolism via several mechanisms. Decline in SREBP down-regulates expression of LDLR and reduces the synthesis and activity of the rate-limiting enzyme for cholesterol synthesis, hydroxy-methyl-glutaryl-co-enzyme A (HMGCoA) reductase. Counterintuitively, this is accompanied by an increase in an important regulator of LDLR levels, proprotein convertase subtilisin kexin 9 (PCSK9), which targets LDLR for degradation. Intracellular free cholesterol concentrations are maintained within a narrow range by the inhibitory effects of LDL on expression of LDLR, modulation of the half-life of LDLR through PCSK9, and control of cholesterol synthesis and esterification.

Peripheral tissues are guarded against excessive cholesterol accumulation by high-density lipoproteins (HDLs; see Fig. 19.12). Lipid-poor Apo A1 (derived from the liver, intestine and the outer layer of chylomicrons and VLDL) accepts cellular cholesterol and phospholipid from a specific membrane transporter known as the ATP-binding cassette A1 (ABCA1). This produces small HDLs that are able to accept more free cholesterol from cholesterol-rich regions of the cell membrane known as 'rafts' via another membrane transporter (ABCG1). The cholesterol that has been accepted by these small HDLs is esterified by lecithin cholesterol acyl transferase (LCAT), thus maintaining an uptake gradient and remodelling the particle into a mature spherical HDL. These HDLs release their cholesterol to the liver and other cholesterol-requiring tissues via the scavenger receptor B1 (SRB1).

The cholesterol ester transfer protein (CETP) in plasma allows transfer of cholesterol from HDLs or LDLs to VLDLs or chylomicrons in exchange for TG. When TG is elevated, the action of CETP may reduce HDL cholesterol and remodel LDLs into 'small, dense' LDL particles that may be more atherogenic in the blood-vessel wall. Animal species that lack CETP seem resistant to atherosclerosis.

## Lipids and cardiovascular disease

Plasma lipoprotein levels are major modifiable risk factors for cardiovascular disease. Increased levels of atherogenic lipoproteins (especially LDL, but also IDL, and possibly chylomicron remnants) contribute to the development of atherosclerosis. A sub-population of LDL particles bears an additional protein known as apolipoprotein (a), which shares homology with plasminogen. The combination of LDL and apolipoprotein (a) is known as lipoprotein (a) (Lp(a)). It transports oxidised phospholipid and is regarded as atherogenic because its plasma concentration is an independent risk factor for cardiovascular disease. Following chemical modifications such as oxidation, Apo B-containing lipoproteins are no longer cleared by the normal LDLR pathway. They trigger a self-perpetuating inflammatory response, during which they are taken up by macrophage 'scavenger receptors' to form foam cells, a hallmark of atherosclerotic lesions. These processes also have an adverse effect on endothelial function.

Conversely, HDL removes cholesterol from the tissues to the liver, where it is metabolised and excreted in bile. HDL may also counteract

some components of the inflammatory response, such as the expression of vascular adhesion molecules by the endothelium. Low HDL cholesterol levels (HDL-C) are usually associated with TG elevation. This inverse relationship may confound the associations between HDL-C and/or TG with atherosclerosis.

## Investigations

Lipid measurements are usually performed for the following reasons:

- screening for primary or secondary prevention of cardiovascular disease
- investigation of patients with clinical features of lipid disorders and their relatives
- monitoring of response to diet, weight control and medication.

Abnormalities of lipid metabolism most commonly come to light following these tests. Convenient non-fasting measurements of total cholesterol (TC) and HDL cholesterol (HDL-C) allow estimation of non-HDL cholesterol (non-HDL-C, calculated as TC – HDL-C). A 12-hour fasting sample is required to standardise TG measurement and allow calculation of LDL cholesterol (LDL-C) according to the Friedewald formula:

$$\text{LDL-C} = \text{TC} - \text{HDL-C} - (\text{TG}/2.2) \text{ mmol/L}$$

or

$$\text{LDL-C} = \text{TC} - \text{HDL-C} - (\text{TG}/5) \text{ mg/dL}$$

The formula becomes unreliable when TG levels exceed 4 mmol/L (350 mg/dL). Measurements of non-HDL-C or Apo B100 may assess risk of cardiovascular disease more accurately than LDL-C, particularly when TG levels are increased. Furthermore, non-fasting TG is a more sensitive marker of the risk of cardiovascular disease. A 12-hour fast is still required for formal diagnosis of hypertriglyceridaemia or use of the Friedewald equation. Consideration must be given to confounding factors, such as recent illness, after which cholesterol, LDL-C and HDL-C levels temporarily decrease in proportion to severity of the episode. Results that will affect major decisions, such as initiation of drug therapy, should be confirmed with a repeat measurement.

Elevated levels of TG are common in obesity, diabetes and insulin resistance and are frequently associated with low HDL and increased 'small, dense' LDL. Under these circumstances, LDL-C may underestimate risk. This is one situation in which measurement of non-HDL-C or Apo B may provide more accurate risk assessment.

## Presenting problems in lipid metabolism

Hyperlipidaemia can occur in association with various diseases and drugs, as summarised in Box 19.23. Overt or subclinical hypothyroidism may cause hypercholesterolaemia. Measurement of thyroid function is warranted in most cases, even in the absence of typical symptoms and signs.

Once secondary causes are excluded, primary lipid abnormalities may be diagnosed. Primary lipid abnormalities can be classified according to the predominant lipid problem: hypercholesterolaemia, hypertriglyceridaemia or mixed hyperlipidaemia (Box 19.24). Although single-gene disorders are encountered in all three categories, most cases are due to multiple-gene (polygenic) loci interacting with environmental factors. The clinical features and complications of dyslipidaemia vary somewhat between these causes.

## Hypercholesterolaemia

Hypercholesterolaemia is a polygenic disorder that is the most common cause of a mild to moderate increase in LDL-C (Box 19.24). Physical signs, such as corneal arcus, xanthelasma, tendon xanthoma and eruptive xanthoma (see p. 615) may be found in this as well as other forms of hyperlipidaemia. The risk of cardiovascular disease is

proportional to the degree of LDL-C (or Apo B) elevation, but is modified by other major risk factors, including low HDL-C and high Lp(a).

Familial hypercholesterolaemia (FH) is a more severe disorder with a prevalence of approximately 0.3% in most populations. It is usually caused by loss-of-function variants affecting the *LDLR* gene, which results in an autosomal dominant pattern of inheritance. A similar syndrome can arise with loss-of-function variants in the ligand-binding domain of Apo B100 or gain-of-function variants in *PCSK9*, which promote LDLR degradation. Pathological variants can be detected in one of these three genes by genetic testing in about 70% of patients with FH. Most patients with FH have LDL-C levels that are approximately twice as high as in normal subjects of the same age and gender. FH may be accompanied by xanthomas of the Achilles or extensor digitorum tendons (p. 614), which are strongly suggestive of FH. The onset of corneal arcus before age 40 is also suggestive of this condition. Identification of an index case of FH (the first case of FH in a family) should trigger genetic and biochemical screening of other family members, which is a cost-effective method for case detection. Affected individuals should be managed from childhood (Box 19.25) because affected patients face the

risk of a 20–40-year acceleration of the risk of premature cardiovascular disease.

Homozygous FH may occur sporadically, especially in populations in which there is a 'founder' gene effect or consanguineous marriage. Homozygosity results in more extensive xanthomas and precocious cardiovascular disease, often in childhood. Hyperalphalipoproteinaemia refers to increased levels of HDL-C. This condition rarely causes cardiovascular disease, but it may reflect HDL dysfunction, so it should not be regarded as universally benign.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypercholesterolaemia (see 'Mixed hyperlipidaemia' below).

## Hypertriglyceridaemia

Hypertriglyceridaemia also usually involves polygenic factors (see Box 19.24). Other common causes include excess alcohol intake, medications (such as  $\beta$ -blockers and retinoids), type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of insulin resistance and impaired absorption of bile acids. It is often accompanied by post-prandial hyperlipidaemia and reduced HDL-C, both of which may contribute to cardiovascular risk. Excessive intake of alcohol or dietary fat, or other exacerbating factors, may precipitate a massive increase in TG levels, which, if they exceed 10 mmol/L (880 mg/dL), may pose a risk of acute pancreatitis.

Monogenic forms of hypertriglyceridaemia also occur due to loss-of-function variants in the genes encoding lipoprotein lipase and Apo C2, which coordinate the lipolytic breakdown of TG-rich lipoproteins. These cause recessively inherited severe hypertriglyceridaemia that is not readily amenable to drug treatment. It may present in childhood with episodes of acute abdominal pain or pancreatitis. In common with other causes of severe hypertriglyceridaemia, hepatomegaly, lipaemia retinalis and eruptive xanthomas may occur (p. 614). Familial hypertriglyceridaemia may also be inherited in a dominant manner due to loss-of-function variants in the *APOA5* gene, which encodes Apo A5 – a co-factor that is essential for lipoprotein lipase activity. Conversely, loss-of-function variants for genes encoding *ANGPTL3* and 4, or Apo C3, may increase lipoprotein lipase activity and reduce TG. Individuals with *APOA5* variants have an increased risk of cardiovascular disease whereas those with *ANGPTL3*, *ANGPTL4* and *APOC3* variants have a reduced risk.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypertriglyceridaemia (see 'Mixed hyperlipidaemia', below).

### 19.23 Causes of secondary hyperlipidaemia

#### Secondary hypercholesterolaemia

##### Moderately common

- Drugs:
  - Diuretics
  - Cyclosporin
  - Glucocorticoids
  - Androgens
  - Antiretroviral agents
- Hypothyroidism
- Pregnancy
- Cholestatic liver disease

##### Less common

- Nephrotic syndrome
- Anorexia nervosa
- Porphyrria
- Hyperparathyroidism

#### Secondary hypertriglyceridaemia

##### Common

- Type 2 diabetes mellitus
- Chronic renal disease
- Abdominal obesity
- Excess alcohol

### 19.24 Classification of hyperlipidaemia

Disease	Elevated lipid results	Elevated lipoprotein	CHD risk	Pancreatitis risk
<b>Predominant hypercholesterolaemia</b>				
Polygenic (majority)	TC $\pm$ TG	LDL $\pm$ VLDL	+	–
Familial hypercholesterolaemia (LDLR defect, defective Apo B100, increased function of <i>PCSK9</i> )	TC $\pm$ TG	LDL $\pm$ VLDL	+++	–
Hyperalphalipoproteinaemia	TC $\pm$ TG	HDL	–	–
<b>Predominant hypertriglyceridaemia</b>				
Polygenic (majority)	TG	VLDL $\pm$ LDL	Variable	+
Lipoprotein lipase deficiency	TG $\gg$ TC	Chylo	?	+++
Familial hypertriglyceridaemia	TG > TC	VLDL $\pm$ chylo	?	++
<b>Mixed hyperlipidaemia</b>				
Polygenic (majority)	TC + TG	VLDL + LDL	Variable	+
Familial combined hyperlipidaemia*	TC and/or TG	LDL and/or VLDL	++	+
Dysbetalipoproteinaemia*	TC and/or TG	IDL	+++	+

\*Familial combined hyperlipidaemia and dysbetalipoproteinaemia may also present as predominant hypercholesterolaemia or predominant hypertriglyceridaemia.

(Apo B100 = apolipoprotein B100; CHD = coronary heart disease; chylo = chylomicrons; HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor; TC = total cholesterol; TG = triglycerides; VLDL = very low-density lipoprotein)

+ = slightly increased risk; ++ = increased risk; +++ = greatly increased risk; ? = risk unclear

### 19.25 Familial hypercholesterolaemia in adolescence

- **Statin treatment:** may be required from the age of about 10. It does not compromise normal growth and maturation.
- **Smoking:** patients should be strongly advised not to smoke.
- **Adherence to medication:** critically important to the success of treatment. Simple regimens should be used and education and support provided.

## Mixed hyperlipidaemia

It is difficult to define quantitatively the distinction between predominant hyperlipidaemias and mixed hyperlipidaemia. The term 'mixed' usually implies the presence of hypertriglyceridaemia, as well as an increase in LDL-C or IDL. Treatment of massive hypertriglyceridaemia may reduce TG faster than cholesterol, thus temporarily mimicking mixed hyperlipidaemia.

Primary mixed hyperlipidaemia is usually polygenic and, like predominant hypertriglyceridaemia, often occurs in association with type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of insulin resistance. Both components of mixed hyperlipidaemia may contribute to the risk of cardiovascular disease.

Familial combined hyperlipidaemia is a term used to identify an inherited tendency towards the over-production of atherogenic Apo B-containing lipoproteins. It results in elevation of cholesterol, TG or both in different family members at different times. It is associated with an increased risk of cardiovascular disease, but it does not produce any pathognomonic physical signs. In practice, this relatively common condition is substantially modified by factors such as age and weight. It may not be a monogenic condition, but rather one end of a heterogeneous spectrum that overlaps insulin resistance.

Dysbetalipoproteinaemia (also referred to as type 3 hyperlipidaemia, broad-beta dyslipoproteinaemia or remnant hyperlipidaemia) involves accumulation of roughly equimolar levels of cholesterol and TG. It is caused by homozygous inheritance of the Apo E2 allele, which is the isoform least avidly recognised by the LDLR. In conjunction with other exacerbating factors, such as obesity or diabetes, it leads to accumulation of atherogenic IDL and chylomicron remnants. Premature cardiovascular disease is common, as is peripheral vascular disease. It may also result in the formation of palmar xanthomas, tuberous xanthomas or tendon xanthomas.

## Rare dyslipidaemias

Several rare disturbances of lipid metabolism have been described (Box 19.26). They provide important insights into lipid metabolism and its impact on risk of cardiovascular disease.

Fish eye disease, Apo A1 Milano and lecithin cholesterol acyl transferase (LCAT) deficiency demonstrate that very low HDL-C levels do not necessarily cause cardiovascular disease, but Apo A1 deficiency, and possibly Tangier disease, demonstrate that low HDL-C can be atherogenic under some circumstances. PCSK9 gain-of-function and autosomal recessive *FH* variants reveal the importance of proteins that chaperone the LDLR. Sitosterolaemia and cerebrotendinous xanthomatosis demonstrate that sterols other than cholesterol can cause xanthomas and cardiovascular disease, while *PCSK9* loss-of-function variants abetalipoproteinaemia and hypobetalipoproteinaemia suggest that low levels of Apo B-containing lipoproteins reduce the risk of cardiovascular disease. Adverse health outcomes associated with extremely low plasma lipid levels in the latter two conditions are attributable to fat-soluble vitamin deficiency, or impaired transport of lipid from intestine or liver.

## Principles of management

Assessment of absolute risk of cardiovascular disease, treatment of all modifiable risk factors and optimisation of lifestyle, especially diet and exercise, are central to management in all cases. Lipid-lowering therapies

have a key role in the primary and secondary prevention of cardiovascular diseases. Patients with the greatest absolute risk of cardiovascular disease derive the greatest absolute benefit from treatment. Public health organisations recommend thresholds for the introduction of lipid-lowering therapy based on the identification of patients in very high-risk categories, or those calculated to be at high absolute risk according to algorithms or tables. The large epidemiological studies on which risk assessment is based should be recalibrated for the local population where possible. The decision to commence lipid-lowering therapy is usually made on the basis of the lifetime risk of cardiovascular disease which takes lipid concentrations into account along with other risk factors and age. This diminishes the pressure to treat older adults who are less likely to benefit and supports earlier intervention in patients who are not yet in old age. Recently released guidelines include ACC/AHA or ESC/EAS guidelines, which differ in some respects (see 'Further information'). Important common themes include additional clinical input for risk calculation tables, expanded lists of risk-enhancing factors, use of coronary calcium scores in intermediate-risk patients and adoption of more aggressive LDL-C treatment goals. Target levels for LDL-C are at less than 1.8 mmol/l (70 mg/dL) on one hand, or less than 1.4 mmol/l in addition to 50% reduction on the other.

## Non-pharmacological management

Patients with lipid abnormalities should receive medical advice and, if necessary, dietary counselling couched in terms of practical dietary and culinary advice:

- replace sources of saturated fat and cholesterol with alternative foods, such as lean meat, low-fat dairy products, polyunsaturated spreads and low-glycaemic-index carbohydrates
- reduce energy-dense foods such as fats and soft drinks, while increasing activity and exercise to maintain or lose weight
- increase consumption of cardioprotective and nutrient-dense foods, such as vegetables, unrefined carbohydrates, fish, pulses, nuts, legumes and fruit
- adjust alcohol consumption, reducing intake if excessive or if associated with hypertension, hypertriglyceridaemia or central obesity
- achieve additional benefits with preferential intake of foods containing lipid-lowering nutrients such as n-3 fatty acids, dietary fibre and plant sterols
- reduce intake of saturated and *trans*-unsaturated fat to less than 7%–10% of total energy
- reduce intake of cholesterol to <250 mg/day.

These measures should achieve a response within 3–4 weeks but dietary adjustment may need to be introduced gradually. Although

### 19.26 Miscellaneous and rare forms of hyperlipidaemia

Condition	Lipoprotein pattern	CVD risk
Tangier disease	Very low HDL, low TC	+
Apo A1 deficiency	Very low HDL	++
Apo A1 Milano	Very low HDL	–
Fish eye disease	Very low HDL, high TG	–
LCAT deficiency	Very low HDL, high TG	?
Autosomal recessive FH	Very high LDL	++
Sitosterolaemia	High plant sterols including sitosterol	+
Cerebrotendinous xanthomatosis	Bile acid defect (cholestanol accumulation)	+

+ = slightly increased risk; ++ = increased risk

(CVD = cardiovascular disease; FH = familial hypercholesterolaemia; HDL = high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; TC = total cholesterol; TG = triglycerides)

hyperlipidaemia in general, and hypertriglyceridaemia in particular, can be very responsive to these measures, LDL-C reductions are often only modest in routine clinical practice. Explanation, encouragement and persistence are often required to assist patient adherence. Even minor weight loss can substantially reduce cardiovascular risk, especially in centrally obese patients.

All other modifiable cardiovascular risk factors should be assessed and treated. If possible, intercurrent drug treatments that adversely affect the lipid profile should be replaced.

## Pharmacological management

The main diagnostic categories provide a useful framework for management and the selection of first-line pharmacological treatment (Fig. 19.13). Depending on the response, treatment with more than one drug may be required. Advances in understanding the genetic factors that regulate lipid metabolism have led to the identification of several new lipid-lowering agents. Monoclonal antibodies and antisense mRNA therapies directed against PCSK9 are already used in clinical practice whereas antisense mRNA directed against apolipoprotein C3 (*APOC3*) and angiopoietin-like 3 (*ANGPTL3*) are under investigation for the treatment of hypercholesterolaemia and hypertriglyceridaemia.

### Hypercholesterolaemia

The drugs used in the treatment of hypercholesterolaemia target the pathways responsible for cholesterol synthesis, its clearance from the circulation, or its absorption from the diet. Homeostatic mechanisms orchestrated by steroid regulatory element binding protein (SREBP) to maintain intracellular cholesterol concentrations, blunt the effectiveness of statins, ezetimibe and resins but this does not apply to PCSK9 inhibitors, which are extremely effective cholesterol-lowering agents, as summarised in (Fig. 19.14).

#### Statins

Statins reduce cholesterol synthesis by inhibiting the HMGCoA reductase enzyme. The reduction in cholesterol synthesis up-regulates production of the LDLR, which increases clearance of LDL and its precursor, IDL, resulting in a secondary reduction in LDL synthesis. Statins reduce LDL-C by up to 60%, reduce TG by up to 40% and increase HDL-C by

up to 10%. They also reduce the concentration of intermediate metabolites such as isoprenes, which may lead to other effects such as suppression of the inflammatory response. There is clear evidence of protection against total and coronary mortality, stroke and cardiovascular events across the spectrum of cardiovascular disease risk.

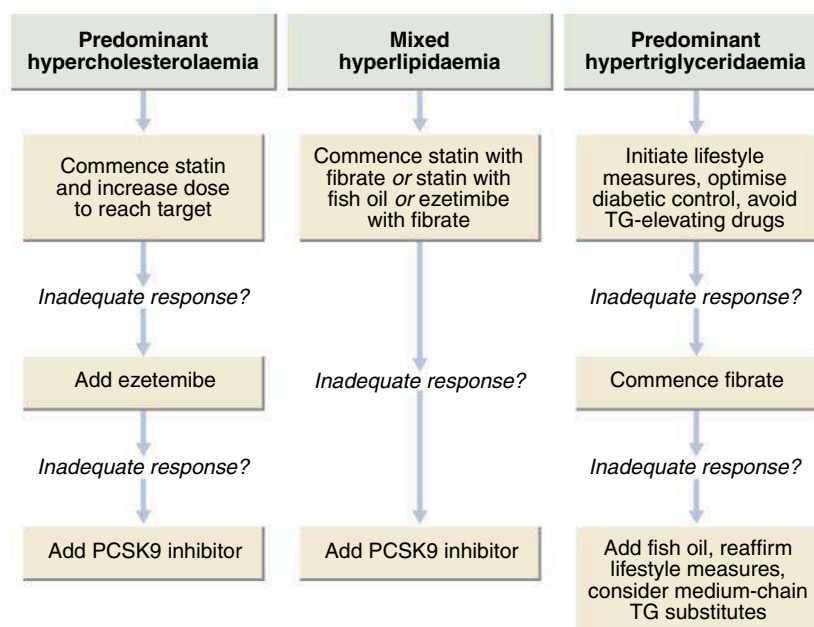

Statins are generally well tolerated and serious side-effects are infrequent. Liver function test abnormalities and muscle problems, such as myalgia, asymptomatic increase in creatine kinase (CK), myositis and, infrequently, rhabdomyolysis, are the most common. Side-effects are more likely in older adults and in patients who are debilitated or receiving other drugs that interfere with statin degradation, which usually involves cytochrome P450 3A4 or glucuronidation.

#### PCSK9 inhibitors

Several drugs have been developed that neutralise PCSK9, an enzyme that degrades the LDLR. This causes levels of LDLR to increase, which markedly reduces LDL-C by clearing LDL from the circulation. The PCSK9 inhibitors currently available are the monoclonal antibodies (Mab) evolocumab and alirocumab, which are administered by subcutaneous injection every 2–4 weeks, and the PCSK9 antisense mRNA inclisiran, which is administered subcutaneously every 6 months. These drugs are all highly effective. Inclisiran inhibits PCSK9 by binding to and degrading its mRNA intracellularly whereas the Mab bind and inhibit PCSK9 at the cell surface. Reductions in LDL-C of about 50%–60% have been observed with these agents in patients who have not responded adequately to standard lipid-lowering therapy and this has been accompanied by a reduction in the risk of cardiovascular events of about 15%. The reason PCSK9 inhibitors are so highly effective is that they do not lower intracellular levels of cholesterol and hence do not trigger the compensatory mechanisms that blunt the effect of other cholesterol-lowering medications (Fig. 19.14). The PCSK9 inhibitors also act synergistically with statins and ezetimibe and lower lipoprotein (a) by mechanisms that are unclear.

#### Ezetimibe

Ezetimibe inhibits activity of the intestinal mucosal transporter NPC1L1, which is responsible for absorption of dietary and biliary cholesterol. The resulting depletion of hepatic cholesterol up-regulates hepatic LDLR production. This mechanism of action is synergistic with the effect of statins. Monotherapy in a 10 mg/day dose reduces LDL-C by 15%–20%. Slightly

**Fig. 19.13** Flow chart for the drug treatment of hyperlipidaemia. Triglyceride (TG) elevating drugs include glucocorticoids, antipsychotics, isotretinoin and  $\beta$ -blockers. See text for more details of drugs and dosages. (PCSK9 = proprotein convertase subtilisin kexin 9)

**Fig. 19.14 Mechanism of action for cholesterol-lowering drugs.** Traditional cholesterol-lowering drugs such as statins and ezetimibe lower intracellular cholesterol, causing activation of steroid regulatory element binding protein (SREBP) which increases expression of sterol responsive genes, particularly LDLR, leading to lower plasma LDL. Activation of SREBP also stimulates cholesterol synthesis and absorption which may blunt the therapeutic response to these drugs. SREBP also fine-tunes the restoration of intracellular cholesterol by up-regulating PCSK9 which assists degradation of LDLRs. Inhibitors of PCSK9 do not affect intracellular cholesterol but instead work by causing LDLR to accumulate at the cell surface thereby removing cholesterol bound to LDL from the circulation. (HMGCoA = hydroxy-methyl-glutaryl-co-enzyme A; HMGCoAR = hydroxy-methyl-glutaryl-co-enzyme A reductase; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor; PCSK9 = proprotein convertase subtilisin kexin 9)

greater (17%–25%) incremental LDL-C reduction occurs when ezetimibe is added to statins. Ezetimibe is well tolerated, and evidence of a beneficial effect on cardiovascular disease endpoints is now available. Plant sterol-supplemented foods, which also reduce cholesterol absorption, lower LDL-C by 7%–15%.

#### Bile acid-sequestering resins

Drugs in this class include colestyramine, colestipol and colesevelam, although their use and availability is declining. They prevent the reabsorption of bile acids, thereby increasing de novo bile acid synthesis from hepatic cholesterol. The depletion of bile acids is sensed via the farnesyl X receptor and the response may also improve glucose metabolism. The resultant depletion of hepatic cholesterol up-regulates LDLR activity and reduces LDL-C in a manner that is synergistic with the action of statins. Resins may increase TG or interfere with bioavailability of other drugs. Colesevelam has fewer gastrointestinal effects than the other drugs in this class.

#### Combination therapy

In many patients, treatment of predominant hypercholesterolaemia can be achieved by diet plus the use of a statin in sufficient doses to achieve target LDL-C levels. Patients who do not reach LDL targets on the highest tolerated statin dose, or who are intolerant of statins, may receive plant sterols, ezetimibe, PCSK9 inhibitors, or resins. Ezetimibe and resins are safe and effective in combination with a statin because the mechanisms of action of individual therapies complement each other while blunting each other's compensatory mechanisms.

#### Hypertriglyceridaemia

Predominant hypertriglyceridaemia can be treated with one of the TG-lowering drugs described below, in combination with lifestyle measures such as weight reduction, reduction in alcohol consumption and optimisation of diabetic control.

#### Fibrates

These stimulate peroxisome proliferator-activated receptor (PPAR) alpha, which controls the expression of gene products that mediate the metabolism of TG and HDL. As a result, synthesis of fatty acids, TG and VLDL is reduced, while that of lipoprotein lipase, which catabolises TG, is enhanced. In addition, production of Apo A1 and ABC A1 is up-regulated leading to increased reverse cholesterol transport via HDL. Consequently, fibrates reduce TG by up to 50% and increase HDL-C by up to 20%, but LDL-C changes are variable.

Fewer large-scale trials have been conducted with fibrates than with statins. The results are less conclusive, but reduced rates of cardiovascular disease have been reported with fibrate therapy in the subgroup of patients with low HDL-C levels and elevated TG (TG >2.3 mmol/L (200 mg/dL)). Fibrates are usually well tolerated but share a similar side-effect profile to statins. In addition, they may increase the risk of cholelithiasis and prolong the action of anticoagulants. Accumulating evidence suggests that they may also have a protective effect against diabetic microvascular complications.

#### Highly polyunsaturated long-chain n-3 fatty acids

These include eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which comprise approximately 30% of the fatty acids in fish oil. Both are potent inhibitors of VLDL TG formation. Intakes of more than 2 g n-3 fatty acid (equivalent to 6 g of most forms of fish oil) per day lower TG in a dose-dependent fashion. Up to 50% reduction in TG may be achieved with 15 g fish oil per day. Changes in HDL-C are variable but fish oils do not usually reduce LDL-C. Fish oil fatty acids have also been shown to inhibit platelet aggregation and improve cardiac arrhythmia in animal models. Dietary and pharmacological trials suggest that n-3 fatty acids may reduce mortality from coronary heart disease. The benefit of n-3 fatty acid supplements has been confirmed in a recent trial amongst hypertriglyceridaemic patients. They appear to be safe and well tolerated. Dietary fish consumption is the preferred source for the general population.

Patients with predominant hypertriglyceridaemia who do not respond to lifestyle intervention can be treated with fibrates or n-3 fatty acids, depending on individual response and tolerance. If target levels are not achieved, fibrates and fish oil can be combined along with lifestyle measures, optimising diabetic control and avoidance of drugs that raise triglycerides. Massive hypertriglyceridaemia may require more aggressive limitation of dietary fat intake (<10%–20% energy as fat). Any degree of insulin deficiency should be corrected because insulin is required for optimal activity of lipoprotein lipase. The initial target for patients with massive hypertriglyceridaemia is TG <10 mmol/L (880 mg/dL), to reduce the risk of acute pancreatitis.

### Mixed hyperlipidaemia

Mixed hyperlipidaemia can be difficult to treat. First-line therapy with statins alone is unlikely to achieve target levels once fasting TGs exceed approximately 4 mmol/L (350 mg/dL). Fibrates are first-line therapy for dysbetalipoproteinaemia, but they may not control the cholesterol component in other forms of mixed hyperlipidaemia. Combination therapy is often required. Effective combinations include:

- statin plus fenofibrate (recognising that the risk of myopathy is increased with gemfibrozil, but fenofibrate is relatively safe in this regard)
- statin plus fish oil when TG is not too high
- fibrate plus ezetimibe when cholesterol is not too high.

### Monitoring of therapy

The effects of lipid-lowering therapy should be assessed after 6 weeks (12 weeks for fibrates). At this point, it is prudent to review side-effects, lipid response (see target levels above), CK and liver function tests. During longer-term follow-up, adherence to treatment, diet and exercise should be assessed, with monitoring of weight, blood pressure and lipid levels. The presence of cardiovascular symptoms or signs should be noted, and absolute cardiovascular risk assessed periodically. Effective statin therapy may be associated with a paradoxical and as yet unexplained increase in coronary calcium score.

It is not necessary to perform routine checks of CK and liver function unless symptoms occur, or if statins are used in combination with fibrates, or other drugs that may interfere with their clearance. If myalgia

or weakness occurs in association with CK elevation over 5–10 times the upper limit of normal, or if sustained alanine aminotransferase (ALT) elevation more than 2–3 times the upper limit of normal occurs that is not accounted for by fatty liver, treatment should be discontinued and alternative therapy sought.

The principles of the management of dyslipidaemia can be applied broadly, but the objectives of treatment in old age (Box 19.27) and the safety of pharmacological therapy in pregnancy (Box 19.28) warrant special consideration.

## Inherited metabolic disorders

Inherited metabolic disorders are a large group of rare genetic diseases which result in disordered cellular metabolism. The majority are caused by variants in single genes that code for enzymes, leading to defective or absent enzyme activity. This leads to: (1) the accumulation of toxic metabolites that lie upstream within the pathway or (2) an inability to synthesise essential metabolites that are required for cellular function (Fig. 19.15). The vast majority of disorders are autosomal recessive.

Newborn screening, the availability of specific therapies, increased access to genetic testing and the recognition of attenuated, later-onset forms has led to a significant increase in the incidence and prevalence of inherited metabolic disorders, many of which are treatable. Treatment options are rapidly expanding with the use of gene therapies, RNA-based therapies and precision medicine techniques.

## Disorders of amino acid metabolism

Inherited disorders of amino acid metabolism usually present in the neonatal period, but some disorders, especially of amino acid transport, may not present until later in life.

### Phenylketonuria

The identification and successful dietary treatment of babies with phenylketonuria (PKU) has profoundly changed the outcome of this disorder, with patients now expected to live normal lives. PKU is caused by loss-of-function variants in the *PAH* gene, which encodes phenylalanine hydroxylase, an enzyme required for the degradation of phenylalanine, an essential amino acid. Undegraded phenylalanine accumulates, causing direct neurotoxicity and profound neurodevelopmental disability. Treatment involves lifelong adherence to a low-phenylalanine diet with additional amino acid and nutrient supplements. Early and adequate dietary treatment prevents major neurodisability, and lifelong adherence is thought to prevent psychiatric morbidity and improve cognitive function. Treatment with sapropterin, which acts as a co-factor for phenylalanine hydroxylase, has been shown to reduce blood phenylalanine concentrations and increase phenylalanine tolerance in adults and children with PKU. However, its use is limited to patients with milder variants as well as by cost.

Maternal phenylketonuria syndrome, causing microcephaly, developmental delay and cardiac defects, is caused by exposure of the developing fetus to high levels of phenylalanine. Strict dietary adherence, both preconception and during pregnancy, prevents any deleterious effects in the offspring.

### Homocystinuria

Homocystinuria is usually caused by variants in the *CBS* gene, leading to defective activity of the enzyme cystathione beta-synthase. This prevents homocysteine degradation, and causes toxic accumulation of homocysteine and methionine (upstream of the metabolic block). Multiple body systems are affected, including the central nervous system (developmental delay, intellectual disability, seizures and psychiatric disturbance); skeleton (tall stature, osteoporosis); eye (ectopia lentis – lens displacement) and cardiovascular system (arterial and venous thromboembolic disease). The

### 19.27 Management of hyperlipidaemia in old age

- Prevalence of atherosclerotic cardiovascular disease: greatest in old age.
- Associated cardiovascular risk: lipid levels become less predictive, as do other risk factors apart from age itself.
- Benefit of statin therapy: maintained up to the age of 80 years but evidence is lacking beyond this.
- Life expectancy and statin therapy: lives saved by intervention are associated with shorter life expectancy than in younger patients, and so the impact of statins on quality-adjusted life years is smaller in old age.

### 19.28 Dyslipidaemia in pregnancy

- **Lipid metabolism:** lipid and lipoprotein levels increase during pregnancy. This includes an increase in low-density lipoprotein cholesterol, which resolves post-partum. Remnant dyslipidaemia and hypertriglyceridaemia may be exacerbated during pregnancy.
- **Treatment:** dyslipidaemia is rarely thought to warrant urgent treatment so pharmacological therapy is usually contraindicated when conception or pregnancy is anticipated. Teratogenicity has been reported with systemically absorbed agents, and non-absorbed agents may interfere with nutrient bioavailability.
- **Monitoring:** while still uncommon among women of child-bearing age, cardiovascular disease is increasing in prevalence. Pre-conception cardiovascular review should be considered for women at high risk to optimise medications for pregnancy and to ensure that the patient will be able to withstand the demands of pregnancy and labour.

**Normal metabolic pathway****Inherited metabolic disorder**

**Fig. 19.15 Pathophysiology of inherited metabolic disorders.** Inherited metabolic disorders cause disease either because there is lack of synthesis of an essential metabolite as the result of enzyme deficiency, or because there is accumulation of a toxic metabolite upstream of the deficient enzyme.

phenotypic spectrum is extremely variable and adults may present later in life, often with thromboembolic disease. Treatment aims to reduce homocysteine levels – through vitamin B6 (pyridoxine) – which acts as a cofactor to increase CBS enzyme activity, betaine, folate and vitamin B12 (to utilise the alternative homocysteine remethylation pathway) and consumption of a low-methionine diet. Early treatment and good compliance can prevent many of the expected complications.

**Disorders of the urea cycle**

Ammonia is generated by metabolism in all organs and transported to the liver for disposal by the urea cycle. Defects in any of the six urea cycle enzymes prevents normal ammonia degradation and can lead to life-threatening hyperammonaemia.

**Ornithine tricarbonylase deficiency**

Ornithine tricarbonylase (OTC) deficiency is the most common urea cycle disorder, and is an X-linked recessive disorder. Males often have severe neonatal disease, but the phenotypic spectrum, especially among women, is extremely wide. It may present later in life, often following a physiological stress such as trauma, surgery or post-partum. Acute hyperammonaemia may present as unexplained encephalopathy, often with respiratory alkalosis. If unrecognized, it can rapidly lead to cerebral oedema and death. Severe, neonatal onset disease can be treated by liver transplantation (the donated liver has normal enzyme activity). Later-onset disease can be managed with a protein-restricted diet, arginine supplementation and urea-scavenging medication (sodium benzoate and sodium or glycerol phenylbutyrate) to promote nitrogen excretion via alternative pathways.

**Disorders of carbohydrate metabolism****Galactosaemia**

Inherited variations in the *GALT* gene, causing loss of function of the enzyme galactose-1-phosphate uridylyl transferase, lead to galactosaemia and an inability to metabolise galactose. In countries that do not screen for galactosaemia, patients usually present with neonatal crisis, with life-threatening liver and kidney failure, diarrhoea and cataracts,

often complicated by fulminant sepsis. Treatment is with a lactose- and galactose-free diet. This effectively prevents acute symptoms, but even with treatment there is almost always neuropsychological impairment and many patients exhibit slowly progressive neurological dysfunction over time. Premature ovarian failure occurs in almost all affected women.

**Glycogen storage diseases**

Glycogen storage diseases are a group of rare disorders that result from inherited defects in one of the many enzymes responsible for the formation, mobilisation or breakdown of glycogen, or of utilisation of glucose. The classification and enzyme defects responsible are summarised in Box 19.29. While glycogen storage disease type II (Pompe) is listed in this box, it is caused by deficiency in alpha glucosidase which is a lysosomal enzyme responsible for degradation of glycogen. Accordingly it is now classified as a lysosomal storage disease. The specific enzyme defect predicts symptomology and age of onset. Management is based upon avoidance of fasting, dietary modifications with frequent administration of carbohydrates and carefully managed exercise programmes to avoid hypoglycaemia. Enzyme replacement therapy with alglucosidase alfa is available for the treatment of Pompe disease.

**Disorders of mitochondrial energy metabolism**

During fasting or increased energy demand, fatty acid oxidation is an important source of mitochondrial energy production. Inherited variants causing loss of function in many of the enzymes involved in fatty acid oxidation and electron transfer within mitochondria have been identified. Many disorders have a catastrophic neonatal presentation, with hypoketotic hypoglycaemia, encephalopathy and liver dysfunction. Attenuated adult-onset forms are increasingly recognised, often with significant myopathy and/or acute rhabdomyolysis. Common precipitants in adulthood are endurance exercise events, such as running marathons, and alcohol. Management centres on the avoidance of fasting and provision of a regular carbohydrate energy source, with or without dietary modification of long chain or medium chain fats. Examples include carnitine palmitoyl-transferase 2 (CPT2) deficiency, very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency, medium-chain acyl-CoA dehydrogenase (MCAD) deficiency and multiple acyl-CoA dehydrogenase (MADD) deficiency.

**Lysosomal storage disorders**

The lysosome is an organelle responsible for the breakdown and resynthesis of macromolecules – essentially recycling and waste disposal – within the cell. Variants in genes encoding specific lysosomal enzymes cause loss of enzymatic function, and the accumulation of undegraded or partially degraded macromolecules within the lysosome, eventually leading to tissue damage in multiple body systems (Box 19.30). Biologic therapies with recombinant enzyme replacement therapy (ERT) have been developed to correct the metabolic defect and slow disease progression. The greatest benefit of ERT is seen with early treatment but it does not penetrate the blood–brain barrier and is ineffective in treating neurological manifestations of disease. Some diseases appear more amenable to therapy than others. As ever, there is usually a spectrum of disease severity depending on the degree of residual enzyme function, and treating partial-loss-of-function variants with small molecule therapies to improve trafficking or support enzyme function, or as substrate reduction therapy, has shown promise as an alternative therapeutic strategy.

**The porphyrias**

These disorders are caused by enzymatic defects in the heme-biosynthesis pathway. Most are partial loss of function, with autosomal dominant inheritance and variable penetrance. Diagnosis relies on the detection of characteristic biochemical metabolites, as well as genetic variants and/or enzyme activity levels (Box 19.31)

<b>i</b> 19.29 Glycogen storage diseases*				
Type	Enzyme/transporter deficiency	Major phenotype	Clinical features/complications	Other names
0	Glycogen synthase	Liver	Fasting ketotic hypoglycaemia, postprandial lactic acidaemia	
I	Glucose-6-phosphatase	Liver Kidney Neutropenia	Infantile hypoglycaemia, ketosis, lactic acidosis and hepatomegaly	Von Gierke
II	Alpha-glucosidase	Muscle Heart Brain	Hypotonia, hypertrophic cardiomyopathy and developmental delay in infancy Limb girdle myopathy. Respiratory muscle weakness in adulthood	Pompe
III	Glycogen debrancher	Muscle Heart Liver	Infantile hepatomegaly and hypoglycaemia. Rhabdomyolysis, myopathy and cardiomyopathy in adulthood	Coris/Forbes
IV	Brancher	Muscle Brain Liver	Hepatomegaly, liver failure, myopathy	Anderson
V	Myophosphorylase	Muscle	Exercise intolerance and rhabdomyolysis	McArdle
VI	Glycogen phosphorylase	Liver	Hepatomegaly	Hers
VII	Muscle phosphofructokinase	Muscle	Exercise intolerance, rhabdomyolysis	Tarui
IX	Glycogen phosphorylase kinase	Liver Muscle	Hypoglycaemia Hepatomegaly	
X	Phosphoglycerate mutase	Muscle	Exercise intolerance, rhabdomyolysis	
XI	GLUT-2	Liver Kidney	Hypoglycaemia, tubular dysfunction, hepatosplenomegaly, bone disease	Fanconi–Bickel

\*Types II and IV are the most common syndromes. Some rarer causes of glycogen storage disease have not been included in this box.

<b>i</b> 19.30 Lysosomal storage diseases*				
Disease	Enzyme deficiency	Inheritance	Clinical features	Treatment
Fabry disease 1	Alpha-galactosidase	XLR	Acroparaesthesia, angiokeratoma, corneal verticillata Kidney disease (proteinuria and progressive CKD) Cardiomyopathy and arrhythmias Stroke and white matter changes	Enzyme replacement therapy Small molecule chaperone (amenable variants)
Gaucher disease	Glucocerebrosidase	AR	Hepatosplenomegaly Bone marrow infiltration and skeletal disease Thrombocytopenia Infantile neuronopathic form	Enzyme replacement therapy (not for neuronopathic disease) Substrate reduction therapies
Mucopolysaccharidosis	Eight different enzymes involved in the degradation of glycosaminoglycans	AR	Vary dependent on syndrome Skeletal, joint, valvular disease Characteristic facies Intellectual disability	Enzyme replacement therapy for MPSI; MPSII; MPS IV Limited by lack of efficacy in CNS disease
Gangliosidosis*	GM-1 beta-galactosidase GM-2 beta-hexosaminidase	AR	Severe progressive neurological disease	No specific treatment

\*Some rare lysosomal storage diseases have been described which are not included in this box.  
(AR = autosomal recessive; CKD = chronic kidney disease; CNS = central nervous system; MPS = mucopolysaccharidosis; XLR = X-linked recessive)

Acute porphyrias (the neurovisceral form) are characterised by acute attacks of abdominal pain and neuropathic symptoms, with neuropsychiatric symptoms, tachycardia, hypertension and hyponatraemia. Classically, the urine is pigmented, and darkens on exposure to light. The most common form is acute intermittent porphyria, caused by variants in *PBGD*, which encodes the enzyme porphobilinogen deaminase. Attacks are provoked by a relative depletion of heme, which removes the negative feedback regulation of the heme production pathway and stimulates heme biosynthesis. This results in the accumulation of delta-aminolaevulinic acid (ALA) and

porphobilinogen (PBG) pre-cursors upstream of the metabolic block. ALA causes direct neurotoxicity. Urgent testing of urine for the presence of ALA and/or PBG will confirm the presence of an acute attack, and can be useful to differentiate between acute porphyria attacks and other causes.

Attacks can be provoked by fasting, trauma, intercurrent infection, alcohol, drugs, the menstrual cycle and hormonal contraceptives. A list of safe drugs can be found at [www.drugs-porphyria.org](http://www.drugs-porphyria.org). Cyclical attacks in menstruating women can respond to suppression of the menstrual cycle with gonadotrophin-releasing hormone analogues.

## 19.31 Diagnostic biochemical findings in the porphyrias

Condition	Biochemical abnormalities (protect specimens from light)		
	Urine	Blood	Faeces
Acute intermittent porphyria	↑ALA ↑PBG		
Hereditary coproporphyria	↑ALA ↑PBG ↑ Copro III		↑ Copro III
Variagate porphyria	↑ALA ↑PBG ↑ Copro III		↑ Proto IX
Erythropoietic protoporphyria		↑ Proto IX	↑ Proto IX
Porphyria cutanea tarda	↑ Uro I		

(ALA = delta-aminolaevulinic acid; Copro III = coproporphyrin III; PBG = porphobilinogen; Proto IX = protoporphyrin IX; Uro I = uroporphyrin I)

Management centres on the avoidance of provoking factors, and the provision of an 'emergency protocol' to administer oral carbohydrates (glucose polymer) or intravenous dextrose with electrolytes in order to terminate an acute attack. In severe cases, intravenous heme arginate inhibits the heme biosynthesis pathway, thereby reducing the production of toxic metabolites. However, it is an irritant and frequently causes local phlebitis. Recently, RNA interference therapy has been shown to inhibit ALA synthesis and reduce the rate of acute porphyria attacks in severely affected patients.

### Cutaneous porphyrias

The cutaneous manifestations of porphyria cutanea tarda, erythropoietic porphyria, variagate porphyria and hereditary coproporphyria are discussed in more detail in [Chapter 27](#). It should be noted, however, that variagate porphyria and hereditary coproporphyria can have both neurovisceral and cutaneous features.

## Multiple Choice Questions

19.1. A pregnant woman with phenylketonuria (PKU) attends a routine obstetric appointment, worried about the risk of her unborn baby inheriting the same condition. What is the risk of the fetus also having PKU?

- A. 1 in 4
- B. 1 in 2
- C. Only a risk for male offspring
- D. <1/50
- E. No risk

Answer: D.

PKU is autosomal recessive, and only results in disease when two faulty copies of the affected gene are inherited. A mother with PKU will always pass on one copy to her offspring – who will therefore be a carrier. However, the fetus would only be affected if, by chance, her partner was also a carrier, and passed on their affected gene (1 in 2 chance). Population carrier rates are estimated at ~1/50 so the risk of the fetus being affected by PKU remains low. However, in some countries this population carrier frequency would allow access to pre-natal testing.

More importantly, the fetus is at significant risk from high phenylalanine levels in the mother, who should follow a strictly managed low-phenylalanine diet in order to avoid maternal PKU syndrome.

19.2. A 35-year-old man attends the nephrology clinic with proteinuria. What features would be suspicious for a diagnosis of Fabry disease?

- A. Pain in hands and feet
- B. Peri-umbilical skin rash
- C. Mother had stroke aged 56
- D. LVH on echocardiogram
- E. All of the above

Answer: E.

Acroparaesthesia (burning pain in hands and feet) and angiokeratomas (small, red, raised spots often around the genitals and umbilicus) are features of classical Fabry disease, often present from childhood or adolescence. Cardiomyopathy begins to develop in mid-life. Women with Fabry disease have a variable presentation, but can present with young stroke.

19.3. A 59-year-old man presents for cardiovascular risk assessment, but he has not fasted for the blood collection that was to be performed during his appointment. Which of the following plasma lipid or lipoprotein levels is most likely to be significantly affected by his recent consumption of food?

- A. HDL cholesterol
- B. Lipoprotein (a)
- C. Calculated LDL cholesterol
- D. Non-HDL cholesterol
- E. Total cholesterol

Answer: C.

Calculated LDL cholesterol is correct because the calculation includes the triglyceride level, which increases following food consumption. The effect of food consumption on the other measurements is small by comparison, especially in relative terms.

19.4. The same 59-year-old man returns with a set of fasting results that include: Total cholesterol 6.7 mmol/l (260 mg/dL), fasting triglyceride 3.3 mmol/l (290 mg/dL), HDL cholesterol 0.9 (35 mmol/L (mg/dL), calculated LDL cholesterol 4.3 mmol/L (167mg/dL), non-HDL cholesterol 5.8 mmol/L (225 mg/dL) and fasting serum glucose 6.9 mmol/L (124 mg/dL). The best indicator of the metabolic component of his cardiovascular risk is his level of

- A. HDL cholesterol
- B. Non-HDL cholesterol
- C. Fasting plasma glucose
- D. Calculated LDL cholesterol
- E. Total cholesterol

Answer: B.

Non-HDL cholesterol is correct because it allows for the presence of small dense LDL and other atherogenic lipoproteins. This is particularly relevant in hypertriglyceridaemia, with or without accompanying elevation of fasting plasma glucose. It is more strongly associated with CVD in studies where comparison has been made with the other alternatives.

19.5. The same 59-year-old man fails to improve his lipid profile following diet and exercise advice, and treatment is deemed necessary. Which of the following medications may have a detrimental effect on the triglyceride component of his lipid profile?

- A. Rosuvastatin
- B. Ezetimibe
- C. An anti-PCSK9 monoclonal antibody
- D. Niacin
- E. Cholestyramine

Answer: E.

Cholestyramine reduces re-circulation of bile acids, down-regulates the FXR receptor and stimulates the replacement of the bile acids by conversion of cholesterol via 7-alpha hydroxylase. The response to the down-regulation of FXR includes increased synthesis and secretion of triglyceride and VLDL. The other agents have neutral or favourable effects on triglyceride levels.

19.6. The same 59-year-old man commences atorvastatin 20 mg nocte. His follow-up lipid profile and glucose reveal: total cholesterol 3.7 mmol/L (144 mg/dL), fasting triglyceride 1.1 mmol/L (97 mg/dL), HDL cholesterol 1.1 mmol/L (43mg/dL), calculated LDL cholesterol 2.1 mmol/L (81 mg/dL), non-HDL cholesterol 2.6 mmol/L (101 mg/dL) and fasting serum glucose 8.9 mmol/L (160 mg/dL). A subsequent glucose tolerance test is diagnostic of new onset type 2 diabetes. The onset of diabetes and the use of statins is

- A. A completely unrelated phenomenon
- B. More likely in those with pre-existing impaired fasting glucose
- C. A contraindication to statin use due to CVD risk associated with type 2 diabetes
- D. Unrelated to the dose or potency of the statin
- E. Inconsistent with the fact that fasting triglyceride has improved

Answer: B.

Type 2 diabetes following statin therapy is likely in those with pre-existing impaired fasting glucose. It is proportional to the dose and potency of the statin, but the CVD benefit of the response clearly outweighs the CVD risk of the diabetes. Statins modestly improve triglyceride, even in the presence of diabetes.

19.7. A 24-year-old man presents for assessment of his lipid profile because severe hypercholesterolaemia was detected as part of his life insurance application. His LDL cholesterol was 8.2 mmol/L (318 mg/dL) and his mother's level is thought to be even higher. Which of the following is true?

- A. Genetic testing for familial hypercholesterolaemia (FH) should be performed on his original blood sample as an add-on test
- B. In his case, the severity of his LDL cholesterol elevation invalidates the use of population-based absolute risk calculators
- C. The main advantage of genetic diagnosis in FH is that it can be used to guide the selection of first line therapy
- D. The very high level of LDL cholesterol makes his continuation or cessation of smoking irrelevant from the CVD point of view
- E. A non-elevated level of LDL cholesterol earlier in life is possible because the metabolic changes associated with FH emerge after childhood

Answer: B.

LDL is above the 99th percentile in most cases of FH, so population studies do not have sufficient power to estimate the increase in CVD risk. Genetic testing requires explanation and counselling, but it cannot guide treatment. Smoking amplifies CVD risk in FH. FH is manifest from birth.

19.8. The same 24-year-old patient undertakes genetic testing, which yields a variant of unknown significance in the LDL receptor gene. Which of the following is true?

- A. This result explains the increase in LDL cholesterol level in the patient and his mother
- B. This result can be used to screen his siblings for familial hypercholesterolaemia (FH)
- C. This result means that there are some cholesterol-lowering drugs that will not work in this patient
- D. Genetic testing is guaranteed to find the cause of FH in every case
- E. The patient should have been counselled before the test was performed in case he had any questions, concerns or misconceptions, e.g. the need to disclose results for life insurance purposes

Answer: E.

Insurance requirements vary between jurisdictions and there are many ethical and clinical issues that need to be considered. The test may not explain the results in the patient or his mother and it may not be conclusive for screening of siblings. Genetic diagnosis is only achieved in about 80% of cases with clinical FH and it rarely informs about the effectiveness of therapy.

## Clinical examination in endocrine disease

Endocrine disease causes clinical syndromes with symptoms and signs involving many organ systems. The emphasis of the clinical examination depends on the gland or hormone that is thought to be abnormal.

Diabetes mellitus (described in detail in Ch. 21) and thyroid disease are the most common endocrine disorders.

### 3 Blood pressure

Hypertension in Cushing's and Conn syndromes, pheochromocytoma  
Hypotension in adrenal insufficiency

### 4 Pulse

Atrial fibrillation  
Sinus tachycardia  
Bradycardia

### 3 Skin

Hair distribution  
Dry/greasy  
Pigmentation/pallor  
Bruising  
Vitiligo  
Striae  
Thickness

▲ Vitiligo in organ-specific autoimmune disease

### 2 Hands

Palmar erythema  
Tremor  
Acromegaly  
Carpal tunnel syndrome

▲ Pigmentation of creases due to high ACTH levels in Addison's disease

▲ Acromegalic hands. Note soft tissue enlargement causing 'spade-like' changes

### 1 Height and weight

### 5 Head

▲ Prognathism in acromegaly

Eyes  
Graves' disease (see opposite)

Pubertal development  
Testicular volume

### 12 Legs

Proximal myopathy  
Myxoedema

▲ Pretibial myxoedema in Graves' disease

### Observation

- Most examination in endocrinology is by observation
- Astute observation can often yield 'spot' diagnosis of endocrine disorders
- The emphasis of examination varies depending on which gland or hormone is thought to be involved

**6 Examination of the visual fields by confrontation**

- Sit opposite patient
- You and patient cover opposite eyes
- Bring red pin (or wiggling finger) slowly into view from extreme of your vision, as shown
- Ask patient to say 'now' when it comes into view
- Continue to move pin into centre of vision and ask patient to tell you if it disappears
- Repeat in each of four quadrants
- Repeat in other eye

A bitemporal hemianopia is the classical finding in pituitary macroadenomas (p. 695)

**6 Examination in Graves' ophthalmopathy**

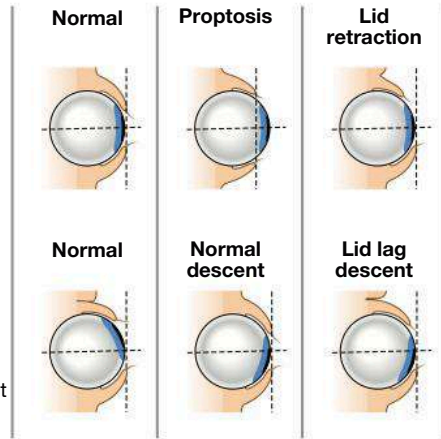

- **Inspect** from front and side  
Periorbital oedema (Fig. 20.9)  
Conjunctival inflammation (chemosis)  
Corneal ulceration  
Proptosis (exophthalmos)\*  
Lid retraction\*

- **Range of eye movements**  
Lid lag on descending gaze\*  
Diplopia on lateral gaze

- **Pupillary reflexes**  
Afferent defect (pupils constrict further on swinging light to unaffected eye, Box 28.21)

- **Vision**  
Visual acuity impaired  
Loss of colour vision  
Visual field defects

- **Ophthalmoscopy**  
Optic disc pallor  
Papilloedema

**Right proptosis and afferent pupillary defect**

\*Note position of eyelids relative to iris.

## FCPS Single Best Question

**7 Examination of the thyroid gland**

- **Inspect** from front to side
- **Palpate** from behind  
Thyroid moves on swallowing  
Check if lower margin is palpable  
Cervical lymph nodes  
Tracheal deviation
- **Auscultate** for bruit  
Ask patient to hold breath  
If present, check for radiating murmur
- **Percuss** for retrosternal thyroid
- Consider systemic signs of thyroid dysfunction (Box 20.7) incl. tremor, palmar erythema, warm peripheries, tachycardia, lid lag
- Consider signs of Graves' disease incl. ophthalmopathy, pretibial myxoedema
- Check for Pemberton's sign, i.e. facial engorgement when arms raised above head

**Abnormal findings**

- Diffuse soft goitre with bruit  
Graves' disease (p. 660)
- Diffuse firm goitre  
Hashimoto's thyroiditis (p. 663)
- Diffuse tender goitre  
Subacute thyroiditis (p. 663)

- Multinodular goitre (p. 664)  
± Retrosternal extension,  
tracheal compression

- Solitary nodule (p. 659)  
Adenoma, cyst or carcinoma
- Cervical lymphadenopathy  
Suggests carcinoma

Endocrinology concerns the synthesis, secretion and action of hormones. These are chemical messengers released from endocrine glands that coordinate the activities of many different cells. Endocrine diseases can therefore affect multiple organs and systems. This chapter describes the principles of endocrinology before dealing with the function and diseases of each gland in turn.

Some endocrine disorders are common, particularly those of the thyroid, parathyroid glands, reproductive system and  $\beta$  cells of the pancreas (Ch. 21). For example, thyroid dysfunction occurs in more than 10% of the population in areas with iodine deficiency, such as the Himalayas, and 4% of women aged 20–50 years in the UK. Less common endocrine syndromes are described later in the chapter.

Few endocrine therapies have been evaluated by randomised controlled trials, in part because hormone replacement therapy (e.g. with levothyroxine) has obvious clinical benefits and placebo-controlled trials would be unethical. Where trials have been performed, they relate mainly to use of therapy that is 'optional' and/or more recently available, such as oestrogen replacement in post-menopausal women, androgen therapy in older men and growth hormone replacement.

## An overview of endocrinology

### Functional anatomy and physiology

Some endocrine glands, such as the parathyroids and pancreas, respond directly to metabolic signals, but most are controlled by hormones released from the pituitary gland. Anterior pituitary hormone secretion is controlled in turn by substances produced in the hypothalamus and released into portal blood, which drains directly down the pituitary stalk (Fig. 20.1). Posterior pituitary hormones are synthesised in the hypothalamus and transported down nerve axons, to be released from the posterior pituitary. Hormone release in the hypothalamus and pituitary is regulated by numerous stimuli and through feedback control by hormones produced by the target glands (thyroid, adrenal cortex and gonads). These integrated endocrine systems are called 'axes' and are listed in Figure 20.2.

A wide variety of molecules can act as hormones, including peptides such as insulin and growth hormone, glycoproteins such as thyroid-stimulating hormone, and amines such as noradrenaline (norepinephrine). The biological effects of hormones are mediated by binding to receptors. Many receptors are located on the cell surface. These interact with various intracellular signalling molecules on the cytosolic side of the plasma membrane to affect cell function, usually through changes in gene expression. Some hormones, most notably steroids, bind to specific intracellular receptors. The hormone/receptor complex forms a ligand-activated transcription factor, which regulates gene expression directly.

The classical model of endocrine function involves hormones synthesised in endocrine glands, which are released into the circulation and act at sites distant from those of secretion (as in Fig. 20.1). However, additional levels of regulation are now recognised. Many other organs secrete hormones or contribute to the peripheral metabolism and activation of prohormones. A notable example is the production of oestrogens from adrenal androgens in adipose tissue by the enzyme aromatase. Some hormones, such as neurotransmitters, act in a paracrine fashion to affect adjacent cells, or act in an autocrine way to affect behaviour of the cell that produces the hormone.

### Endocrine pathology

For each endocrine axis or major gland, diseases can be classified as shown in Box 20.1. Pathology arising within the gland is often called 'primary' disease (e.g. primary hypothyroidism in Hashimoto's thyroiditis), while abnormal stimulation of the gland is often called 'secondary' disease (e.g. secondary hypothyroidism in patients with a pituitary tumour

**Fig. 20.1** An archetypal endocrine axis. Regulation by negative feedback and direct control is shown, along with the equilibrium between active circulating free hormone and bound or metabolised hormone.

## 20.1 Classification of endocrine disease

### Hormone excess

- Primary gland over-production
- Secondary to excess trophic substance

### Hormone deficiency

- Primary gland failure
- Secondary to deficient trophic hormone

### Hormone hypersensitivity

- Failure of inactivation of hormone
- Target organ over-activity/hypersensitivity

### Hormone resistance

- Failure of activation by hormone
- Target organ resistance

### Non-functioning tumours

- Benign
- Malignant

and thyroid-stimulating hormone deficiency). Some pathological processes can affect multiple endocrine glands; these may have a genetic basis (such as organ-specific autoimmune endocrine disorders and the multiple endocrine neoplasia (MEN) syndromes) or be a consequence of therapy for another disease (e.g. following treatment of childhood cancer with chemotherapy and/or radiotherapy).

## Investigation of endocrine disease

Biochemical investigations play a central role in endocrinology. Most hormones can be measured in blood but the circumstances in which the sample is taken are often crucial, especially for hormones with pulsatile secretion, such as growth hormone; those that show circadian variation,

**Fig. 20.2** The principal endocrine ‘axes’. Some major endocrine glands are not controlled by the pituitary. These include the parathyroid glands (regulated by calcium concentrations, p. 675), the adrenal zona glomerulosa (regulated by the renin–angiotensin system, p.679) and the endocrine pancreas (p. 689). Italics show negative regulation. (ACTH = adrenocorticotropic hormone; CRH = corticotrophin-releasing hormone; GH = growth hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotrophin-releasing hormone; IGF-1 = insulin-like growth factor-1; IGF-BP3 = IGF-binding protein-3; LH = luteinising hormone;  $T_3$  = triiodothyronine;  $T_4$  = thyroxine; TRH = thyrotrophin-releasing hormone; TSH = thyroid-stimulating hormone; vasopressin = antidiuretic hormone (ADH))

such as cortisol; or those that demonstrate monthly variation, such as oestrogen or progesterone. Some hormones are labile and need special collection, handling and processing requirements, e.g. collection in a special tube and/or rapid transportation to the laboratory on ice. Local protocols for hormone measurement should be carefully followed. Other investigations, such as imaging and biopsy, are more frequently reserved for patients who present with a tumour. The principles of investigation are shown in [Box 20.2](#). The choice of test is often pragmatic, taking local access to reliable sampling facilities and laboratory measurements into account.

### Presenting problems in endocrine disease

Endocrine diseases present in many different ways and to clinicians in many different disciplines. Classical syndromes are described in relation to individual glands in the following sections. Often, however, the presentation is with non-specific symptoms ([Box 20.3](#)) or with asymptomatic biochemical abnormalities. In addition, endocrine diseases are encountered in the differential diagnosis of common complaints discussed in other chapters of this book, including electrolyte abnormalities ([Ch. 19](#)), hypertension ([Ch. 16](#)), obesity ([Ch. 22](#)) and osteoporosis ([Ch. 26](#)). Although diseases of the adrenal glands, hypothalamus and pituitary are relatively rare, their diagnosis often relies on astute clinical observation in a patient with non-specific complaints, so it is important that clinicians are familiar with their key features.

## The thyroid gland

Diseases of the thyroid, summarised in [Box 20.4](#), predominantly affect females and are common, occurring in about 5% of the population. The thyroid axis is involved in the regulation of cellular differentiation and metabolism in virtually all nucleated cells, so that disorders of thyroid function have diverse manifestations. Structural diseases of the thyroid gland, such as goitre, commonly occur in patients with normal thyroid function.

### i

## 20.2 Principles of endocrine investigation

### Timing of measurement

- Release of many hormones is rhythmical (pulsatile, circadian or monthly), so random measurement may be invalid and sequential or dynamic tests may be required

### Choice of dynamic biochemical test

- Abnormalities are often characterised by loss of normal regulation of hormone secretion
- If hormone deficiency is suspected, choose a stimulation test
- If hormone excess is suspected, choose a suppression test
- The more tests there are to choose from, the less likely it is that any single test is infallible, so avoid interpreting one result in isolation

### Imaging

- ‘Functional’ as well as conventional ‘structural’ imaging can be performed as secretory endocrine cells can also take up labelled substrates, e.g. radio-labelled iodine or octreotide
- Most endocrine glands have a high prevalence of ‘incidentalomas’, so do not scan unless the biochemistry confirms endocrine dysfunction or the primary problem is a tumour

### Biopsy

- Many endocrine tumours are difficult to classify histologically (e.g. adrenal carcinoma and adenoma)

## Functional anatomy, physiology and investigations

Thyroid physiology is illustrated in [Figure 20.3](#). The parafollicular C cells secrete calcitonin, which is of no apparent physiological significance in humans. The follicular epithelial cells synthesise thyroid hormones by incorporating iodine into the amino acid tyrosine on the surface of thyroglobulin (Tg), a protein secreted into the colloid of the follicle. Iodide is a key substrate for thyroid hormone synthesis; a dietary intake in excess of 100 µg/day is required to maintain thyroid function in adults. The thyroid secretes predominantly thyroxine ( $T_4$ ) and only a small amount of

20.3 Examples of non-specific presentations of endocrine disease*	
Symptom	Most likely endocrine disorder(s)
Lethargy and depression	Hypothyroidism, diabetes mellitus, hyperparathyroidism, hypogonadism, adrenal insufficiency, Cushing's syndrome
Weight gain	Hypothyroidism, Cushing's syndrome
Weight loss	Thyrotoxicosis, adrenal insufficiency, diabetes mellitus
Polyuria and polydipsia	Diabetes mellitus, diabetes insipidus, hyperparathyroidism, hypokalaemia (Conn syndrome)
Heat intolerance*	Thyrotoxicosis
Palpitation	Thyrotoxicosis, pheochromocytoma
Headache	Acromegaly, pituitary tumour, pheochromocytoma
Muscle weakness (usually proximal)	Thyrotoxicosis, Cushing's syndrome, hypokalaemia (e.g. Conn syndrome), hyperparathyroidism, hypogonadism
Coarsening of features	Acromegaly, hypothyroidism

\*Heat intolerance is a common feature of menopause.

triiodothyronine ( $T_3$ ); approximately 85% of  $T_3$  in blood is produced from  $T_4$  by a family of monodeiodinase enzymes that are active in many tissues, including liver, muscle, heart and kidney. Selenium is an integral component of these monodeiodinases.  $T_4$  can be regarded as a pro-hormone, since it has a longer half-life in blood than  $T_3$  (approximately 1 week compared with approximately 18 hours), and binds and activates thyroid hormone receptors less effectively than  $T_3$ .  $T_4$  can also be converted to the inactive metabolite, reverse  $T_3$ .

$T_3$  and  $T_4$  circulate in plasma almost entirely (>99%) bound to transport proteins, mainly thyroxine-binding globulin (TBG). It is the unbound or free hormones that diffuse into tissues and exert diverse metabolic actions. Some laboratories use assays that measure total  $T_4$  and  $T_3$  in plasma but it is increasingly common to measure free  $T_4$  and free  $T_3$ . The theoretical advantage of the free hormone measurements is that they are not influenced by changes in the concentration of binding proteins. For example, TBG levels are increased by oestrogen (such as in the combined oral contraceptive pill) and this will result in raised total  $T_3$  and  $T_4$ , although free thyroid hormone levels are normal.

Production of  $T_3$  and  $T_4$  in the thyroid is stimulated by thyrotrophin (thyroid-stimulating hormone, TSH), a glycoprotein released from the thyrotroph cells of the anterior pituitary in response to the hypothalamic tripeptide, thyrotrophin-releasing hormone (TRH). A circadian rhythm of TSH secretion can be demonstrated with a peak at 0100hrs and trough at 1100hrs, but the variation is small so that thyroid function can be assessed reliably from a single blood sample taken at any time of day and does not usually require any dynamic stimulation or suppression tests. There is a negative feedback of thyroid hormones on the hypothalamus and pituitary such that in thyrotoxicosis, when plasma concentrations of  $T_3$  and  $T_4$  are raised, TSH secretion is suppressed. Conversely, in hypothyroidism due to disease of the thyroid gland, low  $T_3$  and  $T_4$  are associated with high circulating TSH levels. The relationship between TSH and  $T_4$  is classically described as inverse log-linear (Fig. 20.4). The anterior pituitary is, though, very sensitive to minor changes in thyroid hormone levels within the reference range. For example, in an individual whose free  $T_4$  level is usually 15 pmol/L (1.17 ng/dL), a rise or fall of 5 pmol/L (0.39 ng/dL) would be associated on the one hand with undetectable TSH, and on the other hand with a raised TSH. For this reason, TSH is usually regarded as the most useful investigation of thyroid function. However, interpretation of TSH values without considering thyroid hormone levels may be misleading

20.4 Classification of thyroid disease		
	Primary	Secondary
Hormone excess	Graves' disease Multinodular goitre Adenoma Subacute thyroiditis	TSHoma
Hormone deficiency	Hashimoto's thyroiditis Atrophic hypothyroidism	Hypopituitarism
Hormone hypersensitivity	—	
Hormone resistance	Thyroid hormone resistance syndrome 5'-monodeiodinase deficiency	
Non-functioning tumours	Differentiated carcinoma Medullary carcinoma Lymphoma	

in patients with pituitary disease; for example, TSH is inappropriately low or 'normal' in secondary hypothyroidism (see Box 20.5 and Box 20.51). Moreover, TSH may take several weeks to 'catch up' with  $T_4$  and  $T_3$  levels; for example, levothyroxine therapy will raise  $T_4$  and  $T_3$  levels within approximately 2 weeks but it may take 4–6 weeks for the TSH to reach a steady state. Heterophilic antibodies (host antibodies with affinity to the animal antibodies used in biological assays) can also interfere with the TSH assay and cause a spurious high or low measurement. Common patterns of abnormal thyroid function test results and their interpretation are shown in Box 20.5.

Other modalities commonly employed in the investigation of thyroid disease include measurement of antibodies against the TSH receptor or other thyroid antigens (see Box 20.8), radioisotope imaging, fine needle aspiration biopsy and ultrasound. Their use is described below.

## Presenting problems in thyroid disease

The most common presentations are hyperthyroidism (thyrotoxicosis), hypothyroidism and enlargement of the thyroid (goitre or thyroid nodule). Widespread availability of thyroid function tests has led to the increasingly frequent identification of patients with abnormal results who either are asymptomatic or have non-specific complaints such as tiredness and weight gain.

### Thyrotoxicosis

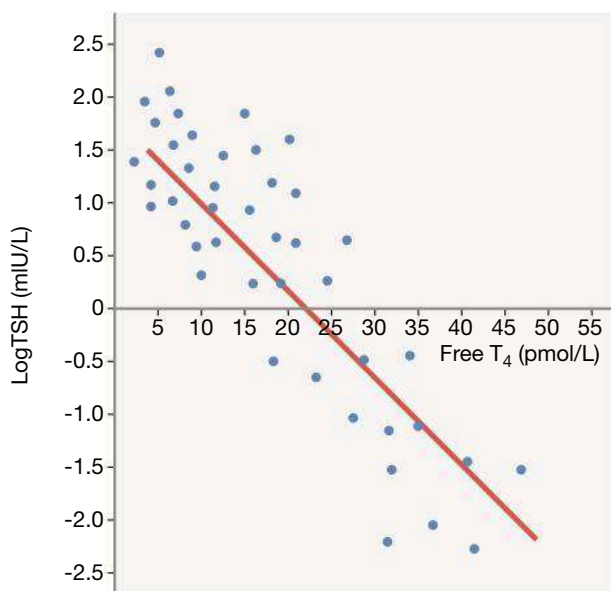

Thyrotoxicosis describes a constellation of clinical features arising from elevated circulating levels of thyroid hormone. The most common causes are Graves' disease, multinodular goitre, autonomously functioning thyroid nodules (toxic adenoma) and thyroiditis (Box 20.6).

#### Clinical assessment

The clinical manifestations of thyrotoxicosis are shown in Box 20.7 and an approach to differential diagnosis is given in Figure 20.5. The most common symptoms are weight loss with a normal or increased appetite, heat intolerance, palpitations, tremor and irritability. Tachycardia, palmar erythema and lid lag are common signs. Not all patients have a palpable goitre, but experienced clinicians can discriminate the diffuse soft goitre of Graves' disease from the irregular enlargement of a multinodular goitre. All causes of thyrotoxicosis can cause lid retraction and lid lag, due to potentiation of sympathetic innervation of the levator palpebrae muscles, but only Graves' disease causes other features of ophthalmopathy, including periorbital oedema, conjunctival irritation, exophthalmos

**Fig. 20.3** Structure and function of the thyroid gland. (1) Thyroglobulin (Tg) is synthesised and secreted into the colloid of the follicle. (2) Inorganic iodide ( $I^-$ ) is actively transported into the follicular cell ('trapping'). (3) Iodide is transported on to the colloidal surface by a transporter (pendrin, defective in Pendred syndrome, p. 667) and 'organified' by the thyroid peroxidase enzyme, which incorporates it into the amino acid tyrosine on the surface of Tg to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). (4) Iodinated tyrosines couple to form triiodothyronine ( $T_3$ ) and thyroxine ( $T_4$ ). (5) Tg is endocytosed. (6) Tg is cleaved by proteolysis to free the iodinated tyrosine and thyroid hormones. (7) Iodinated tyrosine is dehalogenated to recycle the iodide. (8)  $T_4$  is converted to  $T_3$  by 5'-monodeiodinase. (CNS = central nervous system; TSH = thyroid-stimulating hormone)

**Fig. 20.4** The relationship between serum thyroid-stimulating hormone (TSH) and free  $T_4$ . Due to the classic negative feedback loop between  $T_4$  and TSH, there is an inverse relationship between serum free  $T_4$  and the log of serum TSH. To convert pmol/L to ng/dL, divide by 12.87.

and diplopia. Pretibial myxoedema (see p. 663) and the rare thyroid acropachy (a periosteal hypertrophy, indistinguishable from finger clubbing) are also specific to Graves' disease.

### Investigations

The first-line investigations are serum  $T_3$ ,  $T_4$  and TSH. If abnormal values are found, the tests should be repeated and the abnormality confirmed in view of the likely need for prolonged medical treatment or destructive therapy. In most patients, serum  $T_3$  and  $T_4$  are both elevated, but  $T_4$  is in the upper part of the reference range and  $T_3$  is raised ( $T_3$  toxicosis) in about 5%. Serum TSH is undetectable in primary thyrotoxicosis, but values can be raised in the very rare syndrome of secondary thyrotoxicosis caused by a TSH-producing pituitary adenoma. When biochemical thyrotoxicosis has been confirmed, measurement of TSH receptor antibodies (TRAb, elevated in Graves' disease; Box 20.8) is recommended. Where TRAb is not available, radioisotope scanning is an alternative diagnostic approach, as shown in Figure 20.5. Other non-specific abnormalities are common (Box 20.9). An electrocardiogram (ECG) may demonstrate sinus tachycardia or atrial fibrillation.

Radio-iodine uptake tests measure the proportion of isotope that is trapped in the whole gland but have been largely superseded by  $^{99m}Tc$  scintigraphy scans, which also indicate trapping, are quicker to perform with a lower dose of radioactivity, and provide a higher-resolution image. In low-uptake thyrotoxicosis, the cause is usually a transient thyroiditis. Occasionally, patients induce 'factitious thyrotoxicosis' by consuming excessive amounts of a thyroid hormone preparation, most often levothyroxine. The exogenous levothyroxine suppresses pituitary TSH secretion and hence iodine uptake, serum thyroglobulin and release

20.5 How to interpret thyroid function test results			
TSH	T <sub>4</sub>	T <sub>3</sub>	Most likely interpretation(s)
Undetectable	Raised	Raised	Primary thyrotoxicosis
Undetectable or low	Raised	Normal	Over-treatment of hypothyroidism with levothyroxine Factitious thyrotoxicosis
Undetectable	Normal <sup>1</sup>	Raised	Primary T <sub>3</sub> toxicosis
Undetectable	Normal <sup>1</sup>	Normal <sup>1</sup>	Subclinical thyrotoxicosis
Undetectable or low	Raised	Low or normal	Non-thyroidal illness Amiodarone therapy
Undetectable or low	Low	Raised	Over-treatment of hypothyroidism with liothyronine (T <sub>3</sub> )
Undetectable	Low	Low	Secondary hypothyroidism <sup>4</sup> Transient thyroiditis in evolution
Normal	Low	Low <sup>2</sup>	Secondary hypothyroidism <sup>4</sup>
Mildly elevated 5–20 mIU/L	Low	Low <sup>2</sup>	Primary hypothyroidism Secondary hypothyroidism <sup>4</sup>
Elevated >20 mIU/L	Low	Low <sup>2</sup>	Primary hypothyroidism
Mildly elevated 5–20 mIU/L	Normal <sup>3</sup>	Normal <sup>2</sup>	Subclinical hypothyroidism
Elevated 20–500 mIU/L	Normal	Normal	Artefact Heterophilic antibodies (host antibodies with affinity to the animal antibodies used in TSH assays)
Elevated	Raised	Raised	Non-adherence to levothyroxine replacement – recent 'loading' dose Secondary thyrotoxicosis <sup>4</sup> Thyroid hormone resistance

<sup>1</sup>Usually upper part of reference range. <sup>2</sup>T<sub>3</sub> is not a sensitive indicator of hypothyroidism and should not be requested. <sup>3</sup>Usually lower part of reference range. <sup>4</sup>i.e. Secondary to pituitary or hypothalamic disease. Note that TSH assays may report detectable TSH. (TSH = thyroid-stimulating hormone)

20.6 Causes of thyrotoxicosis and their relative frequencies	
Cause	Frequency <sup>1</sup> (%)
<b>Graves' disease</b>	76
<b>Multinodular goitre</b>	14
<b>Solitary thyroid adenoma</b>	5
<b>Thyroiditis</b>	
Subacute (de Quervain's) <sup>2</sup>	3
Post-partum <sup>2</sup>	0.5
<b>Iodide-induced</b>	
Drugs (amiodarone) <sup>2</sup>	1
Radiographic contrast media <sup>2</sup>	–
Iodine supplementation programme <sup>2</sup>	–
<b>Extrathyroidal source of thyroid hormone</b>	
Factitious thyrotoxicosis <sup>2</sup>	0.2
Struma ovarii <sup>2,3</sup>	–
<b>TSH-induced</b>	
TSH-secreting pituitary adenoma	0.2
Choriocarcinoma and hydatidiform mole <sup>4</sup>	–
Follicular carcinoma±metastases	0.1

<sup>1</sup>In a series of 2087 patients presenting to the Royal Infirmary of Edinburgh over a 10-year period. <sup>2</sup>Characterised by negligible radioisotope uptake. <sup>3</sup>i.e. Ovarian teratoma containing thyroid tissue. <sup>4</sup>Human chorionic gonadotrophin has thyroid-stimulating activity. (TSH = thyroid-stimulating hormone)

of endogenous thyroid hormones. The T<sub>4</sub>:T<sub>3</sub> ratio (typically 30:1 in conventional thyrotoxicosis) is increased to above 70:1 because circulating T<sub>3</sub> in factitious thyrotoxicosis is derived exclusively from the peripheral monodeiodination of T<sub>4</sub> and not from thyroid secretion. The combination

of negligible iodine uptake, high T<sub>4</sub>:T<sub>3</sub> ratio and a low or undetectable thyroglobulin is diagnostic.

### Management

Definitive treatment of thyrotoxicosis depends on the underlying cause and may include antithyroid drugs, radioactive iodine or surgery. A non-selective β-adrenoceptor antagonist (β-blocker), such as propranolol (160 mg daily), will alleviate but not abolish symptoms in most patients within 24–48 hours. Beta-blockers should not be used for long-term treatment of thyrotoxicosis but are extremely useful in the short term, while patients are awaiting hospital consultation or following <sup>131</sup>I therapy. Verapamil may be used as an alternative to β-blockers, e.g. in patients with asthma, but usually is only effective in improving tachycardia and has little effect on the other systemic manifestations of thyrotoxicosis.

### Atrial fibrillation in thyrotoxicosis

Atrial fibrillation occurs in about 10% of patients with thyrotoxicosis. The incidence is higher in men and increases with age, so that almost half of all males with thyrotoxicosis over the age of 60 are affected. Moreover, subclinical thyrotoxicosis (see p. 659) is a risk factor for atrial fibrillation. Characteristically, the ventricular rate is little influenced by digoxin but responds to the addition of a β-blocker. Thromboembolic vascular complications are particularly common in thyrotoxic atrial fibrillation so that anticoagulation is required, unless contraindicated. Once thyroid hormone and TSH concentrations have been returned to normal, atrial fibrillation will spontaneously revert to sinus rhythm in about 50% of patients but cardioversion may be required in the remainder.

### Thyrotoxic crisis ('thyroid storm')

This is a rare but life-threatening complication of thyrotoxicosis. The most prominent signs are fever, agitation, delirium, tachycardia or atrial fibrillation and, in the older patient, cardiac failure. Thyrotoxic crisis is a

## 20.7 Clinical features of thyroid dysfunction

Thyrotoxicosis		Hypothyroidism	
Symptoms	Signs	Symptoms	Signs
<b>Common</b>			
Weight loss despite normal or increased appetite	Weight loss	Weight gain	Weight gain
Heat intolerance, sweating	Tremor	Cold intolerance	
Palpitations, tremor	Palmar erythema	Fatigue, somnolence	
Dyspnoea, fatigue	Sinus tachycardia	Dry skin	
Irritability, emotional lability	Lid retraction, lid lag	Dry hair	
		Menorrhagia	
<b>Less common</b>			
Osteoporosis (fracture, loss of height)	Goitre with bruit <sup>1</sup>	Constipation	Hoarse voice
Diarrhoea, steatorrhoea	Atrial fibrillation <sup>2</sup>	Hoarseness	Facial features:
Angina	Systolic hypertension/increased pulse pressure	Carpal tunnel syndrome	Purplish lips
Ankle swelling	Cardiac failure <sup>2</sup>	Alopecia	Malar flush
Anxiety, psychosis	Hyper-reflexia	Aches and pains	Periorbital oedema
Muscle weakness	Ill-sustained clonus	Muscle stiffness	Loss of lateral eyebrows
Periodic paralysis (predominantly in Chinese and other Asian groups)	Proximal myopathy	Deafness	Anaemia
Pruritus, alopecia	Bulbar myopathy <sup>2</sup>	Depression	Carotenaemia
Amenorrhoea/oligomenorrhoea		Infertility	Erythema ab igne
Infertility, spontaneous abortion			Bradycardia hypertension
Loss of libido, impotence			Delayed relaxation of reflexes
Excessive lacrimation			Dermal myxoedema
<b>Rare</b>			
Vomiting	Gynaecomastia	Psychosis (myxoedema madness)	Ileus, ascites
Apathy	Spider naevi	Galactorrhoea	Pericardial and pleural effusions
Anorexia	Onycholysis	Impotence	Cerebellar ataxia
Exacerbation of asthma	Pigmentation		Myotonia

<sup>1</sup>In Graves' disease only. <sup>2</sup>Features found particularly in older patients.

## 20.8 Prevalence of thyroid autoantibodies (%)

	Antibodies to:		
	Thyroid peroxidase <sup>1</sup>	Thyroglobulin	TSH receptor <sup>2</sup>
Normal population	8–27	5–20	0
Graves' disease	50–80	50–70	>95
Autoimmune hypothyroidism	90–100	80–90	10–20
Multinodular goitre	~30–40	~30–40	0
Transient thyroiditis	~30–40	~30–40	0

<sup>1</sup>Thyroid peroxidase (TPO) antibodies are the principal component of what was previously measured as thyroid 'microsomal' antibodies. <sup>2</sup>Thyroid-stimulating hormone receptor antibodies (TRAb) can be agonists (stimulatory, causing Graves' thyrotoxicosis) or antagonists ('blocking', causing hypothyroidism).

medical emergency and has a mortality of 10% despite early recognition and treatment. It is most commonly precipitated by infection in a patient with previously unrecognised or inadequately treated thyrotoxicosis. It may also develop in known thyrotoxicosis shortly after thyroidectomy in an ill-prepared patient or within a few days of <sup>131</sup>I therapy, when acute radiation damage may lead to a transient rise in serum thyroid hormone levels. Urgent specialist endocrine input should be sought in cases of suspected 'thyroid storm', both to confirm the diagnosis and provide advice on appropriate treatment.

Patients should be rehydrated and given propranolol, either orally (80mg 4 times daily) or intravenously (1–5mg 4 times daily). Both glucocorticoids (hydrocortisone 100mg IV every 8 hours) and iodine are important in reducing the conversion of T<sub>4</sub> to active T<sub>3</sub>. Sodium ipodate, a radiographic contrast medium (500mg per day orally), will restore serum T<sub>3</sub> levels to normal in 48–72 hours. Where sodium ipodate is not available, potassium iodide or Lugol's solution are reasonable alternatives. Oral propylthiouracil (PTU) (200mg every 4 hours) should be given to inhibit

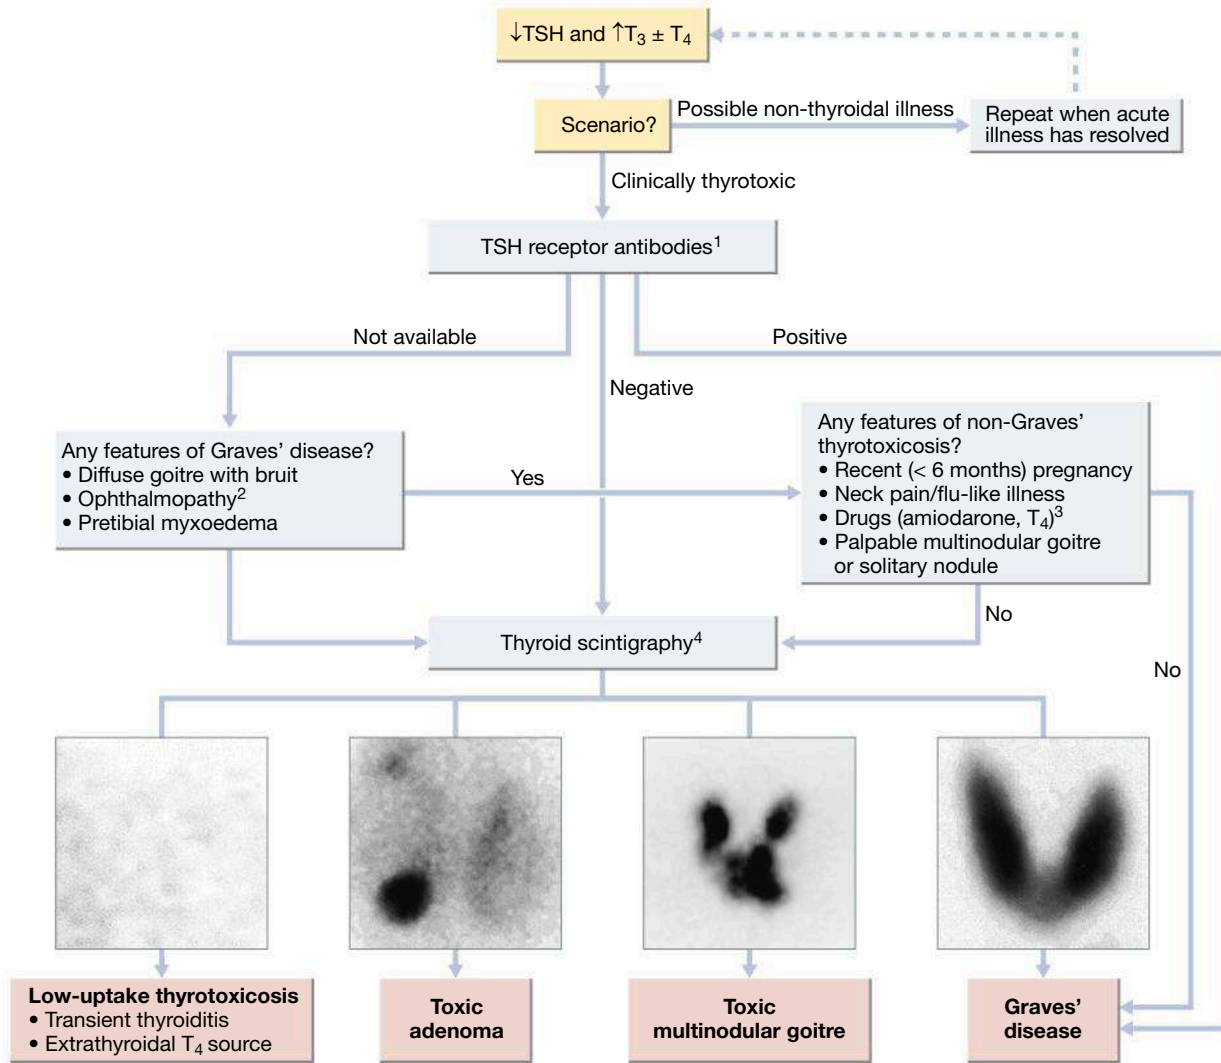

the synthesis of new thyroid hormone. PTU is preferred to carbimazole (20mg every 6 hours) as it also inhibits the conversion of T<sub>4</sub> to T<sub>3</sub>. If the patient is unconscious or uncooperative, PTU and propranolol can be administered by nasogastric tube. After 10–14 days the patient can usually be maintained on carbimazole alone.

### Hyperthyroidism in old age

Some of the diagnostic and management challenges of hyperthyroidism in older people are highlighted in [Box 20.12](#).

### Hypothyroidism

Hypothyroidism is a common condition with various causes ([Box 20.10](#)), but autoimmune disease (Hashimoto's thyroiditis) and thyroid failure following <sup>131</sup>I or surgical treatment of thyrotoxicosis account for over 90% of cases, except in areas where iodine deficiency is endemic. Women are affected approximately six times more frequently than men.

**Fig. 20.5** Establishing the differential diagnosis in thyrotoxicosis. <sup>1</sup>Thyroid-stimulating hormone (TSH) receptor antibodies are very rare in patients without autoimmune thyroid disease but occur in only 80%–95% of patients with Graves' disease; a positive test is therefore confirmatory but a negative test does not exclude Graves' disease. Other thyroid antibodies (e.g. anti-peroxidase and anti-thyroglobulin antibodies) are unhelpful in the differential diagnosis since they occur frequently in the population and are found with several of the disorders that cause thyrotoxicosis. <sup>2</sup>Graves' ophthalmopathy refers to clinical features of exophthalmos and periorbital and conjunctival oedema, not simply the lid lag and lid retraction that can occur in all forms of thyrotoxicosis. <sup>3</sup>Scintigraphy is not necessary in most cases of drug-induced thyrotoxicosis. <sup>4</sup><sup>99m</sup>Tc-technetium pertechnetate scans of patients with thyrotoxicosis. In low-uptake thyrotoxicosis, most commonly due to a viral, post-partum or iodine-induced thyroiditis, there is negligible isotope detected in the region of the thyroid, although uptake is apparent in nearby salivary glands (not shown here). In a toxic adenoma there is lack of uptake of isotope by the rest of the thyroid gland due to suppression of serum TSH. In multinodular goitre there is relatively low, patchy uptake within the nodules; such an appearance is not always associated with a palpable thyroid. In Graves' disease there is diffuse uptake of isotope.

### 20.9 Non-specific laboratory abnormalities in thyroid dysfunction\*

#### Thyrotoxicosis

- Serum enzymes: raised alanine aminotransferase,  $\gamma$ -glutamyl transferase (GGT), and alkaline phosphatase from liver and bone
- Raised bilirubin
- Mild hypercalcaemia
- Glycosuria: associated diabetes mellitus, 'lag storage' glycosuria

#### Hypothyroidism

- Serum enzymes: raised creatine kinase, aspartate aminotransferase, lactate dehydrogenase (LDH)
- Hypercholesterolaemia
- Anaemia: normochromic normocytic or macrocytic
- Hyponatraemia

\*These abnormalities are not useful in differential diagnosis, so the tests should be avoided and any further investigation undertaken only if abnormalities persist when the patient is euthyroid.

### Clinical assessment

The clinical presentation depends on the duration and severity of the hypothyroidism. Those in whom complete thyroid failure has developed insidiously over months or years may present with many of the clinical features listed in Box 20.7. A consequence of prolonged hypothyroidism is the infiltration of many body tissues by the mucopolysaccharides hyaluronic acid and chondroitin sulphate, resulting in a low-pitched voice, poor hearing, slurred speech due to a large tongue, and compression of the median nerve at the wrist (carpal tunnel syndrome). Infiltration of the dermis gives rise to non-pitting oedema (myxoedema), which is most marked in the skin of the hands, feet and eyelids. The resultant periorbital puffiness is often striking and may be combined with facial pallor due to vasoconstriction and anaemia, or a lemon-yellow tint to the skin caused by carotenaemia, along with purplish lips and malar flush. Most cases of hypothyroidism are not clinically obvious, however, and a high index of suspicion needs to be maintained so that the diagnosis is not overlooked in individuals complaining of non-specific symptoms such as tiredness, weight gain, depression or carpal tunnel syndrome.

20.10 Causes of hypothyroidism		
Causes	Anti-TPO antibodies <sup>1</sup>	Goitre <sup>2</sup>
<b>Autoimmune</b>		
Hashimoto's thyroiditis	++	±
Spontaneous atrophic hypothyroidism	-	-

<b>Secondary hypothyroidism</b>		
TSH deficiency	-	-

<sup>1</sup>As shown in Box 20.8, thyroid autoantibodies are common in the healthy population, so might be present in anyone. ++ high titre; + more likely to be detected than in the healthy population; - not especially likely. <sup>2</sup>Goitre: - absent; ± may be present; ++ characteristic. (TPO = thyroid peroxidase; TSH = thyroid-stimulating hormone)

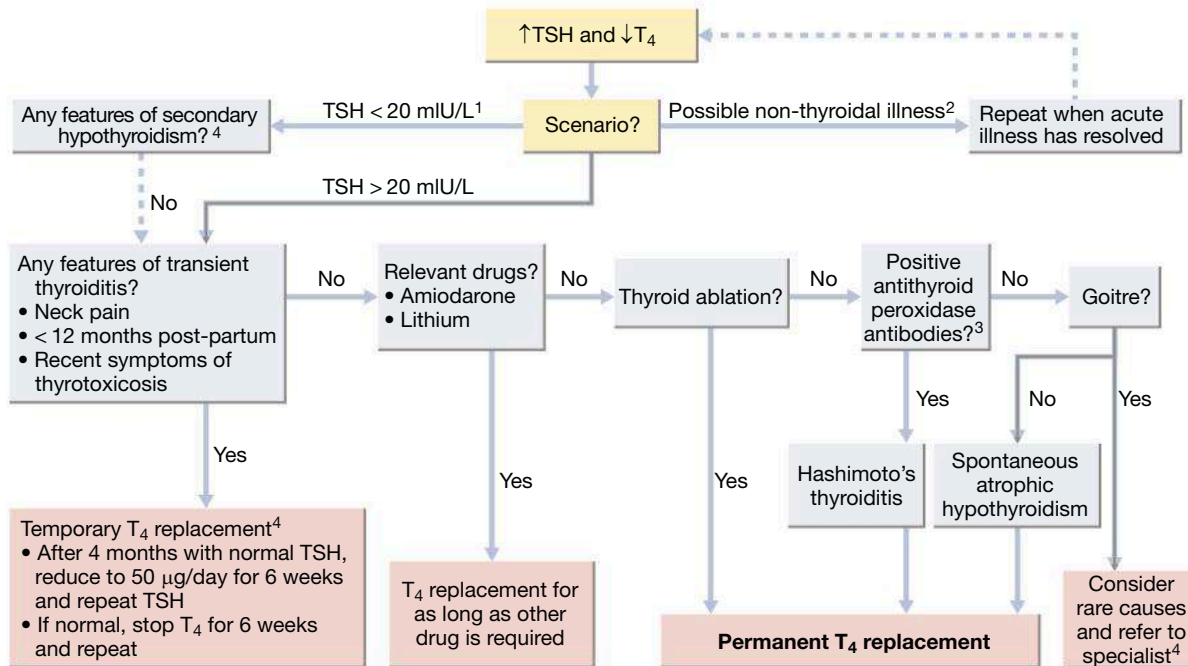

The key discriminatory features in the history and examination are highlighted in Figure 20.6. Care must be taken to identify patients with transient hypothyroidism, in whom life-long levothyroxine therapy is inappropriate. This can be observed during the first 6 months after <sup>131</sup>I treatment of Graves' disease, in the post-thyrotoxic phase of subacute thyroiditis and in post-partum thyroiditis. In these conditions, levothyroxine treatment is not always necessary, as the patient may be asymptomatic during the short period of thyroid failure.

**Investigations**

In the vast majority of cases, hypothyroidism results from an intrinsic disorder of the thyroid gland (primary hypothyroidism). In this situation, serum T<sub>4</sub> is low and TSH is elevated, usually in excess of 20 mIU/L. Measurements of serum T<sub>3</sub> are unhelpful since they do not discriminate reliably between euthyroidism and hypothyroidism. Measurement of thyroid peroxidase antibodies is helpful but further investigations are rarely required (Fig. 20.6). Secondary hypothyroidism is rare and is caused by failure of TSH secretion in an individual with hypothalamic or anterior pituitary disease. Other non-specific abnormalities are shown in Box 20.9. In severe, prolonged hypothyroidism, the ECG classically demonstrates sinus bradycardia with low-voltage complexes and ST-segment and T-wave abnormalities.

**Management**

Treatment is with levothyroxine replacement. The average replacement dose of levothyroxine is 1.6 µg/kg, which equates to around 100 µg in a 70kg adult. In healthy younger adults it is safe to commence an estimated full dose. In older individuals, and those with a history of cardiovascular disease, it is customary to start with a low dose of 50 µg per day for 3 weeks before increasing to the estimated full dose. Levothyroxine has a half-life of 7 days so it should always be taken as a single daily dose and at least 10 weeks should pass before repeating thyroid function tests (as TSH takes several weeks to reach a steady state) and adjusting the dose. Patients feel better within 2–3 weeks. Reduction in weight and periorbital puffiness occurs quickly but the restoration of skin

**Fig. 20.6 An approach to adults with suspected primary hypothyroidism.** This scheme ignores congenital causes of hypothyroidism (see Box 20.10), such as thyroid aplasia and dyshormonogenesis (associated with nerve deafness in Pendred syndrome, p. 667), which are usually diagnosed in childhood. <sup>1</sup>Immunoreactive thyroid-stimulating hormone (TSH) may be detected at normal or even modestly elevated levels in patients with pituitary failure; unless T<sub>4</sub> is only marginally low, TSH should be >20 mIU/L to confirm the diagnosis of primary hypothyroidism. <sup>2</sup>The usual abnormality in sick euthyroidism is a low TSH but any pattern can occur. <sup>3</sup>Thyroid peroxidase (TPO) antibodies are highly sensitive but not very specific for autoimmune thyroid disease (see Boxes 20.8 and 20.10). <sup>4</sup>Specialist advice is most appropriate where indicated. Secondary hypothyroidism is rare, but is suggested by deficiency of pituitary hormones or by clinical features of pituitary tumour such as headache or visual field defect (p. 695). Rare causes of hypothyroidism with goitre include dyshormonogenesis and infiltration of the thyroid (see Box 20.10).

and hair texture and resolution of any effusions may take 3–6 months. As illustrated in [Figure 20.6](#), most patients do not require specialist review but will need life-long levothyroxine therapy.

The dose of levothyroxine should be adjusted to maintain serum TSH within the reference range. To achieve this, serum  $T_4$  often needs to be in the upper part of the reference range because the  $T_3$  required for receptor activation is derived exclusively from conversion of  $T_4$  within the target tissues, without the usual contribution from thyroid secretion. Some physicians advocate combined replacement with  $T_4$  (levothyroxine) and  $T_3$  (liothyronine) or preparations of animal thyroid extract but this approach remains controversial and is not supported by robust evidence. Some patients remain symptomatic despite normalisation of TSH and may wish to take extra levothyroxine, which suppresses TSH. However, suppressed TSH is a risk factor for osteoporosis and atrial fibrillation (see below; subclinical thyrotoxicosis), so this approach cannot be recommended.

It is important to measure thyroid function every 1–2 years once the dose of levothyroxine is stabilised. This encourages adherence to therapy and allows adjustment for variable underlying thyroid activity and other changes in levothyroxine requirements ([Box 20.11](#)). Some patients have a persistent elevation of serum TSH despite an ostensibly adequate replacement dose of levothyroxine; most commonly, this is a consequence of suboptimal concordance. There may be differences in bio-availability between the numerous generic preparations of levothyroxine and so, if an individual is experiencing marked changes in serum TSH despite optimal adherence, the prescription of a branded preparation of levothyroxine could be considered. There is some limited evidence that suggests levothyroxine absorption may be better when the drug is taken before bed. In some individuals with variable concordance, levothyroxine is taken diligently or even in excess for a few days prior to a clinic visit, resulting in the seemingly anomalous combination of a high serum  $T_4$  and high TSH (see [Box 20.5](#)).

### Levothyroxine replacement in ischaemic heart disease

Hypothyroidism and ischaemic heart disease are common conditions that often occur together. Although angina may remain unchanged in severity or paradoxically disappear with restoration of metabolic rate, exacerbation of myocardial ischaemia, infarction and sudden death are recognised complications of levothyroxine replacement, even using doses as low as 25 µg per day. In patients with known ischaemic heart disease, thyroid hormone replacement should be introduced at low

dose and increased very slowly under specialist supervision. Coronary intervention may be required if angina is exacerbated by levothyroxine replacement therapy.

### Hypothyroidism in old age

[Box 20.12](#) illustrates some of the diagnostic and management challenges of hypothyroidism in older people.

### Hypothyroidism in pregnancy

Women with hypothyroidism usually require an increased dose of levothyroxine in pregnancy; inadequately treated hypothyroidism in pregnancy has been associated with impaired cognitive development in the fetus. This is discussed in more detail on page 1273 (see also [Box 20.13](#)).

## 20.12 The thyroid gland in old age

### Thyrotoxicosis

- **Causes:** commonly due to multinodular goitre.
- **Clinical features:** apathy, anorexia, proximal myopathy, atrial fibrillation and cardiac failure predominate.
- **Non-thyroidal illness:** thyroid function tests are performed more frequently in older patients but interpretation may be altered by intercurrent illness.

### Hypothyroidism

- **Clinical features:** non-specific features, such as physical and mental slowing, are often attributed to increasing age and the diagnosis is delayed.
- **Myxoedema coma:** more likely in older people.
- **Levothyroxine dose:** to avoid exacerbating latent or established heart disease, the starting dose should be 25–50 µg daily. Levothyroxine requirements fall with increasing age and few patients need more than 100 µg daily.
- **Other medication** (see [Box 20.10](#)): may interfere with absorption or metabolism of levothyroxine, necessitating an increase in dose.

## 20.13 Thyroid disease in pregnancy

### Normal pregnancy

- **Trimester-specific reference ranges:** should be used to interpret thyroid function test results in pregnancy.

### Iodine deficiency

- **Iodine requirements:** increased in pregnancy. The World Health Organization (WHO) recommends a minimum intake of 250 µg/day.
- **Iodine deficiency:** the major cause of preventable impaired cognitive development in children worldwide.

### Hypothyroidism

- **Impaired cognitive development in the offspring:** may be associated with hypothyroidism that is not adequately treated.
- **Levothyroxine replacement therapy dose requirements:** increase by 30%–50% from early in pregnancy. Monitoring to maintain TSH results within the trimester-specific reference range is recommended in early pregnancy and at least once in each trimester.

### Thyrotoxicosis

- **Gestational thyrotoxicosis:** associated with multiple pregnancies and hyperemesis gravidarum. Transient and usually does not require antithyroid drug treatment.
- **Graves' disease:** the most common cause of sustained thyrotoxicosis in pregnancy.
- **Antithyroid drugs:** propylthiouracil should be used in the first trimester, with carbimazole substituted in the second and third trimesters.

### Post-partum thyroiditis

- **Screening:** not recommended for every woman, but thyroid function should be tested 4–6 weeks post partum in those with a personal history of thyroid disease, goitre or other autoimmune disease including type 1 diabetes, in those known to have positive antithyroid peroxidase antibodies, or when there is clinical suspicion of thyroid dysfunction.

## 20.11 Situations in which an adjustment of the dose of levothyroxine may be necessary

### Increased dose required

#### Pregnancy or oestrogen therapy

- Increases concentration of serum thyroxine-binding globulin

#### Use of other medication

- Increase  $T_4$  clearance: phenobarbital, phenytoin, carbamazepine, rifampicin, sertraline\*, chloroquine\*
- Interfere with intestinal  $T_4$  absorption: colestyramine, sucralate, aluminium hydroxide, ferrous sulphate, dietary fibre supplements, calcium carbonate

#### After surgical or $^{131}\text{I}$ ablation of Graves' disease

- Reduces thyroidal secretion with time

#### Malabsorption

### Decreased dose required

#### Ageing

- Decreases  $T_4$  clearance

#### Graves' disease developing in patient with long-standing primary hypothyroidism

- Switch from production of blocking to stimulating TSH receptor antibodies

\*Mechanism not fully established.

## Myxoedema coma

This is a very rare presentation of hypothyroidism in which there is a depressed level of consciousness, usually in an older patient who appears myxoedematous. Body temperature may be as low as 25°C, convulsions are not uncommon, and cerebrospinal fluid (CSF) pressure and protein content are raised. The mortality rate is 50% and survival depends on early recognition and treatment of hypothyroidism and other factors contributing to the altered consciousness level, such as medication, cardiac failure, pneumonia, dilutional hyponatraemia and respiratory failure.

Myxoedema coma is a medical emergency and treatment must begin before biochemical confirmation of the diagnosis. Suspected cases should be treated with an intravenous injection of 20 µg liothyronine, followed by further injections of 20 µg 3 times daily until there is sustained clinical improvement. In survivors, there is a rise in body temperature within 24 hours and, after 48–72 hours, it is usually possible to switch patients to oral levothyroxine in a dose of 50 µg daily. Unless it is apparent that the patient has primary hypothyroidism, the thyroid failure should also be assumed to be secondary to hypothalamic or pituitary disease and treatment given with hydrocortisone 100 mg intramuscularly 3 times daily, pending the results of T<sub>4</sub>, TSH and cortisol measurement. Other measures include slow rewarming, cautious use of intravenous fluids, broad-spectrum antibiotics and high-flow oxygen.

## Symptoms of hypothyroidism with normal thyroid function tests

The classic symptoms of hypothyroidism are, by their very nature, non-specific (see Box 20.3). There is a wide differential diagnosis for symptoms such as 'fatigue', 'weight gain' and 'low mood'. As has been noted, outside the context of pituitary and hypothalamic disease, serum TSH is an excellent measure of an individual's thyroid hormone status. However, some individuals believe that they have hypothyroidism despite normal serum TSH concentrations. There are a large number of websites that claim that serum TSH is not a good measure of thyroid hormone status and suggest that other factors, such as abnormalities of T<sub>4</sub> to T<sub>3</sub> conversion, may lead to low tissue levels of active thyroid hormones. Such websites often advocate a variety of tests of thyroid function of dubious scientific validity, including measurement of serum reverse T<sub>3</sub>, 24-hour urine T<sub>3</sub>, basal body temperature, skin iodine absorption, and levels of selenium in blood and urine. Individuals who believe they have hypothyroidism, despite normal conventional tests of thyroid function, can be difficult to manage. They require reassurance that their symptoms are being taken seriously and that organic disease has been carefully considered; if their symptoms persist, referral to a team specialising in medically unexplained symptoms should be considered.

## Asymptomatic abnormal thyroid function tests

One of the most common problems in medical practice is how to manage patients with abnormal thyroid function tests who have no obvious signs or symptoms of thyroid disease. These can be divided into three categories.

### Subclinical thyrotoxicosis

Serum TSH is undetectable and serum T<sub>3</sub> and T<sub>4</sub> are at the upper end of the reference range. This combination is most often found in older patients with multinodular goitre. These patients are at increased risk of atrial fibrillation and osteoporosis, and hence the consensus view is that they have mild thyrotoxicosis and require therapy, either with <sup>131</sup>I or low dose thionamide. Otherwise, annual review is essential, as the conversion rate to overt thyrotoxicosis with elevated T<sub>4</sub> and/or T<sub>3</sub> concentrations is 5% each year.

### Subclinical hypothyroidism

Serum TSH is raised and serum T<sub>3</sub> and T<sub>4</sub> concentrations are at the lower end of the reference range. This may persist for many years, although

there is a risk of progression to overt thyroid failure, particularly if antibodies to thyroid peroxidase are present or if the TSH rises above 10 mIU/L. In patients with non-specific symptoms, a trial of levothyroxine therapy may be appropriate. In those with positive autoantibodies or a TSH greater than 10 mIU/L, it is better to treat the thyroid failure early rather than risk loss to follow-up and subsequent presentation with profound hypothyroidism. Levothyroxine should be given in a dose sufficient to restore the serum TSH concentration to normal.

## Non-thyroidal illness ('sick euthyroidism')

This typically presents with a low serum TSH, raised T<sub>4</sub> and normal or low T<sub>3</sub> in a patient with systemic illness who does not have clinical evidence of thyroid disease. These abnormalities are caused by decreased peripheral conversion of T<sub>4</sub> to T<sub>3</sub> (with conversion instead to reverse T<sub>3</sub>), altered levels of binding proteins and their affinity for thyroid hormones, and often reduced secretion of TSH. During convalescence, serum TSH concentrations may increase to levels found in primary hypothyroidism. As thyroid function tests are difficult to interpret in patients with non-thyroidal illness, it is wise to avoid performing thyroid function tests unless there is clinical evidence of concomitant thyroid disease. If an abnormal result is found, treatment should only be given with specialist advice and the diagnosis should be re-evaluated after recovery.

## Thyroid lump or swelling

A lump or swelling in the thyroid gland can be a source of considerable anxiety for patients. There are numerous causes but, broadly speaking, a thyroid swelling is either a solitary nodule, a multinodular goitre or a diffuse goitre (Box 20.14). Nodular thyroid disease is more common in women and occurs in approximately 30% of the adult female population. The majority of thyroid nodules are impalpable but may be identified when imaging of the neck is performed for another reason, such as during Doppler ultrasonography of the carotid arteries or computed tomographic pulmonary angiography. Increasingly, thyroid nodules are identified during staging of patients with cancer with computed tomography (CT), magnetic resonance imaging (MRI) or positron emission tomography (PET) scans. Palpable thyroid nodules occur in 4%–8% of adult women and 1%–2% of adult men, and classically present when the individual (or a friend or relative) notices a lump in the neck. Multinodular goitre and solitary nodules sometimes present with acute painful enlargement due to haemorrhage into a nodule.

Patients with thyroid nodules often worry that they have cancer but the reality is that only 5%–10% of thyroid nodules are malignant. A nodule presenting in childhood or adolescence, particularly if there is a past history of head and neck irradiation, or one presenting in an older patient should heighten suspicion of a primary thyroid malignancy. The presence of cervical lymphadenopathy also increases the likelihood of malignancy.

### 20.14 Causes of thyroid enlargement

#### Diffuse goitre

- Simple goitre
- Hashimoto's thyroiditis<sup>1</sup>
- Graves' disease
- Drugs: iodine, amiodarone, lithium
- Iodine deficiency (endemic goitre)<sup>1</sup>
- Suppurative thyroiditis<sup>2</sup>
- Transient thyroiditis<sup>2</sup>
- Dysrhormonogenesis<sup>1</sup>
- Infiltrative: amyloidosis, sarcoidosis etc.
- Riedel's thyroiditis<sup>2</sup>

#### Multinodular goitre

#### Solitary nodule

- Colloid cyst
- Hyperplastic nodule
- Follicular adenoma
- Papillary carcinoma
- Follicular carcinoma
- Medullary cell carcinoma
- Anaplastic carcinoma
- Lymphoma
- Metastasis

<sup>1</sup>Goitre likely to shrink with levothyroxine therapy. <sup>2</sup>Usually tender.

Rarely, a secondary deposit from a renal, breast or lung carcinoma presents as a painful, rapidly growing, solitary thyroid nodule. Thyroid nodules identified on PET scanning have an approximately 33% chance of being malignant.

### Clinical assessment and investigations

Swellings in the anterior part of the neck most commonly originate in the thyroid and this can be confirmed by demonstrating that the swelling moves on swallowing. It is often possible to distinguish clinically between the three main causes of thyroid swelling. There is a broad differential diagnosis of anterior neck swellings, which includes lymphadenopathy, branchial cysts, dermoid cysts and thyroglossal duct cysts (the latter are classically located in the midline and move on protrusion of the tongue). An ultrasound scan should be performed urgently, if there is any doubt as to the aetiology of an anterior neck swelling.

Serum T<sub>3</sub>, T<sub>4</sub> and TSH should be measured in all patients with a goitre or solitary thyroid nodule. The finding of biochemical thyrotoxicosis or hypothyroidism (both of which may be subclinical) should lead to investigations, as already described in Box 20.5 and on page 657.

### Thyroid scintigraphy

Thyroid scintigraphy with <sup>99m</sup>Tc should be performed in an individual with a low serum TSH and a nodular thyroid to confirm the presence of an autonomously functioning ('hot') nodule (see Fig. 20.5). In such circumstances, further evaluation is not necessary. 'Cold' nodules on scintigraphy have a much higher likelihood of malignancy, but the majority are benign and so scintigraphy is not routinely used in the evaluation of thyroid nodules when TSH is normal.

### Thyroid ultrasound

If thyroid function tests are normal, an ultrasound scan will often determine the nature of the thyroid swelling. Ultrasound can establish whether there is generalised or localised swelling of the thyroid. Inflammatory disorders causing a diffuse goitre, such as Graves' disease and Hashimoto's thyroiditis, demonstrate a diffuse pattern of hypoechogenicity and, in the case of Graves' disease, increased thyroid blood flow may be seen on colour-flow Doppler (although ultrasound should not form part of the routine investigation of Graves' disease). The presence of thyroid autoantibodies will support the diagnosis of Graves' disease or Hashimoto's thyroiditis, while their absence in a younger patient with a diffuse goitre and normal thyroid function suggests a diagnosis of 'simple goitre'.

Ultrasound can readily determine the size and number of nodules within the thyroid and can distinguish solid nodules from those with a cystic element. Ultrasound is used increasingly as the key investigation in defining the risk of malignancy in a nodule. Size of the nodule is not a predictor of the risk of malignancy but there are other ultrasound characteristics that are associated with a higher likelihood of malignancy. These include hypoechogenicity, intranodular vascularity, the presence of microcalcification and irregular or lobulated margins. A purely cystic nodule is highly unlikely to be malignant and a 'spongiform' appearance is also highly predictive of a benign aetiology. Each individual nodule within a multinodular goitre has the same risk of malignancy as a solitary nodule. Thyroid ultrasonography is a highly specialised investigation and the accurate stratification of risk of malignancy of a thyroid nodule requires skill and expertise.

### Fine needle aspiration cytology

Fine needle aspiration cytology is recommended for thyroid nodules that are suspicious for malignancy or are radiologically indeterminate. Fine needle aspiration of a thyroid nodule can be performed in the outpatient clinic, usually under ultrasound guidance. Aspiration may be therapeutic for a cyst, although recurrence on more than one occasion is an indication for surgery or alcohol ablation. Fine needle aspiration cytology cannot differentiate between a follicular adenoma and a follicular carcinoma, and in 10%–20% of cases an inadequate specimen is obtained.

### Management

Nodules with a benign appearance on ultrasound may be observed in an ultrasound surveillance programme; when the suspicion of malignancy is very low, the patient may be reassured and discharged. In regions with borderline low iodine intake, there is evidence that levothyroxine therapy, in doses that suppress serum TSH, may reduce the size of some nodules. This should not be routine practice in iodine-sufficient populations.

Nodules that are suspicious for malignancy are treated by surgical excision, by either lobectomy or thyroidectomy. Nodules that are radiologically and/or cytologically indeterminate are more of a management challenge and often end up being surgically excised. Molecular techniques may, in the future, improve the diagnostic accuracy of thyroid cytology and allow a more conservative strategy for individuals with an indeterminate biopsy. Nodules in which malignancy is confirmed by formal histology are treated as described on page 665.

A diffuse or multinodular goitre may also require surgical treatment for cosmetic reasons or if there is compression of local structures (resulting in stridor or dysphagia). <sup>131</sup>I therapy may also cause some reduction in size of a multinodular goitre. Levothyroxine therapy may shrink the goitre of Hashimoto's disease, particularly if serum TSH is elevated.

## Autoimmune thyroid disease

Thyroid diseases are amongst the most prevalent antibody-mediated autoimmune diseases and are associated with other organ-specific autoimmune diseases. Autoantibodies may produce inflammation and destruction of thyroid tissue, resulting in hypothyroidism, goitre (in Hashimoto's thyroiditis) or sometimes even transient thyrotoxicosis ('Hashitoxicosis'), or they may stimulate the TSH receptor to cause thyrotoxicosis (in Graves' disease). There is overlap between these conditions, since some patients have multiple autoantibodies.

### Graves' disease

Graves' disease can occur at any age but is unusual before puberty and most commonly affects women aged 30–50 years. The most common manifestation is thyrotoxicosis with or without a diffuse goitre. The clinical features and differential diagnosis are described on page 652. Graves' disease also causes ophthalmopathy and, rarely, pretibial myxoedema (p. 663). These extrathyroidal features usually occur in thyrotoxic patients but can arise in the absence of thyroid dysfunction.

### Graves' thyrotoxicosis

#### Pathophysiology

The thyrotoxicosis results from the production of IgG antibodies directed against the TSH receptor on the thyroid follicular cell, which stimulate thyroid hormone production and proliferation of follicular cells, leading to goitre in the majority of patients. These antibodies are termed thyroid-stimulating immunoglobulins or TSH receptor antibodies (TRAb) and can be detected in the serum of >95% of patients with Graves' disease. The concentration of TRAb in the serum is presumed to fluctuate to account for the natural history of Graves' thyrotoxicosis (Fig. 20.7). Thyroid failure seen in some patients may result from the presence of blocking antibodies against the TSH receptor, and from tissue destruction by cytotoxic antibodies and cell-mediated immunity.

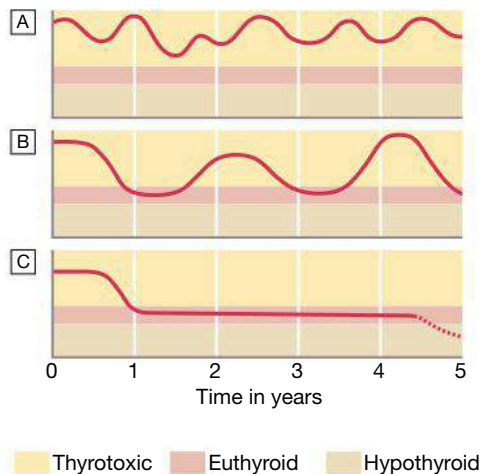

Graves' disease has a strong genetic component. There is 20%–40% concordance for thyrotoxicosis between monozygotic twins but only 5% concordance between dizygotic twins. Genome-wide association studies have identified several genes associated with susceptibility. These include *HLA-DRB-Arg74*, *CTLA4*, *PTPN22*, *TSHR1*, *CD25* and *CD40*. Many of these loci have been implicated in the pathogenesis of other autoimmune diseases.

A suggested trigger for the development of thyrotoxicosis in genetically susceptible individuals may be infection with viruses or bacteria.

In regions of iodine deficiency, iodine supplementation can precipitate thyrotoxicosis, but only in those with pre-existing subclinical Graves' disease. Smoking is associated with Graves' thyrotoxicosis and strongly linked with the development of ophthalmopathy.

### Management

Symptoms of thyrotoxicosis respond to  $\beta$ -blockade but definitive treatment requires control of thyroid hormone secretion. The different options are compared in Box 20.15. Some clinicians adopt an empirical approach of prescribing a course of antithyroid drug therapy and then recommending  $^{131}\text{I}$  or surgery if relapse occurs. In many centres, however,  $^{131}\text{I}$  is used extensively as a first-line therapy, given the high risk of relapse following a course of antithyroid drugs (>60%). A number of observational studies have linked therapeutic  $^{131}\text{I}$  with increased incidence of some malignancies, particularly of the thyroid and gastrointestinal tract, but the results have been inconsistent; the association may be with Graves' disease rather than its therapy, and the magnitude of the effect, if any, is small. Experience from the disaster at the Chernobyl nuclear power plant in 1986 suggests that younger people are more sensitive to radiation-induced thyroid cancer.

**Fig. 20.7** Natural history of the thyrotoxicosis of Graves' disease. **A** and **B** The majority (60%) of patients have either prolonged periods of thyrotoxicosis of fluctuating severity, or periods of alternating relapse and remission. **C** It is the minority who experience a single short-lived episode followed by prolonged remission and, in some cases, by the eventual onset of hypothyroidism.

**Antithyroid drugs** The most commonly used are carbimazole and its active metabolite, methimazole (not available in the UK). Propylthiouracil is equally effective. These drugs reduce the synthesis of new thyroid hormones by inhibiting the iodination of tyrosine (see Fig. 20.3). Carbimazole may also have an immunosuppressive action, leading to a reduction in serum TRAb concentrations, but this is not enough to influence the natural history of the thyrotoxicosis significantly.

Antithyroid drugs are typically introduced at high doses (carbimazole 40–60 mg daily or propylthiouracil 400–600 mg daily), although lower doses are reasonable in individuals with only modest elevation of  $T_4$  and  $T_3$ . Usually, this results in subjective improvement within 10–14 days and renders the patient clinically and biochemically euthyroid at 6–8 weeks. At this point, the dose can be reduced and titrated to maintain  $T_4$  and TSH within their reference range. In most patients, carbimazole is continued at 5–20 mg per day for 12–18 months in the hope that remission will occur. Between 50% and 70% of patients with Graves' disease will subsequently relapse, usually within 2 years of stopping treatment. Risk factors for relapse include younger age, male sex, presence of a goitre and higher TRAb titres at both diagnosis and cessation of antithyroid therapy. Rarely,  $T_4$  and TSH levels fluctuate between those of thyrotoxicosis and hypothyroidism at successive review appointments, despite good drug adherence, presumably due to rapidly changing concentrations of TRAb. In these patients, satisfactory control can be achieved by blocking thyroid hormone synthesis with carbimazole 30–40 mg daily and adding levothyroxine 100–150  $\mu\text{g}$  daily as replacement therapy (a 'block and replace' regimen).

Antithyroid drugs can have adverse effects. The most common is a rash. Agranulocytosis is a rare but potentially serious complication (0.2%–0.5%) that cannot be predicted by routine measurement of white blood cell count but which is reversible on stopping treatment. Patients should be warned to stop the drug and seek medical advice immediately, should a severe sore throat or fever develop while on treatment. Propylthiouracil is associated with a small but definite risk of hepatotoxicity, which, in some instances, has resulted in liver failure requiring liver transplantation, and even in death. It should therefore be considered second-line therapy to carbimazole and be used only during pregnancy or breastfeeding, or if an adverse reaction to carbimazole has occurred.

**Thyroid surgery** Patients should be rendered euthyroid with antithyroid drugs before operation. Oral potassium iodide, 60 mg three times daily, is often added for 10 days before surgery to inhibit thyroid hormone release and reduce the size and vascularity of the gland, making surgery technically easier. The optimal surgical approach is a 'near-total'

### 20.15 Comparison of treatments for the thyrotoxicosis of Graves' disease

Management	Common indications	Contraindications	Disadvantages/complications
<b>Antithyroid drugs</b> (carbimazole, propylthiouracil)	First episode in patients <40 years	Breastfeeding (propylthiouracil suitable)	Hypersensitivity rash 2% Agranulocytosis 0.2% Hepatotoxicity (with propylthiouracil) – very rare but potentially fatal >50% relapse rate usually within 2 years of stopping drug
<b>Thyroidectomy</b>	Large goitre Poor drug adherence, especially in young patients Recurrent thyrotoxicosis after course of antithyroid drugs in young patients	Previous thyroid surgery Dependence on voice, e.g. singer, lecturer <sup>1</sup>	Hypothyroidism (~25%) Transient hypocalcaemia (10%) Permanent hypoparathyroidism (1%) Recurrent laryngeal nerve palsy <sup>1</sup> (1%)
<b>Radio-iodine</b>	Patients >40 years <sup>2</sup> Recurrence following surgery irrespective of age Other serious comorbidity	Pregnancy or planned pregnancy within 6 months of treatment Active Graves' ophthalmopathy <sup>3</sup>	Hypothyroidism: ~40% in first year, 80% after 15 years Most likely treatment to result in exacerbation of ophthalmopathy <sup>3</sup>

<sup>1</sup>It is not only vocal cord palsy due to recurrent laryngeal nerve damage that alters the voice following thyroid surgery; the superior laryngeal nerves are frequently transected and this results in minor changes in voice quality. <sup>2</sup>In many institutions,  $^{131}\text{I}$  is used more liberally and is prescribed for much younger patients. <sup>3</sup>The extent to which radio-iodine exacerbates ophthalmopathy is controversial and practice varies; some use prednisolone to reduce this risk.

thyroidectomy, leaving behind only a small portion of gland adjacent to the recurrent laryngeal nerves. This strategy invariably results in permanent hypothyroidism and is probably associated with a higher risk of hypoparathyroidism, compared to 'subtotal' thyroidectomy, but maximises the potential for cure of thyrotoxicosis.

**Radioactive iodine**  $^{131}\text{I}$  is administered orally as a single dose and is trapped and organified in the thyroid (see Fig. 20.3).  $^{131}\text{I}$  emits both  $\beta$  and  $\gamma$  radiation and, although it decays within a few weeks, it has long-lasting inhibitory effects on survival and replication of follicular cells. The variable radio-iodine uptake and radiosensitivity of the gland means that the choice of dose is empirical; in most centres, approximately 400–600 MBq (approximately 10–15 mCi) is administered. This regimen is effective in 75% of patients within 4–12 weeks. During the lag period, symptoms can be controlled by a  $\beta$ -blocker or, in more severe cases, by carbimazole. However, carbimazole reduces the efficacy of  $^{131}\text{I}$  therapy because it prevents organification of  $^{131}\text{I}$  in the gland, and so should be avoided until 48 hours after radio-iodine administration. If thyrotoxicosis persists after 6 months, a further dose of  $^{131}\text{I}$  can be given. The disadvantage of  $^{131}\text{I}$  treatment is that the majority of patients eventually develop hypothyroidism.  $^{131}\text{I}$  is usually avoided in patients with Graves' ophthalmopathy and evidence of significant active orbital inflammation. It can be administered with caution in those with mild or 'burnt-out' eye disease, when it is customary to cover the treatment with a 6-week tapering course of oral prednisolone. In women of reproductive age, pregnancy must be excluded before administration of  $^{131}\text{I}$  and avoided for at least 6 months thereafter; men are also advised to use strict contraceptive measures for at least 4 months after receiving  $^{131}\text{I}$ , to avoid the possibility of conceiving with sperm that have been exposed to radioactive iodine.

**Thyrotoxicosis in pregnancy** Thyrotoxicosis in pregnancy may be associated with significant maternal and fetal morbidity. Management is very specialised and is discussed on page 1273 (see also Box 20.13).

**Thyrotoxicosis in adolescence** Thyrotoxicosis can occasionally occur in adolescence and is almost always due to Graves' disease. The presentation may be atypical and management challenging, as summarised in Box 20.16.

### Graves' ophthalmopathy

This condition is immunologically mediated with the TSH receptor identified as the main autoantigen. Within the orbit (and the dermis) there is cytokine-mediated proliferation of fibroblasts that secrete hydrophilic glycosaminoglycans. The resulting increase in interstitial fluid content, combined with a chronic inflammatory cell infiltrate, causes marked swelling and ultimately fibrosis of the extraocular muscles (Fig. 20.8) and a rise in retrobulbar pressure. The eye is displaced forwards (proptosis, exophthalmos) and in severe cases there is optic nerve compression.

Ophthalmopathy, like thyrotoxicosis (see Fig. 20.7), typically follows an episodic course and it is helpful to distinguish patients with active inflammation (periorbital oedema and conjunctival inflammation with changing orbital signs) from those in whom the inflammation has 'burnt out'. Eye disease is detectable in up to 50% of thyrotoxic patients at

**Fig. 20.8 Graves' disease.** **A** Bilateral ophthalmopathy in a 42-year-old man. The main symptoms were diplopia in all directions of gaze and reduced visual acuity in the left eye. The periorbital swelling is due to retrobulbar fat prolapsing into the eyelids, and increased interstitial fluid as a result of raised intraorbital pressure. **B** Transverse CT of the orbits, showing the enlarged extraocular muscles. This is most obvious at the apex of the left orbit (arrow), where compression of the optic nerve caused reduced visual acuity.

presentation (although moderate to severe in only 5%), but active ocular inflammation may occur before or after thyrotoxic episodes (exophthalmic Graves' disease). Ophthalmopathy is more common in men and cigarette smokers. It may be exacerbated by radioiodine therapy and poor control of thyroid function, especially hypothyroidism. The most frequent presenting symptoms are related to increased exposure of the cornea, resulting from proptosis and lid retraction. There may be excessive lacrimation made worse by wind and bright light, a 'gritty' sensation in the eye and pain due to conjunctivitis or corneal ulceration. In addition, there may be reduction of visual acuity and/or visual fields as a consequence of corneal oedema or optic nerve compression. Other signs of optic nerve compression include reduced colour vision and a relative afferent pupillary defect (see page 649, Fig. 30.6 and Box 30.8). If the extraocular muscles are involved and do not act in concert, diplopia results.

The majority of patients require no treatment other than reassurance. Smoking cessation should be actively encouraged. Methylcellulose eye drops and gel counter the gritty discomfort of dry eyes, and tinted glasses or side shields attached to spectacle frames reduce the excessive lacrimation triggered by sun or wind. In patients with mild Graves' ophthalmopathy, oral selenium (100  $\mu\text{g}$  twice daily for 6 months) improves quality of life, reduces ocular involvement and slows progression of disease; the mechanism of action is not known but may relate to an antioxidant effect. Moderate to severe ophthalmopathy is optimally managed by an expert multidisciplinary service. More severe inflammatory episodes are treated with glucocorticoids (e.g. pulsed intravenous methylprednisolone) and sometimes orbital radiotherapy. In recent years evidence has emerged to support the use of immunosuppressive therapies (e.g. rituximab and tocilizumab) and the IGF-1 receptor inhibitor teprotumumab in moderate to severe ophthalmopathy. Loss of visual acuity is an indication for urgent surgical decompression of the orbit. In 'burnt-out' disease, surgery to the extraocular muscles,

#### 20.16 Thyrotoxicosis in adolescence

- **Presentation:** may present with a deterioration in school performance or symptoms suggestive of attention deficit hyperactivity disorder.
- **Antithyroid drug therapy:** prolonged courses may be required because remission rates following an 18-month course of therapy are much lower than in adults.
- **Adherence:** adherence to antithyroid drug therapy is often suboptimal, resulting in poor disease control that may adversely affect performance at school.
- **Radio-iodine therapy:** usually avoided in adolescents because of concerns about risk of future malignancy.

and later the eyelids, may improve diplopia, conjunctival exposure and cosmetic appearance.

### Pretibial myxoedema

This infiltrative dermatopathy occurs in fewer than 5% of patients with Graves' disease and has similar pathological features as occur in the orbit. It takes the form of raised pink-coloured or purplish plaques on the anterior aspect of the leg, extending on to the dorsum of the foot (see p. 648). The lesions may be itchy and the skin may have a 'peau d'orange' appearance with growth of coarse hair; less commonly, the face and arms are affected. Treatment is rarely required but in severe cases topical glucocorticoids may be helpful.

## Hashimoto's thyroiditis

Hashimoto's thyroiditis (or 'chronic autoimmune thyroiditis') is characterised by destructive lymphocytic infiltration of the thyroid, ultimately leading to a varying degree of fibrosis and thyroid enlargement. It has atrophic and goitrous variants.

Hashimoto's thyroiditis increases in incidence with age and affects approximately 3.5 per 1000 women and 0.8 per 1000 men each year. Many present with a small or moderately sized diffuse goitre, which is characteristically firm or rubbery in consistency. Around 25% of patients are hypothyroid at presentation. In the remainder, serum  $T_4$  is normal and TSH normal or raised, but these patients are at risk of developing overt hypothyroidism in future years. Antithyroid peroxidase antibodies are present in the serum in more than 90% of patients with Hashimoto's thyroiditis. There is an increased risk of thyroid lymphoma, although this is exceedingly rare.

Levothyroxine therapy is indicated as treatment for hypothyroidism and also to shrink an associated goitre. In this context, the dose of levothyroxine should be sufficient to suppress serum TSH to low but detectable levels.

## Transient thyroiditis

### Subacute (de Quervain's) thyroiditis

In its classical painful form, subacute thyroiditis is a transient inflammation of the thyroid gland occurring after infection with Coxsackie, mumps or adenoviruses. There is pain in the region of the thyroid that may radiate to the angle of the jaw and the ears, and is made worse by swallowing, coughing and movement of the neck. The thyroid is usually palpably enlarged and tender. Systemic upset is common. Affected patients are usually females aged 20–40 years. Painless transient thyroiditis can also occur after viral infection and in patients with underlying autoimmune disease. The condition can also be precipitated by drugs, including interferon- $\alpha$  and lithium.

Irrespective of the clinical presentation, inflammation in the thyroid gland occurs and is associated with release of colloid and stored thyroid hormones, but also with damage to follicular cells and impaired synthesis of new thyroid hormones. As a result,  $T_4$  and  $T_3$  levels are raised for 4–6 weeks until the pre-formed colloid is depleted. Thereafter, there is usually a period of hypothyroidism of variable severity before the follicular cells recover and normal thyroid function is restored within 4–6 months (Fig. 20.9). In the thyrotoxic phase, the iodine uptake is low because the damaged follicular cells are unable to trap iodine and because TSH secretion is suppressed. Low-titre thyroid autoantibodies appear transiently in the serum, and the erythrocyte sedimentation rate (ESR) is usually raised. High-titre autoantibodies suggest an underlying autoimmune pathology and greater risk of recurrence and ultimate progression to hypothyroidism.

The pain and systemic upset usually respond to simple measures such as non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally, however, it may be necessary to prescribe prednisolone 40 mg daily for 3–4 weeks. The thyrotoxicosis is mild and treatment with a  $\beta$ -blocker is

**Fig. 20.9** Thyroid function tests in an episode of transient thyroiditis. This pattern might be observed in classical subacute (de Quervain's) thyroiditis, painless thyroiditis or post-partum thyroiditis. The duration of each phase varies between patients. ( $T_3$  = triiodothyronine;  $T_4$  = thyroxine; TSH = thyroid-stimulating hormone)

usually adequate. Antithyroid drugs are of no benefit because thyroid hormone synthesis is impaired rather than enhanced. Careful monitoring of thyroid function and symptoms is required so that levothyroxine can be prescribed temporarily in the hypothyroid phase. Care must be taken to identify patients presenting with hypothyroidism who are in the later stages of a transient thyroiditis, since they are unlikely to require life-long levothyroxine therapy (see Fig. 20.6).

## Post-partum thyroiditis

The maternal immune response, which is modified during pregnancy to allow survival of the fetus, is enhanced after delivery and may unmask previously unrecognised subclinical autoimmune thyroid disease. Surveys have shown that transient biochemical disturbances of thyroid function occur in 5%–10% of women within 6 months of delivery (see Box 20.13). Those affected are likely to have antithyroid peroxidase antibodies in the serum in early pregnancy. Symptoms of thyroid dysfunction are rare and there is no association between postnatal depression and abnormal thyroid function tests. However, symptomatic thyrotoxicosis presenting for the first time within 12 months of childbirth is likely to be due to post-partum thyroiditis and the diagnosis is confirmed by a negligible radio-isotope uptake. The clinical course and treatment are similar to those of painless subacute thyroiditis (see above). Post-partum thyroiditis tends to recur after subsequent pregnancies, and eventually patients progress over a period of years to permanent hypothyroidism (see also Box 20.13).

## Iodine-associated thyroid disease

### Iodine deficiency

Iodine is an essential micronutrient and is a key component of  $T_4$  and  $T_3$ . The World Health Organization (WHO) recommends a daily intake of iodine of 150  $\mu\text{g}/\text{day}$  for adult men and women; higher levels are recommended for pregnant women (see p. 1273) as iodine deficiency is associated with impaired fetal brain development, and severe deficiency can cause cretinism. Dietary sources of iodine include seafood, dairy products, eggs and grains. Dietary iodine deficiency is a major worldwide public health issue, with an estimated one-third of the world population living in areas of iodine insufficiency. Iodine deficiency is particularly common in Central Africa, South-east Asia and the Western Pacific. It is associated with the development of thyroid nodules and goitre (endemic goitre); the reduced substrate available for thyroid hormone production increases thyroid activity to maximise iodine uptake and recycling, and this acts as a potent stimulus for enlargement of the thyroid and nodule formation. Most affected patients are euthyroid with normal or raised TSH levels, although hypothyroidism can occur with severe iodine

deficiency. Suspected iodine deficiency can be assessed by measuring iodine in urine (either a 24-hour collection or a spot sample). Endemic goitre can be treated by iodine supplementation, and a reduction in nodule and goitre size can be seen, particularly if it is commenced in childhood. Iodine deficiency is not associated with an increased risk of Graves' disease or thyroid cancer, but the high prevalence of nodular autonomy does result in an increased risk of thyrotoxicosis and this risk may be further increased by iodine supplementation. Conversely, iodine supplementation may also increase the prevalence of subclinical hypothyroidism and autoimmune hypothyroidism. These complex effects of iodine supplementation are further discussed below.

### Iodine-induced thyroid dysfunction

Iodine has complex effects on thyroid function. Very high concentrations of iodine inhibit thyroid hormone synthesis and release (known as the Wolff–Chaikoff effect) and this forms the rationale for iodine treatment in thyroid crisis and prior to thyroid surgery for thyrotoxicosis. This is an autoregulatory response to protect the body from the sudden release of large amounts of thyroid hormone in response to the ingestion of a substantial load of iodine. This effect only lasts for about 10 days, after which it is followed by an 'escape phenomenon': essentially, the return to normal organification of iodine and thyroid peroxidase action (see Fig. 20.3). Therefore, if iodine is given to prepare an individual with Graves' disease for surgery, the operation must happen within 10–14 days; otherwise, a significant relapse of the thyrotoxicosis could occur.

Iodine deficiency and underlying thyroid disease can both moderate the effects of iodine on thyroid function. In iodine-deficient parts of the world, transient thyrotoxicosis may be precipitated by prophylactic iodination programmes. In iodine-sufficient areas, thyrotoxicosis can be precipitated by iodine-containing radiographic contrast medium or expectorants in individuals who have underlying thyroid disease predisposing to thyrotoxicosis, such as multinodular goitre or Graves' disease in remission. Induction of thyrotoxicosis by iodine is called the Jod–Basedow effect. Chronic excess iodine administration can also result in hypothyroidism; this is, in effect, a failure to escape from the Wolff–Chaikoff effect and usually occurs in the context of prior insult to the thyroid by, for example, autoimmune disease, thyroiditis, lithium, anti-thyroid drugs or surgery.

### Amiodarone

The anti-arrhythmic agent amiodarone has a structure that is analogous to that of  $T_4$  (Fig. 20.10) and contains huge amounts of iodine; a 200 mg dose contains 75 mg iodine. Amiodarone also has a cytotoxic effect on thyroid follicular cells and inhibits conversion of  $T_4$  to  $T_3$  (increasing the ratio of  $T_4$ :  $T_3$ ). Most patients receiving amiodarone have normal thyroid function but up to 20% develop hypothyroidism or thyrotoxicosis, and so thyroid function should be monitored regularly. TSH provides the best indicator of thyroid function.

The thyrotoxicosis can be classified as either:

- *type I*: iodine-induced excess thyroid hormone synthesis in patients with an underlying thyroid disorder, such as nodular goitre or latent Graves' disease (an example of the Jod–Basedow effect), or

Fig. 20.10 The structure of amiodarone. Note the similarities to thyroxine ( $T_4$ ) (see Fig. 20.3).

- *type II*: thyroiditis due to a direct cytotoxic effect of amiodarone administration.

These patterns can overlap and may be difficult to distinguish clinically, as iodine uptake is low in both. There is no widely accepted management algorithm, although the iodine excess renders the gland resistant to  $^{131}I$ . Antithyroid drugs may be effective in patients with the type I form but are ineffective in type II thyrotoxicosis. Prednisolone is beneficial in the type II form. A pragmatic approach is to commence combination therapy with an antithyroid drug and glucocorticoid in patients with significant thyrotoxicosis. A rapid response (within 1–2 weeks) usually indicates a type II picture and permits withdrawal of the antithyroid therapy; a slower response suggests a type I picture, in which case antithyroid drugs may be continued and prednisolone withdrawn. If the cardiac state allows, amiodarone should be discontinued, but it has a long half-life (50–60 days) and so its effects are long-lasting. To minimise the risk of type I thyrotoxicosis, thyroid function should be measured in all patients prior to commencement of amiodarone therapy, and amiodarone should be avoided if TSH is suppressed.

Hypothyroidism should be treated with levothyroxine, which can be given while amiodarone is continued.

### Simple and multinodular goitre

These terms describe diffuse or multinodular enlargement of the thyroid, which occurs sporadically and is of unknown aetiology.

#### Simple diffuse goitre

This form of goitre usually presents between the ages of 15 and 25 years, often during pregnancy, and tends to be noticed by friends and relatives rather than the patient. Occasionally, there is a tight sensation in the neck, particularly when swallowing. The goitre is soft and symmetrical, and the thyroid enlarged to two or three times normal. There is no tenderness, lymphadenopathy or overlying bruit. Concentrations of  $T_3$ ,  $T_4$  and TSH are normal and no thyroid autoantibodies are detected in the serum. No treatment is necessary and the goitre usually regresses. In some, however, the unknown stimulus to thyroid enlargement persists and, as a result of recurrent episodes of hyperplasia and involution during the following 10–20 years, the gland becomes multinodular with areas of autonomous function.

Age (in years)	15–25	26–55	> 55
Goitre	Diffuse	Nodular	Nodular
Tracheal compression/deviation	No	Minimal	Yes
$T_3$ , $T_4$	Normal	Normal	Raised
TSH	Normal	Normal or undetectable	Undetectable

Fig. 20.11 Natural history of simple goitre. ( $T_3$  = triiodothyronine;  $T_4$  = thyroxine; TSH = thyroid-stimulating hormone)

## Multinodular goitre

The natural history is shown in [Figure 20.11](#). Patients with thyroid enlargement in the absence of thyroid dysfunction or positive autoantibodies (i.e. with 'simple goitre'; see above) as young adults may progress to develop nodules. These nodules grow at varying rates and secrete thyroid hormone 'autonomously', thereby suppressing TSH-dependent growth and function in the rest of the gland. Ultimately, complete suppression of TSH occurs in about 25% of cases, with  $T_4$  and  $T_3$  levels often within the reference range (subclinical thyrotoxicosis), but sometimes elevated (toxic multinodular goitre; see [Fig. 20.5](#)).

### Clinical features and investigations

Multinodular goitre is usually diagnosed in patients presenting with thyrotoxicosis, a large goitre with or without tracheal compression, or sudden painful swelling caused by haemorrhage into a nodule or cyst. The goitre is nodular or lobulated on palpation and may extend retrosternally; however, not all multinodular goitres causing thyrotoxicosis are easily palpable. Very large goitres can cause mediastinal compression with stridor ([Fig. 20.12](#)), dysphagia and obstruction of the superior vena cava. Hoarseness due to recurrent laryngeal nerve palsy can occur but is far more suggestive of thyroid carcinoma.

The diagnosis can be confirmed by ultrasonography and/or thyroid scintigraphy (see [Fig. 20.5](#)). In patients with large goitres, a flow-volume loop is a good screening test for significant tracheal compression (see [Fig. 17.7](#)). If intervention is contemplated, a CT or MRI of the thoracic inlet should be performed to quantify the degree of tracheal displacement or compression and the extent of retrosternal extension. Nodules should be evaluated for the possibility of thyroid neoplasia.

### Management

If the goitre is small, no treatment is necessary but annual thyroid function testing should be arranged, as the natural history is progression to a toxic multinodular goitre. Thyroid surgery is indicated for large goitres that cause mediastinal compression or that are cosmetically unattractive.  $^{131}\text{I}$  can result in a significant reduction in thyroid size and may be of value in older patients. Levothyroxine therapy is of no benefit in shrinking multinodular goitres in iodine-sufficient countries and may simply aggravate any associated thyrotoxicosis.

In toxic multinodular goitre, treatment is usually with  $^{131}\text{I}$ . The iodine uptake is lower than in Graves' disease, so a higher dose may be administered (up to 800Mbq (approximately 20mCi)) and hypothyroidism is less common. In thyrotoxic patients with a large goitre, thyroid surgery may be indicated. Long-term treatment with antithyroid drugs is not usually employed, as relapse is invariable after drug withdrawal; drug therapy

**Fig. 20.12** Computed tomogram showing retrosternal multinodular goitre. The goitre (black arrow) is causing acute severe breathlessness and stridor due to tracheal compression (white arrow).

is normally reserved for frail older patients in whom surgery or  $^{131}\text{I}$  is not an appropriate option.

Asymptomatic patients with subclinical thyrotoxicosis are increasingly being treated with  $^{131}\text{I}$  on the grounds that a suppressed TSH is a risk factor for atrial fibrillation and, particularly in post-menopausal women, osteoporosis.

## Thyroid neoplasia

Patients with thyroid tumours usually present with a solitary nodule. Most are benign and a few of these, called 'toxic adenomas', secrete excess thyroid hormones. Primary thyroid malignancy is rare, accounting for less than 1% of all carcinomas, and has an incidence of 25 per million per annum. As shown in [Box 20.17](#), it can be classified according to the cell type of origin. With the exception of medullary carcinoma, thyroid cancer is more common in females.

### Toxic adenoma

A solitary toxic nodule is the cause of less than 5% of all cases of thyrotoxicosis. The nodule is a follicular adenoma, which autonomously secretes excess thyroid hormones and inhibits endogenous TSH secretion, with subsequent atrophy of the rest of the thyroid gland. The adenoma is usually greater than 3cm in diameter.

Most patients are female and over 40 years of age. Although many nodules are palpable, the diagnosis can be made with certainty only by thyroid scintigraphy (see [Fig. 20.5](#)). The thyrotoxicosis is usually mild and in almost 50% of patients the plasma  $T_3$  alone is elevated ( $T_3$  thyrotoxicosis).  $^{131}\text{I}$  (400–800MBq (10–20mCi)) is highly effective and is an ideal treatment since the atrophic cells surrounding the nodule do not take up iodine and so receive little or no radiation. For this reason, permanent hypothyroidism is unusual. Hemithyroidectomy is an alternative management option.

### Differentiated carcinoma

The incidence of thyroid carcinoma has increased significantly since the early 1990s although this has not been paralleled by any significant increase in thyroid carcinoma deaths over the same period ([Fig. 20.13](#)). Increasing incidence of thyroid carcinoma is, at least in part, explained by an increased rate of incidental detection, which tracks greater use of neck imaging.

#### Papillary carcinoma

This is the most common of the malignant thyroid tumours and accounts for 90% of radiation-induced thyroid cancer. It may be multifocal and

### 20.17 Malignant thyroid tumours

Type of tumour	Frequency (%)	Age at presentation (years)	10-year survival (%)
<b>Follicular cells</b>			
Differentiated carcinoma:			
Papillary	75–85	20–40	98
Follicular	10–20	40–60	94
Anaplastic	<5	>60	9
<b>Parafollicular C cells</b>			
Medullary carcinoma	5–8	>40*	78
<b>Lymphocytes</b>			
Lymphoma	<5	>60	45

\*Patients with medullary carcinoma as part of multiple endocrine neoplasia (MEN) types 2a and 2b (p. 700) may present in childhood.

**Fig. 20.13 Incidence and death rates of thyroid cancer.** Although the incidence has increased from 1990 because of higher rates of discovery due to the use of more imaging, the overall death rate remains very low with an overall 5-year survival of >98%. From National Cancer Institute <https://seer.cancer.gov/statfacts/html/thyro.html>.

spread is initially to regional lymph nodes. Some patients present with cervical lymphadenopathy and no apparent thyroid enlargement; in such instances, the primary lesion may be less than 10 mm in diameter.

#### Follicular carcinoma

This is usually a single encapsulated lesion. Spread to cervical lymph nodes is rare. Metastases are blood-borne and are most often found in bone, lungs and brain.

#### Management

The management of thyroid cancers should be individualised and planned in multidisciplinary team meetings that include all specialists involved in the service; this should include thyroid surgeons, endocrinologists, oncologists, pathologists, radiologists and nurse specialists. Large tumours, those with adverse histological features and/or tumours with metastatic disease at presentation are usually managed by total thyroidectomy followed by a large dose of  $^{131}\text{I}$  (1100 or 3700 MBq (approximately 30 or 100 mCi)) to ablate any remaining normal or malignant thyroid tissue. Thereafter, long-term treatment with levothyroxine in a dose sufficient to suppress TSH (usually 150–200 µg daily) is given, as there is evidence that growth of differentiated thyroid carcinomas is TSH-dependent. Smaller tumours with no adverse histological features may require only thyroid lobectomy.

Follow-up involves measurement of serum thyroglobulin, which should be undetectable in patients whose normal thyroid has been ablated and who are taking a suppressive dose of levothyroxine. Thyroglobulin antibodies may interfere with the assay and, depending on the method employed, may result in a falsely low or high result. Detectable thyroglobulin, in the absence of assay interference, is suggestive of tumour recurrence or metastases, particularly if the thyroglobulin titre is rising across serial measurements. Local recurrence or metastatic disease may be localised by ultrasound, CT, MRI and/or whole-body scanning with  $^{131}\text{I}$ , and may be treated with further surgery and/or  $^{131}\text{I}$  therapy.  $^{131}\text{I}$  treatment in thyroid cancer and isotope scanning both require serum TSH concentrations to be elevated (>20 mIU/L). This may be achieved by levothyroxine withdrawal for 3–4 weeks, inducing symptomatic hypothyroidism, or by administering intramuscular injections of recombinant human TSH. Patients usually find the latter approach preferable but it is more expensive. Those with locally advanced or metastatic papillary and follicular carcinoma that is refractive to  $^{131}\text{I}$  may be considered for therapy with sorafenib, lenvatinib or vandetanib. These drugs are multi-targeted tyrosine kinase inhibitors and have been shown in trials to prolong progression-free survival by between 5 and 14 months. They have multiple toxicities, however, including poor appetite, weight loss, fatigue, diarrhoea, mucositis, rashes, hypertension and blood dyscrasias. The potential benefits of therapy therefore have to be carefully weighed against side-effects that can significantly impair quality of life.

#### Prognosis

Most patients with papillary and follicular thyroid cancer will be cured with appropriate treatment. Adverse prognostic factors include older age at presentation, the presence of distant metastases, male sex and certain histological subtypes. However,  $^{131}\text{I}$  therapy can be effective in treating those with distant metastases, particularly small-volume disease in the lungs, and so prolonged survival is quite common.

#### Anaplastic carcinoma and lymphoma

These two conditions are difficult to distinguish clinically but are distinct cytologically and histologically. Patients are usually over 60 years of age and present with rapid thyroid enlargement over 2–3 months. The goitre is hard and there may be stridor due to tracheal compression and hoarseness due to recurrent laryngeal nerve palsy. There is no effective treatment for anaplastic carcinoma, although surgery and radiotherapy may be considered in some circumstances. In older patients, median survival is only 7 months.

The prognosis for lymphoma, which may arise from pre-existing Hashimoto's thyroiditis, is better, with a median survival of 9 years. Some 98% of tumours are non-Hodgkin lymphomas, usually the diffuse large B-cell subtype. Treatment is with combination chemotherapy and external beam radiotherapy.

#### Medullary carcinoma

This tumour arises from the parafollicular C cells of the thyroid. In addition to calcitonin, the tumour may secrete 5-hydroxytryptamine (5-HT, serotonin), various peptides of the tachykinin family, adrenocorticotrophic hormone (ACTH) and prostaglandins. As a consequence, carcinoid syndrome (see Box 20.49) and Cushing's syndrome (see p. 679) may occur.

Patients usually present in middle age with a firm thyroid mass. Cervical lymph node involvement is common but distant metastases are rare initially. Serum calcitonin levels are raised and are useful in monitoring response to treatment. Despite the very high levels of calcitonin found in some patients, hypocalcaemia is extremely rare; however, hypercalcaemia can be associated with severe, watery diarrhoea.

Treatment is by total thyroidectomy with removal of regional cervical lymph nodes. Since the C cells do not concentrate iodine and are not responsive to TSH, there is no role for  $^{131}\text{I}$  therapy or TSH suppression with levothyroxine. External beam radiotherapy may be considered in some patients at high risk of local recurrence. Vandetanib and cabozantinib are tyrosine kinase inhibitors licensed for patients with progressive advanced medullary cancer. The prognosis is less good than for papillary and follicular carcinoma, but individuals can live for many decades with persistent disease that behaves in an indolent fashion.

Medullary carcinoma of the thyroid occurs sporadically in 70%–90% cases; in 10%–30% there is a genetic predisposition that is inherited in an autosomal dominant fashion and due to an activating mutation in the *RET* gene. This inherited tendency normally forms part of one of the MEN syndromes (MEN 2a (formerly known as MEN 2) or MEN 2b (formerly known as MEN 3), p. 700) but, occasionally, susceptibility to medullary carcinoma is the only inherited trait (familial medullary thyroid cancer and this depends on the particular codon of the *RET* gene that is mutated).

#### Riedel's thyroiditis

This is not a form of thyroid cancer but the presentation is similar and the differentiation can usually be made only by thyroid biopsy. It is an exceptionally rare condition of unknown aetiology, in which there is extensive infiltration of the thyroid and surrounding structures with fibrous tissue. There may be associated mediastinal and retroperitoneal fibrosis. Presentation is with a slow-growing goitre that is irregular and stony-hard. There is usually tracheal and oesophageal compression necessitating partial thyroidectomy. Other recognised complications include recurrent laryngeal nerve palsy, hypoparathyroidism and eventually hypothyroidism.

## Congenital thyroid disease

Early treatment with levothyroxine is essential to prevent irreversible brain damage in children (cretinism) with congenital hypothyroidism. Routine screening of TSH levels in heel-prick blood samples obtained 5–7 days after birth (as part of the Guthrie test) has revealed an incidence of approximately 1 in 3000, resulting from thyroid agenesis, ectopic or hypoplastic glands, or dysmorphogenesis. Congenital hypothyroidism is thus six times more common than phenylketonuria. It is now possible to start levothyroxine replacement therapy within 2 weeks of birth. Developmental assessment of infants treated at this early stage has revealed no differences between cases and controls in most children.

## Dyshormonogenesis

Several autosomal recessive defects in thyroid hormone synthesis have been described; the most common results from deficiency of the intrathyroidal peroxidase enzyme. Homozygous individuals present with congenital hypothyroidism; heterozygotes present in the first two decades of life with goitre, normal thyroid hormone levels and a raised TSH. The combination of dyshormonogenic goitre and nerve deafness is known as Pendred syndrome. Most cases of Pendred syndrome are caused by mutations in the *SLC26A4* gene, which encodes pendrin, the protein that transports iodide to the luminal surface of the follicular cell (see Fig. 20.3).

## Thyroid hormone resistance

This is a rare disorder in which the pituitary and hypothalamus are resistant to feedback suppression of TSH by  $T_3$ , sometimes due to mutations in the thyroid hormone receptor  $\beta$  gene or because of defects in monoiodinase activity. The result is high levels of TSH,  $T_4$  and  $T_3$ , often with a moderate goitre that may not be noted until adulthood. Thyroid hormone signalling is highly complex and involves different isozymes of both monoiodinases and thyroid hormone receptors in different tissues. For that reason, other tissues may or may not share the resistance to thyroid hormone and there may be features of thyrotoxicosis (e.g. tachycardia). This condition can be difficult to distinguish from an equally rare TSH-producing pituitary tumour (TSHoma; see Box 20.5); administration of TRH results in elevation of TSH in thyroid hormone resistance and not in TSHoma, but an MRI scan of the pituitary may be necessary to exclude a macroadenoma.

## The reproductive system

Clinical practice in reproductive medicine is shared between several specialties, including gynaecology, urology, paediatric endocrinologists, psychiatry and endocrinology. The following section is focused on disorders managed by adult endocrinologists.

### Functional anatomy, physiology and investigations

The physiology of male and female reproductive function is illustrated in Figures 20.14 and 20.15, respectively. Pathways for synthesis of sex steroids are shown in Figure 20.20.

#### The male

In the male, the testis serves two principal functions: synthesis of testosterone by the interstitial Leydig cells under the control of luteinising hormone (LH), and spermatogenesis by Sertoli cells under the control of follicle-stimulating hormone (FSH) (but also requiring adequate testosterone). Negative feedback suppression of LH is mediated principally by testosterone, while secretion of another hormone produced by the testis, inhibin, suppresses FSH. The axis can be assessed easily by a random blood sample for testosterone, LH and FSH. Testosterone levels are higher in the morning and

**Fig. 20.14** Male reproductive physiology. (FSH = follicle-stimulating hormone; LH = luteinising hormone)

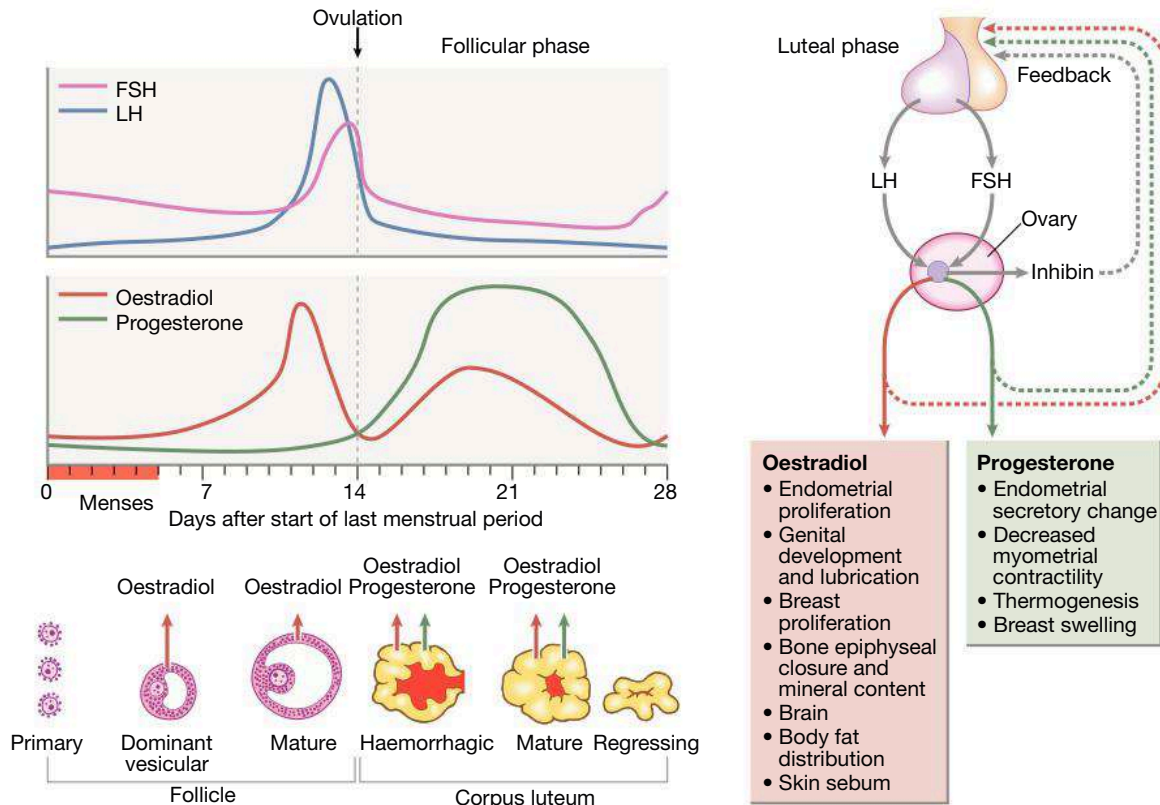

therefore, if testosterone is marginally low, sampling should be repeated with the patient fasted at 0900 hrs. Testosterone is largely bound in plasma to sex hormone-binding globulin and this can also be measured to calculate the 'free androgen index' or the 'bioavailable' testosterone. Testicular function can also be tested by semen analysis.

There is no equivalent of the menopause in men, although testosterone concentrations decline slowly from the fourth decade onwards.

#### The female

In the female, physiology varies during the normal menstrual cycle. FSH stimulates growth and development of ovarian follicles during the first 14 days after the menses. This leads to a gradual increase in oestradiol production from granulosa cells, which initially suppresses FSH secretion (negative feedback) but then, above a certain level, stimulates an increase in both the frequency and amplitude of gonadotrophin-releasing hormone (GnRH) pulses, resulting in a marked increase in LH secretion (positive feedback). The mid-cycle 'surge' of LH induces ovulation. After release of the ovum, the follicle differentiates into a corpus luteum, which secretes progesterone. Unless pregnancy occurs during the cycle, the corpus luteum regresses and the fall in progesterone levels results in menstrual bleeding. Circulating levels of oestrogen and progesterone in pre-menopausal women are, therefore, critically dependent on the time of the cycle. The most useful 'test' of ovarian function is a careful menstrual history: if menses are regular, measurement of gonadotrophins and oestrogen is not necessary. In addition, ovulation can be confirmed by measuring plasma progesterone levels during the luteal phase ('day 21 progesterone').

Cessation of menstruation (the menopause) occurs at an average age of approximately 50 years in high-income countries. In the 5 years before, there is a gradual increase in the number of anovulatory cycles and this is referred to as the climacteric. Oestrogen and inhibin secretion falls and negative feedback results in increased pituitary secretion of LH and FSH (both typically to levels above 30 IU/L (3.3  $\mu$ g/L)).

**Fig. 20.15** Female reproductive physiology and the normal menstrual cycle. (FSH = follicle-stimulating hormone; LH = luteinising hormone)

The pathophysiology of male and female reproductive dysfunction is summarised in [Box 20.18](#).

20.18 Classification of diseases of the reproductive system

## Presenting problems in reproductive disease

### Delayed puberty

Normal pubertal development is discussed in Chapter 33. Puberty is considered to be delayed if the onset of the physical features of sexual maturation has not occurred by a chronological age that is 2.5 standard deviations (SD) above the national average. In the UK, this is by the age of 14 in boys and 13 in girls. Genetic factors have a major influence in determining the timing of the onset of puberty, such that the age of menarche (the onset of menstruation) is often comparable within sibling and mother–daughter pairs and within ethnic groups. However, because there is also a threshold for body weight that acts as a trigger for normal puberty, the onset of puberty can be influenced by other factors, including nutritional status and chronic illness.

### Clinical assessment

The differential diagnosis is shown in [Box 20.19](#). The key issue is to determine whether the delay in puberty is simply because the 'clock is running slow' (constitutional delay of puberty) or because there is pathology in the hypothalamus/pituitary (hypogonadotrophic hypogonadism) or the gonads (hypergonadotrophic hypogonadism). A general history and physical examination should be performed with particular reference to previous or current medical disorders, social circumstances and family history. Body proportions, sense of smell and pubertal stage should be carefully documented and, in boys, the presence or absence of testes in the scrotum noted. Current weight and height may be plotted on centile charts, along with parental heights. Previous growth measurements in childhood, which can usually be obtained from health records, are extremely useful. Healthy growth usually follows a centile. Usually, children with constitutional delay have always been small but have maintained a normal growth velocity that is appropriate for bone age. Poor linear growth, with 'crossing of the height centiles', is more likely to be

## 20.19 Causes of delayed puberty and hypogonadism

### Constitutional delay

#### Hypogonadotrophic hypogonadism

- Structural hypothalamic/pituitary disease (see [Box 20.53](#))
- Functional gonadotrophin deficiency:
  - Chronic systemic illness (e.g. asthma, malabsorption, coeliac disease, cystic fibrosis, renal failure)
  - Psychological stress
  - Anorexia nervosa
  - Excessive physical exercise
  - Hyperprolactinaemia
  - Other endocrine disease (e.g. Cushing's syndrome, primary hypothyroidism)
- Isolated gonadotrophin deficiency (Kallmann syndrome)

#### Hypergonadotrophic hypogonadism

- Acquired gonadal damage:
  - Chemotherapy/radiotherapy to gonads
  - Trauma/surgery to gonads
  - Autoimmune gonadal failure
  - Mumps orchitis
  - Tuberculosis
  - Haemochromatosis
- Developmental/congenital gonadal disorders:
  - Steroid biosynthetic defects
  - Anorchidism/cryptorchidism in males
  - Klinefelter syndrome (47,XXY, male phenotype)
  - Turner syndrome (45,X, female phenotype)

## 20.20 Delayed puberty

- **Aetiology:** in boys the most common cause is constitutional delay, whereas in girls there is inevitably a structural hypothalamic/pituitary abnormality or a factor that affects their function.
- **Psychological effects:** whatever the underlying cause, delayed puberty is often associated with substantial psychological distress.
- **Investigations:** a karyotype should be performed in all adolescents with hypergonadotrophic hypogonadism, to exclude Turner and Klinefelter syndromes, unless there is an obvious precipitating cause.
- **Medical induction of puberty:** if this is being considered, it needs to be managed carefully and carried out in a controlled fashion, to avoid premature fusion of the epiphyses.

associated with acquired disease. Issues that are commonly encountered in the management of adolescents with delayed puberty are summarised in [Box 20.20](#).

### Constitutional delay of puberty

This is the most common cause of delayed puberty, but is a much more frequent explanation for lack of pubertal development in boys than in girls. Affected children are healthy and have usually been more than 2 SD below the mean height for their age throughout childhood. There is often a history of delayed puberty in siblings or parents. Since sex steroids are essential for fusion of the epiphyses, 'bone age' can be estimated by X-rays of epiphyses, usually in the wrist and hand; in constitutional delay, bone age is lower than chronological age. Constitutional delay of puberty should be considered as a normal variant, as puberty will commence spontaneously. However, affected children can experience significant psychological distress because of their lack of physical development, particularly when compared with their peers.

### Hypogonadotrophic hypogonadism

This may be due to structural, inflammatory or infiltrative disorders of the pituitary and/or hypothalamus (see [Box 20.53](#)). In such circumstances, other pituitary hormones, such as growth hormone, are also likely to be deficient.

'Functional' gonadotrophin deficiency is caused by a variety of factors, including low body weight, chronic systemic illness (as a consequence

of the disease itself or secondary malnutrition), endocrine disorders and profound psychosocial stress.

Isolated gonadotrophin deficiency is usually due to a genetic abnormality that affects the synthesis of either GnRH or gonadotrophins. The most common form is Kallmann syndrome, in which there is primary GnRH deficiency and, in most affected individuals, agenesis or hypoplasia of the olfactory bulbs, resulting in anosmia or hyposmia. If isolated gonadotrophin deficiency is left untreated, the epiphyses fail to fuse, resulting in tall stature with disproportionately long arms and legs relative to trunk height (eunuchoid habitus).

Cryptorchidism (undescended testes) and gynaecomastia are commonly observed in all forms of hypogonadotrophic hypogonadism.

### Hypergonadotrophic hypogonadism

Hypergonadotrophic hypogonadism associated with delayed puberty is usually due to Klinefelter syndrome in boys and Turner syndrome in girls. Other causes of primary gonadal failure are shown in [Box 20.19](#).

### Investigations

Key measurements are LH and FSH, testosterone (in boys) and oestradiol (in girls). Chromosome analysis should be performed if gonadotrophin concentrations are elevated. If gonadotrophin concentrations are low, then the differential diagnosis lies between constitutional delay and hypogonadotrophic hypogonadism. A plain X-ray of the wrist and hand may be compared with a set of standard films to obtain a bone age. Full blood count, renal function, liver function, thyroid function and coeliac disease autoantibodies (see p. 819) should be measured, but further tests may be unnecessary if the blood tests are normal and the child has all the clinical features of constitutional delay. If hypogonadotrophic hypogonadism is suspected, neuroimaging and further investigations are required (see [Box 20.51](#)).

### Management

Puberty can be induced using low doses of oral oestrogen in girls (e.g. ethinylestradiol 2 µg daily) or testosterone in boys (testosterone gel or depot testosterone esters). Higher doses carry a risk of early fusion of epiphyses. This therapy should be given in a specialist clinic where the progress of puberty and growth can be carefully monitored. In children with constitutional delay, this 'priming' therapy can be discontinued when endogenous puberty is established, usually in less than a year. In children with hypogonadism, the underlying cause should be treated and reversed if possible. If hypogonadism is permanent, sex hormone doses are gradually increased during puberty and full adult replacement doses given when development is complete.

## Amenorrhoea

Primary amenorrhoea may be diagnosed in a female who has never menstruated; this usually occurs as a manifestation of delayed puberty but may also be a consequence of anatomical defects of the female reproductive system, such as endometrial hypoplasia or vaginal agenesis. Secondary amenorrhoea describes the cessation of menstruation in a female who has previously had periods. The causes of this common presentation are shown in [Box 20.21](#). In non-pregnant women, secondary amenorrhoea is almost invariably a consequence of either ovarian or hypothalamic/pituitary dysfunction. Premature ovarian failure (premature menopause) is defined, arbitrarily, as occurring before 40 years of age. Rarely, endometrial adhesions (Asherman syndrome) can form after uterine curettage, surgery or infection with tuberculosis or schistosomiasis, preventing endometrial proliferation and shedding.

### Clinical assessment

The underlying cause can often be suspected from associated clinical features and the patient's age. Hypothalamic/pituitary disease and premature ovarian failure result in oestrogen deficiency, which causes a variety of symptoms usually associated with the menopause ([Box 20.22](#)). A history of galactorrhoea should be sought. Significant weight loss of

20.21 Causes of secondary amenorrhoea	
<b>Physiological</b>

<b>Psychological</b>	
• Anxiety	• Emotional lability
• Irritability	
<b>Genitourinary</b>	
• Dyspareunia	• Vaginal infections
• Urgency of micturition	

any cause can cause amenorrhoea by suppression of gonadotrophins. Weight gain may suggest hypothyroidism, Cushing's syndrome (if other discriminatory features are present), or very rarely, a hypothalamic lesion. Hirsutism, obesity and long-standing irregular periods suggest polycystic ovary syndrome (PCOS). The presence of other autoimmune disease raises the possibility of autoimmune premature ovarian failure.

### Investigations

Pregnancy should be excluded in women of reproductive age by measuring urine or serum hCG. Serum LH, FSH, oestradiol, prolactin, testosterone,  $T_4$  and TSH should be measured and, in the absence of a menstrual cycle, can be taken at any time. Investigation of hyperprolactinaemia is described on page 697. High concentrations of LH and FSH with low or low-normal oestradiol suggest primary ovarian failure. Ovarian autoantibodies may be positive when there is an underlying autoimmune aetiology, and a karyotype should be performed in younger women to exclude mosaic Turner syndrome. Elevated LH, prolactin and testosterone levels with normal oestradiol are common in PCOS. Low levels of LH, FSH and oestradiol suggest hypothalamic or pituitary disease and a pituitary MRI is indicated.

There is some overlap in gonadotrophin and oestrogen concentrations between women with hypogonadotrophic hypogonadism and PCOS. If there is doubt as to the underlying cause of secondary amenorrhoea, then the response to 5 days of treatment with an oral progestogen (e.g. medroxyprogesterone acetate 10 mg twice daily) can be assessed. In women with PCOS, the progestogen will cause maturation of the endometrium and menstruation will occur a few days after the progestogen is stopped. In women with hypogonadotrophic hypogonadism, menstruation does not occur following progestogen withdrawal because the endometrium is atrophic as a result of oestrogen deficiency. If doubt persists in distinguishing oestrogen deficiency from a uterine abnormality, the capacity for menstruation can be tested with 1 month of treatment with cyclical oestrogen and progestogen (usually administered as a combined oral contraceptive pill).

Assessment of bone mineral density by dual X-ray absorptiometry (DXA, see Ch. 26) may be appropriate in patients with low androgen and oestrogen levels.

### Management

Where possible, the underlying cause should be treated. For example, women with functional amenorrhoea due to excessive exercise and low

weight should be encouraged to reduce their exercise and regain some weight. The management of structural pituitary and hypothalamic disease is described on page 693 and that of PCOS on page 673.

In oestrogen-deficient women, replacement therapy may be necessary to treat symptoms and/or to prevent osteoporosis. Women who have had a hysterectomy can be treated with oestrogen alone but those with a uterus should be treated with combined oestrogen/progestogen therapy, since unopposed oestrogen increases the risk of endometrial cancer. Cyclical hormone replacement therapy (HRT) regimens typically involve giving oestrogen on days 1–21 and progestogen on days 14–21 of the cycle, and this can be conveniently administered as the oral contraceptive pill. If oestrogenic side-effects (fluid retention, weight gain, hypertension and thrombosis) are a concern, then lower-dose oral or transdermal HRT may be more appropriate.

The timing of the discontinuation of oestrogen replacement therapy is still a matter of debate. In post-menopausal women, HRT has been shown to relieve menopausal symptoms and to prevent osteoporotic fractures but is associated with adverse effects, which are related to the duration of therapy and to the patient's age. In patients with premature menopause, HRT should be continued up to the age of around 50 years, but continued beyond this age only if there are continued symptoms of oestrogen deficiency on discontinuation.

Management of infertility in oestrogen-deficient women is described below.

## Male hypogonadism

The clinical features of both hypo- and hypergonadotrophic hypogonadism include loss of libido, lethargy with muscle weakness and decreased frequency of shaving. Patients may also present with gynaecomastia, infertility, delayed puberty, osteoporosis or anaemia of chronic disease. The causes of hypogonadism are listed in Box 20.19. Mild hypogonadism may also occur in older men, particularly in the context of central adiposity and the metabolic syndrome. Postulated mechanisms are complex and include reduction in sex hormone-binding globulin by insulin resistance and reduction in GnRH and gonadotrophin secretion by cytokines or oestrogen released by adipose tissue. Testosterone levels also fall gradually with age in men (see Box 20.24) and this is associated with gonadotrophin levels that are low or inappropriately within the 'normal' range. There is an increasing trend to measure testosterone in older men, typically as part of an assessment of erectile dysfunction and lack of libido.

### Investigations

Male hypogonadism is confirmed by demonstrating a low fasting 0900-hr serum testosterone level. The distinction between hypo- and hypergonadotrophic hypogonadism is by measurement of random LH and FSH. Patients with hypogonadotrophic hypogonadism should be investigated as described for pituitary disease on page 692. Patients with hypergonadotrophic hypogonadism should have the testes examined for cryptorchidism or atrophy, and a karyotype should be performed (to identify Klinefelter syndrome).

### Management

Testosterone replacement is clearly indicated in younger men with significant hypogonadism to prevent osteoporosis and to restore muscle power and libido. Debate exists as to whether replacement therapy is of benefit in mild hypogonadism associated with ageing and central adiposity, particularly in the absence of structural pituitary/hypothalamic disease or other pituitary hormone deficiency. In such instances, a therapeutic trial of testosterone therapy may be considered if symptoms are present (e.g. low libido and erectile dysfunction) and the serum testosterone is consistently low, but the benefits of therapy must be carefully weighed against the potential for harm.

Routes of testosterone administration are shown in Box 20.23. First-pass hepatic metabolism of testosterone is highly efficient, so bioavailability of ingested preparations is poor. Doses of systemic testosterone can be titrated against symptoms; circulating testosterone

## 20.23 Options for androgen replacement therapy

Route of administration	Preparation	Dose	Frequency	Comments
Intramuscular	Testosterone undecanoate	1000 mg	Every 3 months	Smoother profile than testosterone enantate, with less frequent injections
	Testosterone enanthate	50–250 mg	Every 3–4 weeks	Produces peaks and troughs of testosterone levels that are outside the physiological range and may be symptomatic
Transdermal	Testosterone gel	50–100 mg	Daily	Stable testosterone levels; transfer of gel can occur following skin-to-skin contact with another person

## 20.24 Gonadal function in old age

- **Post-menopausal osteoporosis:** a major public health issue due to the high incidence of associated fragility fractures, especially of hip.
- **Hormone replacement therapy:** should be prescribed only above the age of 50 for the short-term relief of symptoms of oestrogen deficiency.
- **Sexual activity:** many older people are sexually active.
- **'Male menopause':** does not occur, although testosterone concentrations do fall with age. Testosterone therapy in mildly hypogonadal men may be of benefit for body composition, muscle and bone. Large randomised trials are required to determine whether benefits outweigh potentially harmful effects on the prostate and cardiovascular system.
- **Androgens in older women:** hirsutism and balding occur. In those rare patients with elevated androgen levels, this may be pathological, e.g. from an ovarian tumour.

levels may provide only a rough guide to dosage because they may be highly variable (Box 20.23). Testosterone therapy can aggravate prostatic carcinoma; prostate-specific antigen (PSA) should be measured before commencing testosterone therapy in men older than 50 years and monitored annually thereafter. Haemoglobin concentration should also be monitored, as androgen replacement can cause polycythaemia. Testosterone replacement inhibits spermatogenesis; treatment for fertility is described below.

Some important aspects of gonadal function in older women and men are summarized in Box 20.24.

## Infertility

Infertility affects around 1 in 7 couples of reproductive age, often causing psychological distress. The main causes are listed in Box 20.25. In women, it may result from anovulation or abnormalities of the reproductive tract that prevent fertilisation or embryonic implantation, often damaged Fallopian tubes from previous infection. In men, infertility may result from impaired sperm quality (e.g. reduced motility) or reduced sperm number. Azoospermia or oligospermia is usually idiopathic but may be a consequence of hypogonadism (see Box 20.19). Microdeletions of the Y chromosome are increasingly recognised as a cause of severely abnormal spermatogenesis. In many couples more than one factor causing subfertility is present, and in a large proportion no cause can be identified.

### Clinical assessment

A history of previous pregnancies, relevant infections and surgery is important in both men and women. A sexual history must be explored sensitively, as some couples have intercourse infrequently or only when they consider the woman to be ovulating, and psychosexual difficulties are common. Irregular and/or infrequent menstrual periods are an indicator of anovulatory cycles in the woman, in which case causes such as PCOS should be considered. In men, the testes should be examined to confirm that both are in the scrotum and to identify any structural abnormality, such as small size, absent vas deferens or the presence of a varicocele.

## 20.25 Causes of infertility

### Female factors (35%–40%)

- **Ovulatory dysfunction:**
  - Polycystic ovary syndrome
  - Hypogonadotrophic hypogonadism (see Box 20.19)
  - Hypergonadotrophic hypogonadism (see Box 20.19)
- **Tubular dysfunction:**
  - Pelvic inflammatory disease (chlamydia, gonorrhoea)
  - Endometriosis
  - Previous sterilisation
  - Previous pelvic or abdominal surgery
- **Cervical and/or uterine dysfunction:**
  - Congenital abnormalities
  - Fibroids
  - Treatment for cervical carcinoma
  - Asherman syndrome

### Male factors (35%–40%)

- **Reduced sperm quality or production:**
  - Y chromosome microdeletions
  - Varicocele
  - Hypergonadotrophic hypogonadism (see Box 20.19)
  - Hypogonadotrophic hypogonadism (see Box 20.19)
- **Tubular dysfunction:**
  - Varicocele
  - Congenital abnormality of vas deferens/epididymis
  - Previous sexually transmitted infection (chlamydia, gonorrhoea)
  - Previous vasectomy

### Unexplained or mixed factors (20%–35%)

### Investigations

Investigations should generally be performed after a couple has failed to conceive despite unprotected intercourse for 12 months, unless there is an obvious abnormality like amenorrhoea. Both partners need to be investigated. The male partner needs a semen analysis to assess sperm count and quality. Home testing for ovulation (by commercial urine dipstick kits, temperature measurement, or assessment of cervical mucus) is not recommended, as the information is often counterbalanced by increased anxiety if interpretation is inconclusive. In women with regular periods, ovulation can be confirmed by an elevated serum progesterone concentration on day 21 of the menstrual cycle. Transvaginal ultrasound can be used to assess uterine and ovarian anatomy. Tubal patency may be examined at laparoscopy or by hysterosalpingography (HSG; a radio-opaque medium is injected into the uterus and should normally outline the Fallopian tubes). In vitro assessments of sperm survival in cervical mucus may be done in cases of unexplained infertility but are rarely helpful.

### Management

Couples should be advised to have regular sexual intercourse, ideally every 2–3 days throughout the menstrual cycle. It is not uncommon for 'spontaneous' pregnancies to occur in couples undergoing investigations for infertility or with identified causes of male or female subfertility.

In women with anovulatory cycles secondary to PCOS, clomifene, which has partial anti-oestrogen action, blocks negative feedback of oestrogen on the hypothalamus/pituitary, causing gonadotrophin secretion and thus ovulation. In women with gonadotrophin deficiency or in whom anti-oestrogen therapy is unsuccessful, ovulation may be induced by direct stimulation of the ovary by daily injection of FSH and an injection of hCG to induce follicular rupture at the appropriate time. In hypothalamic disease, pulsatile GnRH therapy with a portable infusion pump can be used to stimulate pituitary gonadotrophin secretion (note that non-pulsatile administration of GnRH or its analogues paradoxically suppresses LH and FSH secretion). Whatever method of ovulation induction is employed, monitoring of response is essential to avoid multiple ovulation. For clomifene, ultrasound monitoring is recommended for at least the first cycle. During gonadotrophin therapy, closer monitoring of follicular growth by transvaginal ultrasonography and blood oestradiol levels is mandatory. 'Ovarian hyperstimulation syndrome' is characterised by grossly enlarged ovaries and capillary leak with circulatory shock, pleural effusions and ascites. Anovulatory women who fail to respond to ovulation induction or who have primary ovarian failure may wish to consider using donated eggs or embryos, surrogacy and adoption.

Surgery to restore Fallopian tube patency can be effective but in vitro fertilisation (IVF) is normally recommended. IVF is widely used for many causes of infertility and in unexplained cases of prolonged (>3 years) infertility. The success of IVF depends on age, with low success rates in women over 40 years.

Men with hypogonadotropic hypogonadism who wish fertility are usually given injections of hCG several times a week (recombinant FSH may also be required in men with hypogonadism of pre-pubertal origin); it may take up to 2 years to achieve satisfactory sperm counts. Surgery is rarely an option in primary testicular disease but removal of a varicocele can improve semen quality. Extraction of sperm from the epididymis for IVF, and intracytoplasmic sperm injection (ICSI, when single spermatozoa are injected into each oocyte) are being used increasingly in men with oligospermia or poor sperm quality who have primary testicular disease. Azoospermic men may opt to use donated sperm but this may be in short supply.

## Gynaecomastia

Gynaecomastia is the presence of glandular breast tissue in males. Normal breast development in women is oestrogen-dependent, while androgens oppose this effect. Gynaecomastia results from an imbalance between androgen and oestrogen activity, which may reflect androgen deficiency or oestrogen excess. Causes are listed in [Box 20.26](#). The most common are physiological: for example, in the newborn baby (due

to maternal and placental oestrogens), in pubertal boys (in whom oestradiol concentrations reach adult levels before testosterone) and in older men (due to decreasing testosterone concentrations). Prolactin excess alone does not cause gynaecomastia.

### Clinical assessment

A drug history is important. Gynaecomastia is often asymmetrical and palpation may allow breast tissue to be distinguished from the prominent adipose tissue (lipomastia) around the nipple that is often observed in obesity. Features of hypogonadism should be sought (see above) and the testes examined for evidence of cryptorchidism, atrophy or a tumour.

### Investigations

If a clinical distinction between gynaecomastia and adipose tissue cannot be made, then ultrasonography or mammography is required. A random blood sample should be taken for testosterone, LH, FSH, oestradiol, prolactin and hCG. Elevated oestrogen concentrations are found in testicular tumours and hCG-producing neoplasms.

### Management

An adolescent with gynaecomastia who is progressing normally through puberty may be reassured that the gynaecomastia will usually resolve once development is complete. If puberty does not proceed normally, then there may be an underlying abnormality that requires investigation. Gynaecomastia may cause significant psychological distress, especially in adolescent boys, and surgical excision may be justified for cosmetic reasons. Androgen replacement will usually improve gynaecomastia in hypogonadal males and any other identifiable underlying cause should be addressed if possible. The anti-oestrogen tamoxifen may also be effective in reducing the size of the breast tissue.

## Hirsutism

Hirsutism refers to the excessive growth of terminal hair (the thick, pigmented hair usually associated with the adult male chest) in an androgen-dependent distribution in women (upper lip, chin, chest, back, lower abdomen, thigh, forearm) and is one of the most common presentations of endocrine disease. It should be distinguished from hypertrichosis, which is generalised excessive growth of vellus hair (the thin, non-pigmented hair that is typically found all over the body from childhood onwards). The aetiology of androgen excess is shown in [Box 20.27](#).

### Clinical assessment

The severity of hirsutism is subjective. Some women suffer profound embarrassment from a degree of hair growth that others would not consider remarkable. Important observations are a drug and menstrual history, calculation of body mass index, measurement of blood pressure and examination for virilisation (clitoromegaly, deep voice, male-pattern balding, breast atrophy) and associated features, including acne vulgaris or Cushing's syndrome. Hirsutism of recent onset associated with virilisation is suggestive of an androgen-secreting tumour but this is rare.

### Investigations

A random blood sample should be taken for testosterone, prolactin, LH and FSH. If there are clinical features of Cushing's syndrome, further investigations should be performed as detailed on page 679.

If testosterone levels are more than twice the upper limit of normal for females, idiopathic hirsutism and PCOS are less likely, especially if LH and FSH levels are low. Under these circumstances, other causes of androgen excess should be sought. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency is diagnosed by a short ACTH stimulation test with measurement of 17-OH-progesterone. In post-menopausal women with significant hyperandrogenism, administration of GnRH analogue can be helpful in differentiating between an ovarian (>50% suppression of testosterone) or adrenal source (≤50% suppression) of androgen excess. The tumour should then be sought by CT or MRI of the adrenals and ovaries, as indicated by biochemical testing.

### 20.26 Causes of gynaecomastia

#### Idiopathic

#### Physiological

#### Drug-induced

- Cimetidine
- Digoxin
- Anti-androgens (cyproterone acetate, spironolactone)
- Some exogenous anabolic steroids (diethylstilbestrol)
- Cannabis

#### Hypogonadism (see [Box 20.19](#))

#### Androgen resistance syndromes

#### Oestrogen excess

- Liver failure (impaired steroid metabolism)
- Oestrogen-secreting tumour (e.g. of testis)
- Human chorionic gonadotrophin-secreting tumour (e.g. of testis or lung)

i 20.27 Causes of hirsutism			
Cause	Clinical features	Investigation findings	Treatment
<b>Idiopathic</b>	Often familial Mediterranean or Asian background	Normal	Cosmetic measures Anti-androgens
<b>Polycystic ovary syndrome</b>	Obesity Oligomenorrhoea or secondary amenorrhoea Infertility	LH:FSH ratio >2.5:1 Minor elevation of androgens* Mild hyperprolactinaemia	Weight loss Cosmetic measures Anti-androgens (Metformin, glitazones may be useful)
<b>Congenital adrenal hyperplasia (95% 21-hydroxylase deficiency)</b>	Pigmentation History of salt-wasting in childhood, ambiguous genitalia, or adrenal crisis when stressed	Elevated androgens* that suppress with dexamethasone Abnormal rise in 17-OH-progesterone with ACTH	Glucocorticoid replacement administered in reverse rhythm to suppress early morning ACTH
<b>Exogenous androgen administration</b>	Athletes Virilisation	Low LH and FSH Analysis of urinary androgens may detect drug of misuse	Stop steroid misuse
<b>Androgen-secreting tumour of ovary or adrenal cortex</b>	Rapid onset Virilisation: clitoromegaly, deep voice, balding, breast atrophy	High androgens* that do not suppress with GnRH analogues Low LH and FSH CT or MRI usually demonstrates a tumour	Surgical excision
<b>Cushing's syndrome</b>	Clinical features of Cushing's syndrome	Normal or mild elevation of adrenal androgens* See investigations (p. 679)	Treat the cause

\*e.g. Serum testosterone levels in women: <2 nmol/L (<58 ng/dL) is normal; 2–5 nmol/L (58–144 ng/dL) is minor elevation; >5 nmol/L (>144 ng/dL) is high and requires further investigation. (ACTH = adrenocorticotrophic hormone; CT = computed tomography; FH = follicle-stimulating hormone; GnRH = gonadotrophin releasing hormone; LH = luteinising hormone; MRI = magnetic resonance imaging)

### Management

This depends on the cause (Box 20.27). Options for the treatment of PCOS and idiopathic hirsutism are similar and are described below.

### Polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) affects up to 10% of women of reproductive age. It is a heterogeneous disorder (Box 20.28), often associated with obesity, for which the primary cause remains uncertain. Genetic factors probably play a role, since PCOS often affects several family members. The severity and clinical features of PCOS vary markedly between individual patients but diagnosis is usually made during the investigation of hirsutism or amenorrhoea/oligomenorrhoea. Infertility may also be present. There is no universally accepted definition but it has been recommended that a diagnosis of PCOS requires the presence of two of the following three features:

- menstrual irregularity
- clinical or biochemical androgen excess
- multiple cysts in the ovaries (most readily detected by transvaginal ultrasound; Fig. 20.16).

Women with PCOS are at increased risk of glucose intolerance and some authorities recommend screening for type 2 diabetes and other cardiovascular risk factors associated with the metabolic syndrome.

### Management

This should be directed at the presenting complaint but all women with PCOS who are overweight should be encouraged to lose weight, as this can improve several symptoms, including menstrual irregularity, and reduces the risk of type 2 diabetes.

#### Menstrual irregularity and infertility

Most women with PCOS have oligomenorrhoea, with irregular, heavy menstrual periods. This may not require treatment unless fertility is

i 20.28 Features of polycystic ovary syndrome	
Mechanisms*	Manifestations
<b>Pituitary dysfunction</b>	High serum LH High serum prolactin
<b>Anovulatory menstrual cycles</b>	Oligomenorrhoea Secondary amenorrhoea Cystic ovaries Infertility
<b>Androgen excess</b>	Hirsutism Acne
<b>Obesity</b>	Hyperglycaemia Elevated oestrogens
<b>Insulin resistance</b>	Dyslipidaemia Hypertension

\*These mechanisms are interrelated; it is not known which, if any, is primary. PCOS probably represents the common endpoint of several different pathologies. (LH = luteinising hormone)

desired. Metformin may restore regular ovulatory cycles in overweight women by reducing insulin resistance, although it is less effective than clomifene at restoring fertility as measured by successful pregnancy.

In women who have very few periods each year or are amenorrhoeic, the high oestrogen concentrations associated with PCOS can cause endometrial hyperplasia. Progestogens can be administered on a cyclical basis to induce regular shedding of the endometrium and a withdrawal bleed, or a progestogen-impregnated intrauterine coil can be fitted.

#### Hirsutism

For hirsutism, most patients will have used cosmetic measures, such as shaving, bleaching and waxing, before consulting a doctor. Electrolysis and laser treatment are effective for small areas like the upper lip and for

i 20.29 Anti-androgen therapy			
Mechanism of action	Drug	Dose	Hazards
<b>Androgen receptor antagonism</b>	Cyproterone acetate	2, 50 or 100 mg on days 1–11 of 28-day cycle with ethinylestradiol 30 µg on days 1–21	Hepatic dysfunction Feminisation of male fetus Progesterone receptor agonist Dysfunctional uterine bleeding
	Spironolactone Flutamide	100–200 mg daily Not recommended	Electrolyte disturbance Hepatic dysfunction
<b>5<math>\alpha</math>-reductase inhibition</b> (prevent conversion of testosterone to active dihydrotestosterone)	Finasteride	5 mg daily	Limited clinical experience; possibly less efficacious than other treatments
<b>Suppression of ovarian steroid production and elevation of sex hormone-binding globulin</b>	Oestrogen	See combination with cyproterone acetate above <i>or</i> Conventional oestrogen-containing contraceptive	Venous thromboembolism Hypertension Weight gain Dyslipidaemia Increased breast and endometrial carcinoma

**Fig. 20.16 Polycystic ovary.** A transvaginal ultrasound scan showing multiple cysts (some indicated by black arrows) in the ovary (highlighted by white arrows) of a woman with polycystic ovary syndrome.

chest hair but are expensive. Eflornithine cream inhibits ornithine decarboxylase in hair follicles and may reduce hair growth when applied daily to affected areas of the face.

If conservative measures are unsuccessful, anti-androgen therapy is given (Box 20.29). The life cycle of a hair follicle is at least 3 months and no improvement is likely before this time, when follicles have shed their hair and replacement hair growth has been suppressed. Metformin and thiazolidinediones are less effective at treating hirsutism than at restoring menstrual regularity. Unless weight is lost, hirsutism will return if therapy is discontinued. The patient should know that prolonged exposure to some agents may not be desirable and they should be stopped before pregnancy.

## Turner syndrome

Turner syndrome affects around 1 in 2500 females. It is classically associated with a 45,X karyotype but other cytogenetic abnormalities may be responsible, including mosaic forms (e.g. 45,X/46,XX or 45,X/46,XY) and partial deletions of an X chromosome.

### Clinical features

These are shown in Figure 20.17.

Individuals with Turner syndrome invariably have short stature from an early age and this is often the initial presenting symptom. It is probably

due to haploinsufficiency of the *SHOX* gene, one copy of which is found on both the X and Y chromosomes, which encodes a protein that is predominantly found in bone fibroblasts.

The genital tract and external genitalia in Turner syndrome are female in character, since this is the default developmental outcome in the absence of testes. Ovarian tissue develops normally until the third month of gestation, but thereafter there is gonadal dysgenesis with accelerated degeneration of oocytes and increased ovarian stromal fibrosis, resulting in 'streak ovaries'. The inability of ovarian tissue to produce oestrogen results in loss of negative feedback and elevation of FSH and LH concentrations.

There is a wide variation in the spectrum of associated somatic abnormalities. The severity of the phenotype is, in part, related to the underlying cytogenetic abnormality. Mosaic individuals may have only mild short stature and may enter puberty spontaneously before developing gonadal failure.

### Diagnosis and management

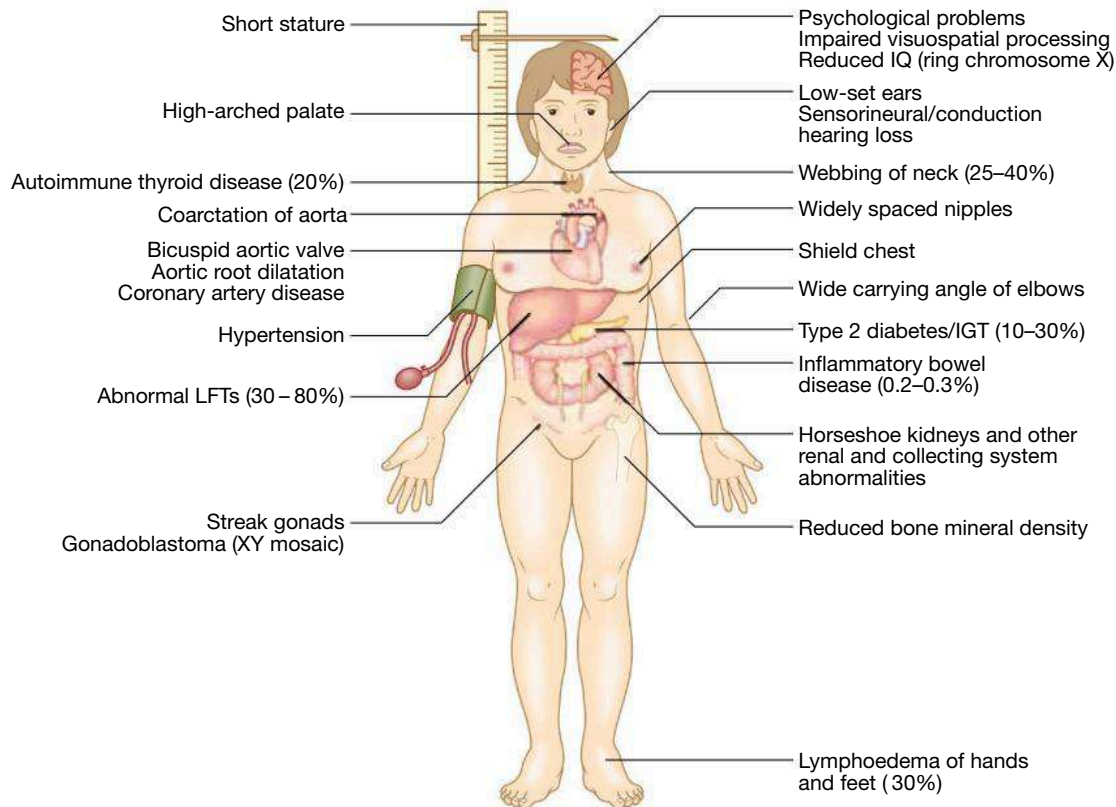

The diagnosis of Turner syndrome can be confirmed by karyotype analysis. Short stature, although not directly due to growth hormone deficiency, responds to high doses of growth hormone. Prophylactic gonadectomy is recommended for individuals with 45,X/46,XY mosaicism because there is an increased risk of gonadoblastoma. Pubertal development can be induced with oestrogen therapy but causes fusion of the epiphyses and cessation of growth. The timing of pubertal induction therefore needs to be carefully planned. Adults with Turner syndrome require long-term oestrogen replacement therapy and should be monitored periodically for the development of aortic root dilatation, hearing loss and other somatic complications.

## Klinefelter syndrome

Klinefelter syndrome affects approximately 1 in 1000 males and is usually associated with a 47,XXY karyotype. However, other cytogenetic variants may be responsible, especially 46,XY/47,XXY mosaicism. The principal pathological abnormality is dysgenesis of the seminiferous tubules. This is evident from infancy (and possibly even in utero) and progresses with age. By adolescence, hyalinisation and fibrosis are present within the seminiferous tubules and Leydig cell function is impaired, resulting in hypogonadism.

### Clinical features

The diagnosis is typically made in adolescents who have presented with gynaecomastia and failure to progress normally through puberty. Affected individuals usually have small, firm testes. Tall stature is apparent from early childhood, reflecting characteristically long leg length associated with 47,XXY, and may be exacerbated by androgen deficiency with

**Fig. 20.17** Clinical features of Turner syndrome (45,X). (IGT = impaired glucose tolerance; LFTs = liver function tests).

lack of epiphyseal closure in puberty. Other clinical features may include learning difficulties and behavioural disorders, as well as an increased risk of breast cancer and type 2 diabetes in later life. The spectrum of clinical features is wide and some individuals, especially those with 46,XY/47,XXY mosaicism, may pass through puberty normally and be identified only during investigation for infertility.

### Diagnosis and management

Klinefelter syndrome is suggested by the typical phenotype in a patient with hypergonadotrophic hypogonadism and can be confirmed by karyotype analysis. Individuals with clinical and biochemical evidence of androgen deficiency require androgen replacement (see [Box 20.23](#)). There are reports of successful pregnancy occurring following ICSI therapy where spermatozoa have been retrieved from the gonads of men with Klinefelter syndrome.

## The parathyroid glands

Parathyroid hormone (PTH) plays a key role in the regulation of calcium and phosphate homeostasis and vitamin D metabolism, as shown in [Fig. 26.62](#). The consequences of altered function of this axis in gut and renal disease are covered in Chapters 23 and 18, respectively. Other metabolic bone diseases are explored in Chapter 26. Here, the investigation of hypercalcaemia and hypocalcaemia and disorders of the parathyroid glands are discussed.

### Functional anatomy, physiology and investigations

The four parathyroid glands lie behind the lobes of the thyroid and are approximately the size of a grain of rice. The parathyroid chief cells respond directly to changes in calcium concentrations via a

G protein-coupled cell surface receptor (the calcium-sensing receptor) located on the cell surface (see [Fig. 26.62](#)). When serum ionised calcium levels fall, PTH secretion rises. PTH is a single-chain polypeptide of 84 amino acids. It acts on the renal tubules to promote reabsorption of calcium and reduce reabsorption of phosphate, and on the skeleton to increase osteoclastic bone resorption and bone formation. PTH also promotes the conversion of 25-hydroxyvitamin D to the active metabolite, 1,25-dihydroxyvitamin D; the 1,25-dihydroxyvitamin D, in turn, enhances calcium absorption from the gut.

More than 99% of total body calcium is in bone. Prolonged exposure of bone to high levels of PTH is associated with increased osteoclastic activity and new bone formation, but the net effect is to cause bone loss with mobilisation of calcium into the extracellular fluid. In contrast, pulsatile release of PTH causes net bone gain. This effect is exploited therapeutically in the treatment of osteoporosis, as discussed in Chapter 26.

The differential diagnosis of disorders of calcium metabolism requires measurement of calcium phosphate, alkaline phosphatase, renal function, PTH and 25-hydroxyvitamin D. Although the parathyroid glands detect and respond to ionised calcium levels, most clinical laboratories measure only total serum calcium levels. About 50% of total calcium is bound to organic ions, such as citrate or phosphate, and to proteins, especially albumin. Accordingly, if the serum albumin level is reduced, total calcium concentrations should be 'corrected' by adjusting the value for calcium upwards by 0.02 mmol/L (0.08 mg/dL) for each 1 g/L reduction in albumin below 40 g/L. If albumin concentrations are significantly low, as in severe acute illness and other chronic illness such as liver cirrhosis, this correction is less accurate and measurement of ionised calcium is needed.

Calcitonin is secreted from the parafollicular C cells of the thyroid gland. Although it is a useful tumour marker in medullary carcinoma of thyroid, its release from the thyroid is of no clinical relevance to calcium homeostasis in humans.

20.30 Classification of diseases of the parathyroid glands		
	Primary	Secondary
Hormone excess	Primary hyperparathyroidism Parathyroid adenoma Parathyroid carcinoma <sup>1</sup> Parathyroid hyperplasia <sup>2</sup> Tertiary hyperparathyroidism Following prolonged secondary hyperparathyroidism	Secondary hyperparathyroidism Chronic kidney disease Malabsorption Vitamin D deficiency
Hormone deficiency	Hypoparathyroidism Post-surgical Autoimmune Inherited	
Hormone hypersensitivity	Autosomal dominant hypercalcaemic hypocalcaemic (CASR-activating mutation)	
Hormone resistance	Pseudohypoparathyroidism Familial hypocalcaemic hypercalcaemia	
Non-functioning tumours	Parathyroid carcinoma <sup>1</sup>	

<sup>1</sup>Parathyroid carcinomas may or may not produce parathyroid hormone. <sup>2</sup>In multiple endocrine neoplasia (MEN) syndromes (p. 700). (CASR = calcium-sensing receptor)

 **20.31 The parathyroid glands in old age**

- **Osteoporosis:** always exclude osteomalacia and hyperparathyroidism by checking vitamin D and calcium concentrations.
- **Primary hyperparathyroidism:** more common with ageing. Older people can often be observed without surgical intervention.
- **Hypercalcaemia:** may cause delirium.
- **Vitamin D deficiency:** common because of limited exposure to the sun and reduced ability of older skin to synthesise cholecalciferol.

 **20.32 Causes of hypercalcaemia**

**With normal or elevated parathyroid hormone (PTH) levels**

- Primary or tertiary hyperparathyroidism
- Lithium-induced hyperparathyroidism
- Familial hypocalcaemic hypercalcaemia

**With low PTH levels**

- Malignancy (lung, breast, myeloma, renal, lymphoma, thyroid)
- Elevated 1,25-dihydroxyvitamin D (vitamin D intoxication, sarcoidosis, human immunodeficiency virus, other granulomatous disease)
- Thyrotoxicosis
- Paget's disease with immobilisation
- Milk-alkali syndrome
- Thiazide diuretics
- Glucocorticoid deficiency

Disorders of the parathyroid glands are summarised in [Box 20.30](#). Some specific features of parathyroid disease in older people are summarised in [Box 20.31](#).

## Presenting problems in parathyroid disease

### Hypercalcaemia

Hypercalcaemia is one of the most common biochemical abnormalities and is often detected during routine biochemical analysis in asymptomatic patients. However, it can present with chronic symptoms, as described below, and occasionally as an acute emergency with severe hypercalcaemia and dehydration.

Causes of hypercalcaemia are listed in [Box 20.32](#). Of these, primary hyperparathyroidism and malignant hypercalcaemia are by far the most

common. Familial hypocalcaemic hypercalcaemia (FHH) is a rare but important cause that needs differentiation from primary hyperparathyroidism (HPT). Lithium may cause hyperparathyroidism by reducing the sensitivity of the calcium-sensing receptor.

### Clinical assessment

Symptoms and signs of hypercalcaemia include polyuria and polydipsia, renal colic, lethargy, anorexia, nausea, dyspepsia and peptic ulceration, constipation, depression, drowsiness and impaired cognition. Patients with malignant hypercalcaemia can have a rapid onset of symptoms and may have clinical features that help to localise the tumour.

The classic symptoms of primary hyperparathyroidism are described by the adage 'bones, stones and abdominal groans', but few patients present in this way nowadays and the disorder is most often picked up as an incidental finding on biochemical testing. About 50% of patients with primary hyperparathyroidism are asymptomatic while others have non-specific symptoms such as polyuria, thirst, fatigue, depression and generalised aches and pains. Some present with renal calculi and it has been estimated that 5% of first stone formers and 15% of recurrent stone formers have primary hyperparathyroidism. Hypertension is a common feature of hyperparathyroidism. Parathyroid tumours are almost never palpable.

A family history of hypercalcaemia raises the possibility of FHH or MEN.

### Investigations

The most discriminatory investigation is measurement of PTH. If PTH levels are detectable or elevated in the presence of hypercalcaemia, then primary hyperparathyroidism is the most likely diagnosis. High plasma phosphate and alkaline phosphatase accompanied by renal impairment suggest tertiary hyperparathyroidism. Hypercalcaemia may cause nephrocalcinosis and renal tubular impairment, resulting in hyperuricaemia and hyperchloraemia.

Patients with FHH can present with a similar biochemical picture to primary hyperparathyroidism but typically have low urinary calcium excretion (a ratio of urinary calcium clearance to creatinine clearance of <0.01). The diagnosis of FHH can be confirmed by screening family members for hypercalcaemia and/or identifying an inactivating mutation in the gene encoding the calcium-sensing receptor. It is important, when considering the differential diagnosis of hypercalcaemia, to recognise that FHH is at least 100 times less common than primary hyperparathyroidism.

If PTH is low and no other cause is apparent, then malignancy with or without bony metastases is likely. PTH-related peptide, which is often

responsible for the hypercalcaemia associated with malignancy, is not detected by PTH assays, but can be measured by a specific assay (although this is not usually necessary). Unless the source is obvious, the patient should be screened for malignancy with a chest X-ray, myeloma screen (see p. 975) and CT as appropriate.

### Management

Treatment of severe hypercalcaemia and primary hyperparathyroidism is described below and on p. 142. FHH does not require any specific intervention.

## Hypocalcaemia

### Aetiology

Hypocalcaemia is much less common than hypercalcaemia. The differential diagnosis is shown in [Box 20.33](#). The most common cause of hypocalcaemia is a low serum albumin with normal ionised calcium concentration. Conversely, ionised calcium may be low in the face of normal total serum calcium in patients with alkalosis: for example, as a result of hyperventilation.

Hypocalcaemia may also develop as a result of magnesium depletion and should be considered in patients with malabsorption, those on diuretic or proton pump inhibitor therapy, and/or those with a history of alcohol excess. Magnesium deficiency causes hypocalcaemia by impairing the ability of the parathyroid glands to secrete PTH (resulting in PTH concentrations that are low or inappropriately in the reference range) and may also impair the actions of PTH on bone and kidney.

### Clinical assessment

Mild hypocalcaemia is often asymptomatic but, with more profound reductions in serum calcium, tetany can occur. This is characterised by muscle spasms due to increased excitability of peripheral nerves.

Children are more liable to develop tetany than adults and present with a characteristic triad of carpopedal spasm, stridor and convulsions, although one or more of these may be found independently of the others. In carpopedal spasm, the hands adopt a characteristic position with flexion of the metacarpophalangeal joints of the fingers and adduction of the thumb ('main d'accoucheur'). Pedal spasm can also occur but is less frequent. Stridor is caused by spasm of the glottis. Adults can also develop carpopedal spasm in association with tingling of the hands and feet and around the mouth, but stridor and fits are rare.

Latent tetany may be detected by eliciting Trousseau's sign: inflation of a sphygmomanometer cuff on the upper arm to more than the systolic blood pressure is followed by carpal spasm within 3 minutes. Less

specific is Chvostek's sign, in which tapping over the branches of the facial nerve as they emerge from the parotid gland produces twitching of the facial muscles.

Hypocalcaemia can cause papilloedema and prolongation of the ECG QT interval, which may predispose to ventricular arrhythmias. Prolonged hypocalcaemia and hyperphosphataemia (as in hypoparathyroidism) may cause calcification of the basal ganglia, grand mal epilepsy, psychosis and cataracts. Hypocalcaemia associated with hypophosphataemia, as in vitamin D deficiency, causes rickets in children and osteomalacia in adults.

### Management

Emergency management of hypocalcaemia associated with tetany is given in [Box 20.34](#). Treatment of chronic hypocalcaemia is described on p. 1053.

## Primary hyperparathyroidism

Primary hyperparathyroidism is caused by autonomous secretion of PTH, usually by a single parathyroid adenoma, which can vary in diameter from a few millimetres to several centimetres. It should be distinguished from secondary hyperparathyroidism, in which there is a physiological increase in PTH secretion to compensate for prolonged hypocalcaemia (such as in vitamin D deficiency); and from tertiary hyperparathyroidism, in which continuous stimulation of the parathyroids over a prolonged period of time results in adenoma formation and autonomous PTH secretion ([Box 20.35](#)). This is most commonly seen in individuals with advanced chronic kidney disease.

### 20.34 Management of severe hypocalcaemia

#### Immediate management

- 10–20 mL 10% calcium gluconate IV over 10–20 mins
- Continuous IV infusion may be required for several hours (equivalent of 10 mL 10% calcium gluconate/hr)
- Cardiac monitoring is recommended

#### If associated with hypomagnesaemia

- 50 mmol (1.23 g) magnesium chloride IV over 24 hrs
- Most parenteral magnesium will be excreted in the urine, so further doses may be required to replenish body stores

(IV = intravenous)

## i

### 20.33 Differential diagnosis of hypocalcaemia

	Total serum calcium	Ionised serum calcium	Serum phosphate	Serum PTH	Comments

(↑ = levels increased; ↓ = levels reduced; ↔ = levels normal)

20.35 Hyperparathyroidism		
Type	Serum calcium	PTH
<b>Primary</b> Single adenoma (90%) Multiple adenomas (4%) Nodular hyperplasia (5%) Carcinoma (1%)	Raised	Not suppressed
<b>Secondary</b> Chronic renal failure Malabsorption Osteomalacia and rickets	Low	Raised
<b>Tertiary</b>	Raised	Not suppressed

The prevalence of primary hyperparathyroidism is about 1 in 500 and it is 2–3 times more common in women than men; 90% of patients are over 50 years of age. It also occurs in the familial MEN syndromes, in which case hyperplasia or multiple adenomas of all four parathyroid glands are more likely than a solitary adenoma.

### Clinical and radiological features

The clinical presentation of primary hyperparathyroidism is described on page 676. Parathyroid bone disease is now extremely rare due to earlier diagnosis and treatment and plain X-ray assessment is not routinely recommended. Osteitis fibrosa results from increased bone resorption by osteoclasts with fibrous replacement in the lacunae. This may present as bone pain and tenderness, fracture and deformity. Chondrocalcinosis can occur due to deposition of calcium pyrophosphate crystals within articular cartilage. It typically affects the menisci at the knees and can result in secondary degenerative arthritis or predispose to attacks of acute pseudogout. Skeletal X-rays are usually normal in mild primary hyperparathyroidism but DXA should be obtained as a matter of routine in people with primary hyperparathyroidism to exclude osteoporosis (a potential indication for surgical intervention). Renal imaging (typically ultrasound) is recommended to screen for asymptomatic nephrocalcinosis or nephrolithiasis.

### Investigations

The diagnosis can be confirmed by finding a raised (or inappropriately normal) PTH level in the presence of hypercalcaemia, provided that FHH is excluded. Parathyroid scanning by ultrasound examination is often sufficient to localise an adenoma prior to surgery, although it is highly dependent on an experienced operator. Where ultrasound is equivocal, or does not identify an adenoma, a range of additional imaging modalities are available. These include  $^{99m}\text{Tc}$ -sestamibi scintigraphy (MIBI; Fig. 20.18),  $^{99m}\text{Tc}$ -SPECT/CT and, most recently,  $^{18}\text{F}$ -fluorocholine PET/CT. Negative imaging does not exclude the diagnosis, however, and four-gland exploration may be needed. Genetic testing should be considered when primary hyperparathyroidism is diagnosed before the age of 40, as the likelihood of underlying MEN syndromes is greater in this situation.

### Management

The treatment of choice for primary hyperparathyroidism is surgery, with excision of a solitary parathyroid adenoma or hyperplastic glands. Experienced surgeons will identify solitary tumours in more than 90% of cases. Patients with parathyroid bone disease run a significant risk of developing hypocalcaemia post-operatively but the risk of this can be reduced by correcting vitamin D deficiency pre-operatively.

Surgery is usually indicated for individuals with clear-cut symptoms or documented complications (such as renal stones, renal impairment or osteoporosis), and (in asymptomatic patients) significant hypercalcaemia (corrected serum calcium  $>2.85$  mmol/L ( $>11.4$  mg/dL)). Patients who are treated conservatively without surgery should have calcium biochemistry and renal function checked annually and bone density monitored periodically. They should be encouraged to maintain a high oral fluid intake to avoid renal stones.

Occasionally, primary hyperparathyroidism presents with severe life-threatening hypercalcaemia. This is often due to dehydration and should be managed medically with intravenous fluids and bisphosphonates, as described on page 142. If this is not effective, then urgent parathyroidectomy should be considered.

Cinacalcet is a calcimimetic that enhances the sensitivity of the calcium-sensing receptor, so reducing PTH levels, and is licensed for tertiary hyperparathyroidism (page 592) and as a treatment for patients with primary hyperparathyroidism who are unwilling to have surgery or are medically unfit.

### Familial hypocalcaemic hypercalcaemia

This autosomal dominant disorder is caused by an inactivating mutation in one of the alleles of the calcium-sensing receptor gene, which reduces the ability of the parathyroid gland to 'sense' ionised calcium concentrations. As a result, higher than normal calcium levels are required to suppress PTH secretion. The typical presentation is with mild hypercalcaemia with PTH concentrations that are 'inappropriately' at the upper end of the reference range or are slightly elevated. Calcium-sensing receptors in the renal tubules are also affected and this leads to increased renal tubular reabsorption of calcium and hypocalcauria (as measured in the vitamin D-replete individual by a fractional calcium excretion or 24-hour calcium excretion). The hypercalcaemia of FHH is always asymptomatic and complications do not occur. The main risk of FHH is that of the patient being subjected to an unnecessary (and ineffective) parathyroidectomy if misdiagnosed as having primary hyperparathyroidism. Testing of family members for hypercalcaemia is helpful in confirming the diagnosis and it is also possible to perform genetic testing. No treatment is necessary.

### Hypoparathyroidism

The most common cause of hypoparathyroidism is damage to the parathyroid glands (or their blood supply) during thyroid surgery. Rarely, hypoparathyroidism can occur as a result of infiltration of the glands with iron in haemochromatosis or copper in Wilson's disease.

**Fig. 20.18**  $^{99m}\text{Tc}$ -sestamibi scan of a patient with primary hyperparathyroidism secondary to a parathyroid adenoma. **A** After 1 hour, there is uptake in the thyroid gland (thick arrow) and the enlarged left inferior parathyroid gland (thin arrow). **B** After 3 hours, uptake is evident only in the parathyroid (thin arrow).

There are a number of rare congenital or inherited forms of hypoparathyroidism. One form is associated with autoimmune polyendocrine syndrome type 1 and another with DiGeorge syndrome. Autosomal dominant hypoparathyroidism is the mirror image of FHH (see above), in that an activating mutation in the calcium-sensing receptor reduces PTH levels, resulting in hypocalcaemia and hypercalciuria.

### Pseudohypoparathyroidism

In this disorder, the individual is functionally hypoparathyroid but, instead of PTH deficiency, there is tissue resistance to the effects of PTH, such that PTH concentrations are markedly elevated. The PTH receptor itself is normal but the downstream signalling pathways are defective due to mutations that affect *GNAS1*, which encodes the Gs $\alpha$  protein, a molecule involved in signal transduction downstream of the PTH receptor and other G protein-coupled receptors. There are several subtypes but the most common (pseudohypoparathyroidism type 1a) is characterised by hypocalcaemia and hyperphosphataemia, in association with short stature, short fourth metacarpals and metatarsals, rounded face, obesity and subcutaneous calcification; these features are collectively referred to as Albright's hereditary osteodystrophy (AHO). Type 1a pseudohypoparathyroidism occurs only when the *GNAS1* mutation is inherited on the maternal chromosome.

The term pseudopseudohypoparathyroidism is used to describe patients who have clinical features of AHO but normal serum calcium and PTH concentrations; it occurs when the *GNAS1* mutation is inherited on the paternal chromosome. The inheritance of these disorders is an example of genetic imprinting (see Ch. 3). The difference in clinical features occurs as a result of the fact that renal cells exclusively express the maternal *GNAS1* allele, whereas both maternal and paternal alleles are expressed in other cell types; this explains why maternal inheritance is associated with hypocalcaemia and resistance to PTH (which regulates serum calcium and phosphate levels largely by an effect on the renal tubule), and why paternal inheritance is associated with skeletal and other abnormalities in the absence of hypocalcaemia and raised PTH values.

### Management of hypoparathyroidism

Persistent hypoparathyroidism and pseudohypoparathyroidism are treated with oral calcium salts and vitamin D analogues, either 1 $\alpha$ -hydroxycholecalciferol (alfacalcidol) or 1,25-dihydroxycholecalciferol (calcitriol). This therapy needs careful monitoring because of the risks of iatrogenic hypercalcaemia, hypercalciuria and nephrocalcinosis. Recombinant PTH is available as a subcutaneous injection and has been used in hypoparathyroidism (but not in pseudohypoparathyroidism). It is much more expensive than calcium and vitamin D analogues and remains a second-line therapy but has the advantage that it is less likely to cause hypercalciuria. There is no specific treatment for AHO other than to try to maintain calcium levels within the reference range using active vitamin D metabolites.

## The adrenal glands

The adrenals comprise several separate endocrine glands within a single anatomical structure. The adrenal medulla is an extension of the sympathetic nervous system that secretes catecholamines into capillaries rather than synapses. Most of the adrenal cortex is made up of cells that secrete cortisol and adrenal androgens, and form part of the hypothalamic–pituitary–adrenal (HPA) axis. The small outer glomerulosa of the cortex secretes aldosterone under the control of the renin–angiotensin system. These functions are important in the integrated control of cardiovascular, metabolic and immune responses to stress.

There is increasing evidence that subtle alterations in adrenal function contribute to the pathogenesis of common diseases such as hypertension, obesity and type 2 diabetes mellitus. However, classical syndromes of adrenal hormone deficiency and excess are relatively rare.

## Functional anatomy and physiology

Adrenal anatomy and function are shown in [Figure 20.19](#). Histologically, the cortex is divided into three zones, but these function as two units (zona glomerulosa and zonae fasciculata/reticularis) that produce corticosteroids in response to humoral stimuli. Pathways for the biosynthesis of corticosteroids are shown in [Figure 20.20](#). Investigation of adrenal function is described under specific diseases below. The different types of adrenal disease are shown in [Box 20.36](#).

### Glucocorticoids

Cortisol is the major glucocorticoid in humans. Levels are highest in the morning on waking and lowest in the middle of the night. Cortisol rises dramatically during stress, including any illness. This elevation protects key metabolic functions (such as the maintenance of cerebral glucose supply during starvation) and inhibits potentially damaging inflammatory responses to infection and injury. The clinical importance of cortisol deficiency is, therefore, most obvious at times of stress.

More than 95% of circulating cortisol is bound to protein, principally cortisol-binding globulin, which is increased by oestrogens. It is the free fraction that is biologically active. Cortisol regulates cell function by binding to glucocorticoid receptors that regulate the transcription of many genes. Cortisol can also activate mineralocorticoid receptors, but it does not normally do so because most cells containing mineralocorticoid receptors also express an enzyme called 11 $\beta$ -hydroxysteroid dehydrogenase type 2 (11 $\beta$ -HSD2), which inactivates cortisol by converting it to cortisone. Inhibitors of 11 $\beta$ -HSD2 (such as some liquorice) or mutations in the gene that encodes 11 $\beta$ -HSD2 cause cortisol to act as a mineralocorticoid, resulting in sodium retention and hypertension (see [Box 20.45](#)).

### Mineralocorticoids

Aldosterone is the most important mineralocorticoid. It binds to mineralocorticoid receptors in the kidney and causes sodium retention and increased excretion of potassium and protons (see [Fig. 19.2](#)). The principal stimulus to aldosterone secretion is angiotensin II, a peptide produced by activation of the renin–angiotensin system (see [Fig. 20.19](#)). Renin activity in the juxtaglomerular apparatus of the kidney is stimulated by low perfusion pressure in the afferent arteriole, low sodium filtration leading to low sodium concentrations at the macula densa, or increased sympathetic nerve activity. As a result, renin activity is increased in hypovolaemia and renal artery stenosis, and is approximately doubled when standing up from a recumbent position.

### Catecholamines

In humans, only a small proportion of circulating noradrenaline (norepinephrine) is derived from the adrenal medulla; much more is released from sympathetic nerve endings. Conversion of noradrenaline to adrenaline (epinephrine) is catalysed by catechol *O*-methyltransferase (COMT), which is induced by glucocorticoids. Blood flow in the adrenal is centripetal, so that the medulla is bathed in high concentrations of cortisol and is the major source of circulating adrenaline. However, after surgical removal of the adrenal medullae, there appear to be no clinical consequences attributable to deficiency of circulating catecholamines.

### Adrenal androgens

Adrenal androgens are secreted in response to ACTH and are the most abundant steroids in the blood stream. They are probably important in the initiation of puberty (adrenarche). The adrenals are also the major source of androgens in adult females and may be important in female libido.

## Presenting problems in adrenal disease

### Cushing's syndrome

Cushing's syndrome is caused by excessive activation of glucocorticoid receptors. It is most commonly iatrogenic, due to prolonged administration

**Fig. 20.19** Structure and function of the adrenal glands. (ACE = angiotensin-converting enzyme; ACTH = adrenocorticotrophic hormone; JGA = juxtaglomerular apparatus; MR = mineralocorticoid receptor)

**Fig. 20.20** The major pathways of synthesis of steroid hormones. (DHEAS = dehydroepiandrosterone sulphate; HSD = hydroxysteroid dehydrogenase)

### 20.36 Classification of diseases of the adrenal glands

	Primary	Secondary
<b>Hormone excess</b>	Non-ACTH-dependent Cushing's syndrome Primary hyperaldosteronism Pheochromocytoma	ACTH-dependent Cushing's syndrome Secondary hyperaldosteronism
<b>Hormone deficiency</b>	Addison's disease Congenital adrenal hyperplasia	Hypopituitarism
<b>Hormone hypersensitivity</b>	11 $\beta$ -hydroxysteroid dehydrogenase type 2 deficiency Liddle syndrome	
<b>Hormone resistance</b>	Pseudohypoaldosteronism Glucocorticoid resistance syndrome	
<b>Non-functioning tumours</b>	Adenoma Carcinoma (usually functioning) Metastatic tumours	

(ACTH = adrenocorticotrophic hormone)

### 20.37 Classification of endogenous Cushing's syndrome

#### ACTH-dependent – 80%

- Pituitary adenoma secreting ACTH (Cushing's disease) – 70%
- Ectopic ACTH syndrome (bronchial carcinoid, small-cell lung carcinoma, other neuro-endocrine tumour) – 10%

#### Non-ACTH-dependent – 20%

- Adrenal adenoma – 15%
- Adrenal carcinoma – 5%
- ACTH-independent macronodular hyperplasia; primary pigmented nodular adrenal disease; McCune–Albright syndrome (together < 1%)

#### Hypercortisolism due to other causes (also referred to as pseudo-Cushing's syndrome)

- Alcohol excess (biochemical and clinical features)
- Major depressive illness (biochemical features only, some clinical overlap)
- Primary obesity (mild biochemical features, some clinical overlap)

(ACTH = adrenocorticotrophic hormone)

of synthetic glucocorticoids such as prednisolone. Endogenous Cushing's syndrome is uncommon but is caused by chronic over-production of cortisol by the adrenal glands, either as the result of an adrenal tumour or because of excessive production of ACTH by a pituitary tumour or ectopic ACTH production by other tumours.

#### Aetiology

The causes are shown in [Box 20.37](#). Amongst endogenous causes, pituitary-dependent cortisol excess (by convention, called Cushing's disease) accounts for approximately 80% of cases. Both Cushing's disease and cortisol-secreting adrenal tumours are four times more common in women than men. In contrast, ectopic ACTH syndrome (often due to a small-cell carcinoma of the bronchus) is more common in men.

#### Clinical assessment

The diverse manifestations of glucocorticoid excess are shown in [Figure 20.21](#). Many of these are not specific to Cushing's syndrome and, because spontaneous Cushing's syndrome is rare, the positive predictive value of any single clinical feature alone is low. Moreover, some common disorders can be confused with Cushing's syndrome because they are associated with alterations in cortisol secretion, e.g. obesity and

depression ([Box 20.37](#)). Features that favour Cushing's syndrome in an obese patient are those of protein-wasting, including bruising, proximal myopathy and thin skin. Any clinical suspicion of cortisol excess is best resolved by further investigation.

It is vital to exclude iatrogenic causes in all patients with Cushing's syndrome since even inhaled or topical glucocorticoids can induce the syndrome in susceptible individuals. A careful drug history must therefore be taken before embarking on complex investigations. An 0800–0900 hrs serum cortisol of <100 nmol/L (3.6 $\mu$ g/dL) in a patient with a normal sleep–wake pattern and Cushingoid appearance is consistent with exogenous synthetic glucocorticoid use (common) or cyclical secretion of cortisol from endogenous Cushing's (uncommon).

Some clinical features are more common in ectopic ACTH syndrome. While ACTH-secreting pituitary tumours retain some negative feedback sensitivity to cortisol, this is absent in tumours that produce ectopic ACTH, typically resulting in higher levels of both ACTH and cortisol than are observed in pituitary-driven disease. The high ACTH levels are associated with marked pigmentation because of binding to melanocortin 1 receptors on melanocytes in the skin. The high cortisol levels also overcome the capacity of 11 $\beta$ -HSD2 to inactivate cortisol in the kidney, causing hypokalaemic alkalosis that aggravates myopathy and hyperglycaemia (by inhibiting insulin secretion). When the tumour that is secreting ACTH is malignant, then the onset is usually rapid and may be associated with cachexia. For these reasons, the classical features of Cushing's syndrome are less common in ectopic ACTH syndrome; if present, they suggest that a less aggressive tumour, such as a bronchial carcinoid, is responsible.

In Cushing's disease, the pituitary tumour is usually a microadenoma (<10mm in diameter); hence other features of a pituitary macroadenoma (visual failure or disconnection hyperprolactinaemia, p. 696) are rare, but there may be secondary hypogonadism due to the inhibitory effects of excess glucocorticoids on gonadotropin secretion. If a diagnosis of Cushing's is suspected, early discussion/referral to a specialist is recommended.

#### Investigations

The large number of tests available for Cushing's syndrome reflects the fact that each one has limited specificity and sensitivity in isolation. Accordingly, several tests are usually combined to establish the diagnosis. Testing for Cushing's syndrome should be avoided under conditions of stress, such as an acute illness, because this activates the HPA axis, causing potentially spurious results. The diagnosis of Cushing's is a two-step process:

**Fig. 20.21 Cushing's syndrome.** **A** Clinical features common to all causes. **B** A patient with Cushing's disease before treatment. **C** The same patient 1 year after the successful removal of an ACTH-secreting pituitary microadenoma by trans-sphenoidal surgery.

1. to establish whether the patient has Cushing's syndrome (Fig. 20.22), and
2. to define its cause (Fig. 20.23).

Some additional tests are useful in all cases of Cushing's syndrome, including plasma electrolytes, glucose, glycosylated haemoglobin and bone mineral density measurement.

#### Establishing the presence of Cushing's syndrome

In patients where there is appropriate clinical suspicion, Cushing's syndrome is confirmed by using two of three main tests:

1. Failure to suppress serum cortisol with low doses of oral dexamethasone
2. Loss of the normal circadian rhythm of cortisol, with inappropriately elevated late-night serum or salivary cortisol
3. Increased 24-hour urine free cortisol (lower sensitivity than the above tests) (see Fig. 20.22).

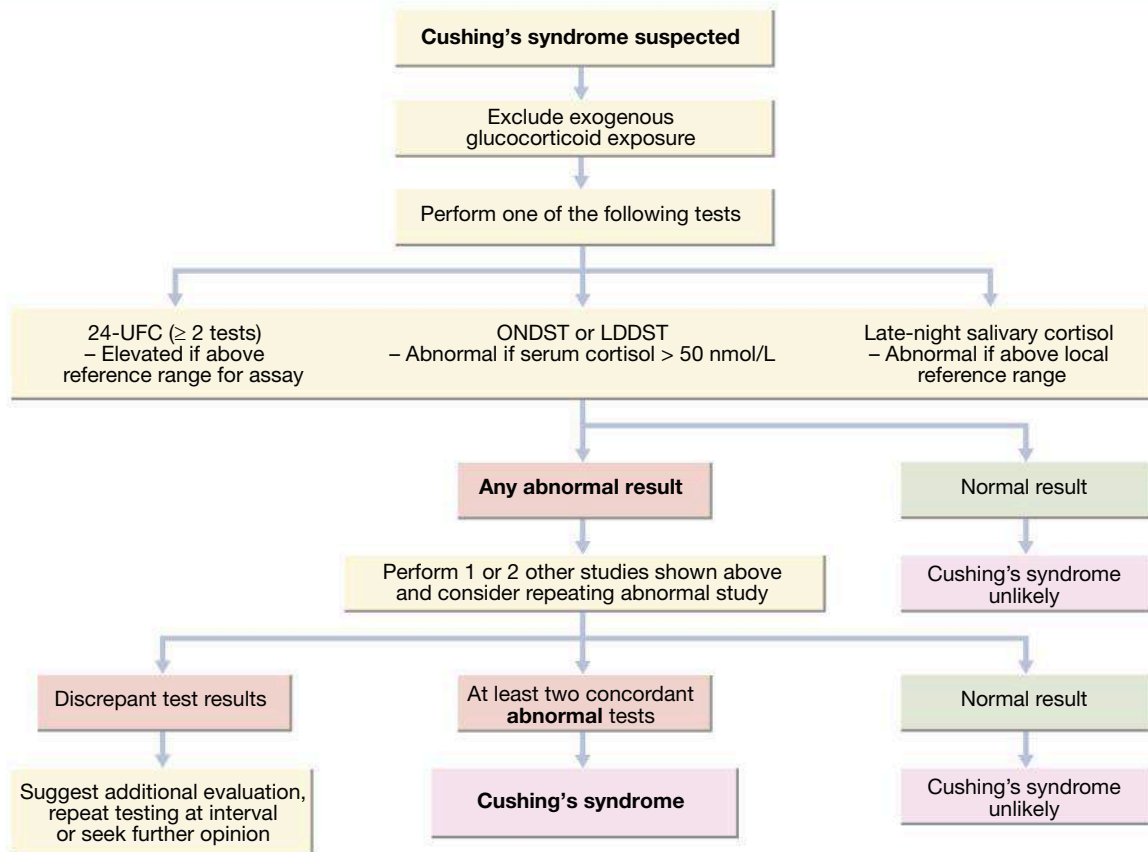

Dexamethasone is used for suppression testing because it does not cross-react in immunoassays for cortisol. An overnight dexamethasone suppression test (ONDST) involves administration of 1 mg dexamethasone at 2300 hrs and measurement of serum cortisol at 0900 hrs the following day. In a low-dose dexamethasone suppression test (LDDST), serum cortisol is measured following administration of 0.5 mg dexamethasone 4 times daily for 48 hours. For either test, a normal response is a serum cortisol of  $<50$  nmol/L (1.8  $\mu$ g/dL). It is important for any oestrogens to be stopped for 6 weeks prior to investigation to allow corticosteroid-binding globulin (CBG) levels to return to normal and to avoid false-positive responses, as most cortisol assays measure total cortisol, including that bound to CBG. Cyclicity of cortisol

secretion is a feature of all types of Cushing's syndrome and, if very variable, can confuse diagnosis. Use of multiple salivary cortisol samples over weeks or months can be helpful in diagnosis but an elevated salivary cortisol alone should not be taken as proof of diagnosis. In iatrogenic Cushing's syndrome, cortisol levels are low unless the patient is taking a glucocorticoid (such as prednisolone) that cross-reacts in immunoassays with cortisol.

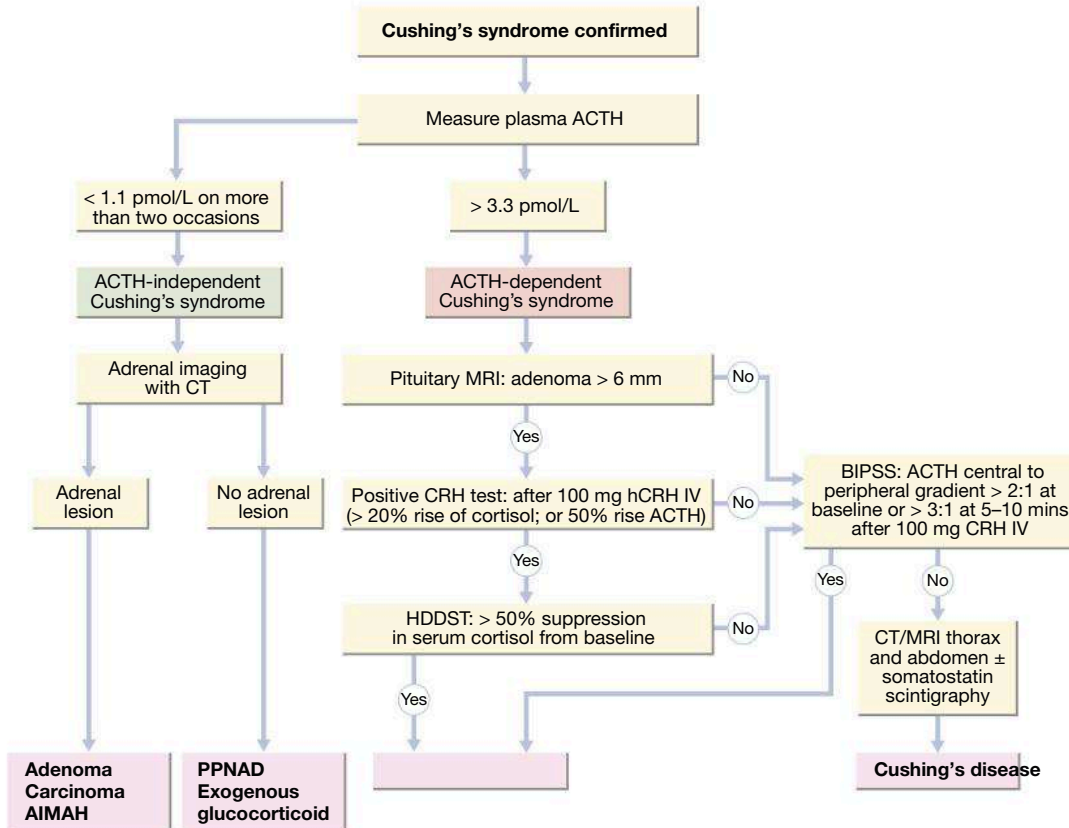

#### Determining the underlying cause

Once the presence of Cushing's syndrome is confirmed, measurement of plasma ACTH is the key to establishing the differential diagnosis; it is best measured in the morning around 0900 hrs. In the presence of excess cortisol secretion, an undetectable ACTH ( $<1.1$  pmol/L (5 ng/L)) indicates an adrenal cause, while ACTH levels of  $>3.3$  pmol/L (15 ng/L) suggest a pituitary cause or ectopic ACTH. ACTH levels between these values represent a 'grey area' and further evaluation by a specialist is required. Tests to discriminate pituitary from ectopic sources of ACTH rely on the fact that pituitary tumours, but not ectopic tumours, retain some features of normal regulation of ACTH secretion. Thus, in pituitary-dependent Cushing's disease, ACTH secretion is suppressed by high-dose dexamethasone and ACTH is stimulated by corticotrophin-releasing hormone (CRH). In a high-dose dexamethasone suppression test (HDDST), serum cortisol is measured before and after administration of 2 mg of dexamethasone 4 times daily for 48 hours.

Techniques for localisation of tumours secreting ACTH or cortisol are listed in Figure 20.23. MRI detects around 60% of pituitary microadenomas secreting ACTH. If available, bilateral inferior petrosal sinus sampling (BIPSS) with measurement of plasma ACTH near the pituitary and comparing this to peripheral levels is the best means of confirming Cushing's disease (increased gradient), unless MRI shows a tumour bigger than 6 mm, in which case it may not be needed. CT or MRI detects most

**Fig. 20.22** Sequence of investigations in suspected spontaneous Cushing's syndrome. A serum cortisol of 50 nmol/L is equivalent to 1.8 µg/dL. (LDDST = low-dose dexamethasone suppression test; ONDST = overnight dexamethasone suppression test; UFC = urinary free cortisol)

**Fig. 20.23** Determining the cause of confirmed Cushing's syndrome. To convert pmol/L to ng/L, multiply by 4.541. (ACTH = adrenocorticotrophic hormone; AIMAH = ACTH-independent macronodular adrenal hyperplasia; BIPSS = bilateral inferior petrosal sinus sampling; hCRH = human corticotrophin-releasing hormone; HDDST = high-dose dexamethasone suppression test; IV = intravenous; MRI = magnetic resonance imaging; PPNAD = primary pigmented nodular adrenal disease)

adrenal tumours; adrenal carcinomas are usually large (>5 cm) and have other features of malignancy.

### Management

Untreated severe Cushing's syndrome has a 50% 5-year mortality. Most patients are treated surgically, but medical therapy may be given in severe cases for a few weeks prior to operation to improve the clinical state, or where there is recurrent or incurable disease. Drugs that inhibit glucocorticoid biosynthesis form the mainstay or management, with the most widely available and established being metyrapone and ketoconazole, with osilodrostat becoming available more recently. The dose of these agents is best titrated against serum cortisol levels or 24-hour urine free cortisol.

### Cushing's disease

Trans-sphenoidal surgery carried out by an experienced surgeon with selective removal of the adenoma is the treatment of choice, with approximately 70% of patients going into immediate remission. Around 20% of patients suffer a recurrence, often years later, emphasising the need for life-long follow-up.

Laparoscopic bilateral adrenalectomy performed by an expert surgeon effectively cures any type of ACTH-dependent Cushing's syndrome, but in patients with Cushing's disease (pituitary) this can result in Nelson syndrome – an invasive pituitary macroadenoma (which causes local mass effects) and very high ACTH levels (which cause pigmentation). The risk of Nelson syndrome is reported as being reduced by pituitary irradiation in some series, but not all.

The somatostatin analogue pasireotide is also licensed for the treatment of Cushing's disease and works by suppressing ACTH secretion by the tumour.

### Adrenal tumours

Laparoscopic adrenal surgery is the treatment of choice for adrenal adenomas. Surgery offers the only prospect of cure for adrenocortical carcinomas but, in general, prognosis is poor with high rates of recurrence, even in patients with localised disease at presentation. Radiotherapy to the tumour bed reduces the risk of local recurrence; systemic therapy consists of the adrenolytic drug mitotane and chemotherapy, but responses are often poor.

### Ectopic ACTH syndrome

Localised tumours, such as bronchial carcinoids, should be removed surgically. In patients with incurable malignancy, it is important to reduce the severity of the Cushing's syndrome using medical therapy (see above) or, if appropriate, bilateral adrenalectomy.

## Therapeutic use of glucocorticoids

The remarkable anti-inflammatory properties of glucocorticoids have led to their use in a wide variety of clinical conditions but the hazards are significant. Equivalent doses of commonly used glucocorticoids are listed in Box 20.38. Topical preparations (dermal, rectal and inhaled) can also be absorbed into the systemic circulation, and although this rarely occurs to a sufficient degree to produce clinical features of Cushing's syndrome, it can result in significant suppression of endogenous ACTH and cortisol secretion. Severe Cushing's syndrome can result if there is concomitant administration of inhaled glucocorticoids and strong inhibitors of the liver enzyme CYP450 3A4, such as the antiretroviral drug ritonavir.

### 20.38 Approximate equivalent doses of glucocorticoids

- Hydrocortisone: 20 mg
- Cortisone acetate: 25 mg
- Prednisolone: 5 mg
- Dexamethasone: 0.5 mg

### Adverse effects of glucocorticoids

The clinical features of glucocorticoid excess are illustrated in Figure 20.21. Adverse effects are related to dose, duration of therapy, and pre-existing conditions that might be worsened by glucocorticoid therapy, such as diabetes mellitus or osteoporosis. Osteoporosis is a particularly important problem because, for a given bone mineral density, the fracture risk is greater in glucocorticoid-treated patients than in post-menopausal osteoporosis. Therefore, when systemic glucocorticoids are prescribed and the anticipated duration of steroid therapy is more than 3 months, bone-protective therapy should be considered. Rapid changes in glucocorticoid levels can also lead to marked mood disturbances, including depression, mania and insomnia. Glucocorticoid use also increases the white blood cell count (predominantly neutrophils), which must be taken into account when assessing patients with possible infection.

The anti-inflammatory effect of glucocorticoids may mask signs of disease. For example, perforation of a viscus may be masked and the patient may show no febrile response to an infection. Although there is debate about whether or not glucocorticoids increase the risk of peptic ulcer when used alone, they act synergistically with NSAIDs, including aspirin, to increase the risk of serious gastrointestinal adverse effects. Latent tuberculosis may be reactivated and patients on glucocorticoids are at risk of severe varicella zoster virus infection, so should avoid contact with chickenpox or shingles if they are non-immune.

### Management of glucocorticoid withdrawal

All glucocorticoid therapy, even if inhaled or applied topically, can suppress the HPA axis. In practice, this is likely to result in a crisis due to adrenal insufficiency on withdrawal of treatment only if glucocorticoids have been administered orally or systemically for longer than 3 weeks, if repeated courses have been prescribed within the previous year, or if the dose is higher than the equivalent of 7.5 mg prednisolone per day. In these circumstances, the drug, when it is no longer required for the underlying condition, must be withdrawn slowly at a rate dictated by the duration of treatment. If glucocorticoid therapy has been prolonged, then it may take many months for the HPA axis to recover. All patients must be advised to avoid sudden drug withdrawal. They should be issued with a steroid card and/or wear an engraved bracelet (Box 20.39).

Recovery of the HPA axis is aided if there is no exogenous glucocorticoid present during the nocturnal surge in ACTH secretion. This can be achieved by giving glucocorticoid in the morning. Giving ACTH

### 20.39 Advice to patients on glucocorticoid replacement therapy

#### Intercurrent stress

- Febrile illness: double dose of hydrocortisone

#### Surgery

- Minor operation: hydrocortisone 100 mg IM with pre-medication
- Major operation: hydrocortisone 100 mg 4 times daily for 24 hrs, then 50 mg IM 4 times daily until ready to take tablets

#### Vomiting

- Patients must have parenteral hydrocortisone if unable to take it by mouth

#### Steroid card

- Patient should carry this at all times; it should give information regarding diagnosis, steroid, dose and doctor

#### Bracelet and emergency pack

- Patients should be encouraged to buy a bracelet and have it engraved with the diagnosis, current treatment and a reference number for a central database
- Patients should be given a hydrocortisone emergency pack and trained in the self-administration of hydrocortisone 100 mg IM; they should be advised to take the pack on holidays/trips abroad

(IM = intramuscular)

to stimulate adrenal recovery is of no value, as the pituitary remains suppressed.

In patients who have received glucocorticoids for longer than a few weeks, especially if the period is months to years, it is often valuable to confirm that the HPA axis is recovering during glucocorticoid withdrawal. Withdrawal has to be very slow, usually by a dose reduction equivalent of prednisolone 1 mg per month or slower. Once the dose of glucocorticoid is reduced to a minimum (e.g. 5 mg prednisolone), then serum cortisol can be measured at 0900 hrs before the next dose. If this is <100 nmol/L (3.6 µg/dL), slow reduction should be continued with a repeat 0900 hrs serum cortisol when the dose of prednisolone is 3 mg per day. Once 0900 hrs serum cortisol is >150–200 nmol/L, then an ACTH stimulation test should be performed (see Box 20.42) to confirm if glucocorticoids can be withdrawn completely. Even when glucocorticoids have been successfully withdrawn, short-term replacement therapy is often advised

during significant intercurrent illness occurring in subsequent months, as the HPA axis may not be able to respond fully to severe stress.

## Adrenal insufficiency

Adrenal insufficiency results from inadequate secretion of cortisol and/or aldosterone. It is potentially fatal and notoriously variable in its presentation. A high index of suspicion is therefore required in patients with unexplained fatigue, hyponatraemia or hypotension. Causes are shown in Box 20.40. The most common is ACTH deficiency (secondary adrenocortical failure), usually because of inappropriate withdrawal of chronic glucocorticoid therapy or a pituitary tumour. Congenital adrenal hyperplasia and Addison's disease (primary adrenocortical failure) are rare causes.

### Clinical assessment

The clinical features of adrenal insufficiency are shown in Box 20.41. In Addison's disease, either glucocorticoid or mineralocorticoid deficiency may come first, but eventually all patients fail to secrete both classes of corticosteroid.

Patients may present with chronic features and/or in acute circulatory shock. With a chronic presentation, initial symptoms are often misdiagnosed as chronic fatigue syndrome or depression. In primary adrenal insufficiency, weight loss is a uniform presenting feature. Adrenocortical insufficiency should also be considered in patients with hyponatraemia, even in the absence of symptoms.

Features of an acute adrenal crisis include circulatory shock with severe hypotension, hyponatraemia, hyperkalaemia and, in some instances, hypoglycaemia and hypercalcaemia. Muscle cramps, nausea, vomiting, diarrhoea and unexplained fever may be present. The crisis is often precipitated by intercurrent disease, surgery or infection.

Vitiligo occurs in 10%–20% of patients with autoimmune Addison's disease.

### Investigations

Treatment should not be delayed to wait for results in patients with suspected acute adrenal crisis. Here, a random blood sample should be stored for subsequent measurement of serum cortisol and, if possible, plasma ACTH; if the patient's clinical condition permits, it may be appropriate to spend 30 minutes performing a short ACTH stimulation test (Box 20.42) before administering hydrocortisone, but delays must be avoided if there is circulatory compromise. Investigations should be

**20.42 How and when to do an ACTH stimulation test****Use**

- Diagnosis of primary or secondary adrenal insufficiency
- Assessment of HPA axis in patients taking suppressive glucocorticoid therapy
- Relies on ACTH-dependent adrenal atrophy in secondary adrenal insufficiency, so may not detect acute ACTH deficiency<sup>1</sup> (e.g. in pituitary apoplexy)

**Dose**

- 250 µg ACTH<sub>1-24</sub> (Synacthen) by IM injection at any time of day

**Blood samples**

- 0 and 30 mins for plasma cortisol
- 0 mins also for ACTH (on ice) if Addison's disease is being considered (patient not known to have pituitary disease or to be taking exogenous glucocorticoids)

**Results**

- Normal subjects: plasma cortisol >430 nmol/L (approximately 15.6 µg/dL)<sup>2</sup> either at baseline or at 30 mins
- Incremental change in cortisol is not a criterion

<sup>1</sup>In acute secondary adrenal insufficiency the adrenal cortex will still respond normally on the SST making the test unreliable in that setting. It usually takes around 6 weeks of ACTH-deficiency for the adrenal cortex to atrophy sufficiently for the response on and SST to be inadequate.<sup>2</sup>The exact cortisol concentration depends on the cortisol assay being used. (ACTH = adrenocorticotrophic hormone; HPA = hypothalamic-pituitary-adrenal; IM = intramuscular)

performed before treatment is given in patients who present with features suggestive of chronic adrenal insufficiency.

**Assessment of glucocorticoids**

Random plasma cortisol is usually low in patients with adrenal insufficiency but it may be within the reference range, yet inappropriately low, for a seriously ill patient. Random measurement of normal levels of plasma cortisol cannot therefore be used to confirm or refute the diagnosis, unless the value is above 430 nmol/L (>15.6 µg/dL), which effectively excludes adrenal insufficiency.

More useful is the short ACTH stimulation test (also called the tetracosactrin or short Synacthen test) described in [Box 20.42](#). Cortisol levels fail to increase in response to exogenous ACTH in patients with primary or secondary adrenal insufficiency. These can be distinguished by measurement of ACTH (which is low in ACTH deficiency and high in Addison's disease).

**Assessment of mineralocorticoids**

Mineralocorticoid secretion in patients with suspected Addison's disease cannot be adequately assessed by electrolyte measurements since hyponatraemia occurs in both aldosterone and cortisol deficiency (see [Box 20.41](#) and page 629). Hyperkalaemia is common, but not universal, in aldosterone deficiency. Plasma renin and aldosterone should be measured in the supine position. In mineralocorticoid deficiency, plasma renin activity is high, with plasma aldosterone being either low or in the lower part of the reference range.

**Assessment of adrenal androgens**

This is not necessary in men because testosterone from the testes is the principal androgen. In women, dehydroepiandrosterone sulphate (DHEAS) and androstenedione may be measured in a random specimen of blood, though levels are highest in the morning.

**Other tests to establish the cause**

Patients with unexplained secondary adrenocortical insufficiency should be investigated as described in [Box 20.51](#). In patients with elevated ACTH, further tests are required to establish the cause of Addison's disease. Adrenal autoantibodies to 21-hydroxylase are frequently positive in autoimmune adrenal failure. If antibody tests are negative, imaging of the adrenal glands with CT or MRI is indicated. Tuberculosis causes adrenal calcification, visible on plain X-ray or ultrasound scan. A human immunodeficiency virus (HIV) test should be performed if relevant risk factors

are present. Adrenal metastases are a rare cause of adrenal insufficiency. Patients with evidence of autoimmune adrenal failure should be screened for other organ-specific autoimmune diseases, such as thyroid disease, pernicious anaemia and type 1 diabetes.

**Management**

Patients with adrenocortical insufficiency always need glucocorticoid replacement therapy and usually, but not always, mineralocorticoid therapy. There is some evidence that adrenal androgen replacement may also be beneficial in some women. Other treatments depend on the underlying cause. The emergency management of adrenal crisis is described in [Box 20.43](#).

**Glucocorticoid replacement**

Adrenal replacement therapy consists of oral hydrocortisone (cortisol) 15–20mg daily in divided doses, typically 10mg on waking and 5mg at around 1500 hrs. These are physiological replacement doses that should not cause Cushingoid side-effects. The dose may need to be adjusted for the individual patient but this is subjective. Excess weight gain usually indicates over-replacement, while persistent lethargy or hyperpigmentation may be due to an inadequate dose or lack of absorption. Measurement of serum cortisol levels is not usually helpful. Advice to patients dependent on glucocorticoid replacement is given in [Box 20.39](#) and considerations in respect of glucocorticoids in old age are given in [Box 20.44](#).

**Mineralocorticoid replacement**

Fludrocortisone (9α-fluoro-hydrocortisone) is administered at the usual dose of 0.05–0.15mg daily, and adequacy of replacement may be assessed by measurement of blood pressure, plasma electrolytes and

**20.43 Management of adrenal crisis****Correct volume depletion**

- IV saline as required to normalise blood pressure and pulse
- In severe hyponatraemia (<125 mmol/L) avoid increases of plasma Na >10 mmol/L/day to prevent pontine demyelination
- Fludrocortisone is not required during the acute phase of treatment

**Replace glucocorticoids**

- IV hydrocortisone succinate 100 mg stat, and 100 mg 4 times daily for first 12–24 hrs
- Continue parenteral hydrocortisone (50–100 mg IM 4 times daily) until patient is well enough for reliable oral therapy

**Correct other metabolic abnormalities**

- Acute hypoglycaemia: IV 10% glucose
- Hyperkalaemia: should respond to volume replacement but occasionally requires specific therapy (see [Box 19.17](#))

**Identify and treat underlying cause**

- Consider acute precipitant, such as infection
- Consider adrenal or pituitary pathology (see [Box 20.40](#))

(IM = intramuscular; IV = intravenous)

**20.44 Glucocorticoids in old age**

- **Adrenocortical insufficiency:** often insidious and may present with tiredness, drowsiness, delirium, falls, immobility and orthostatic hypotension.
- **Glucocorticoid therapy:** especially hazardous in older people, who are already relatively immunocompromised and susceptible to osteoporosis, diabetes, hypertension and other complications.
- **'Physiological' glucocorticoid replacement therapy:** increased risk of adrenal crisis because adherence may be poor and there is a greater incidence of intercurrent illness. Patient and carer education, with regular reinforcement of the principles described in [Box 20.39](#), is crucial.

plasma renin. It is indicated for virtually every patient with primary adrenal insufficiency but is not needed in secondary adrenal insufficiency.

### Androgen replacement

Androgen replacement with DHEAS (50mg/day) is occasionally given to women with primary adrenal insufficiency who have symptoms of reduced libido and fatigue, but the evidence in support of this is not robust and treatment may be associated with side-effects such as acne and hirsutism.

## Incidental adrenal mass

Enlarged or hyperplastic adrenal glands are commonly found on CT or MRI scans of the abdomen that have been performed for other indications. Such lesions are known as adrenal 'incidentalomas'. The prevalence increases with age and they are present in up to 10% of adults aged 70 years and older.

Sixty per cent of adrenal incidentalomas are non-functioning adrenal adenomas. The remainder includes functional tumours of the adrenal cortex (secreting cortisol, aldosterone or androgens), pheochromocytomas, primary and secondary carcinomas, hamartomas and other rare disorders, including granulomatous infiltrations.

### Clinical assessment and investigations

There are two key questions to be resolved: is the lesion secreting hormones, and is it benign or malignant? These are best assessed by a dedicated adrenal multidisciplinary team (MDT).

Patients with an adrenal incidentaloma are usually asymptomatic. However, clinical signs and symptoms of excess glucocorticoids, mineralocorticoids, catecholamines and, in women, androgens should be sought, as discussed elsewhere in this chapter. Investigations should include a dexamethasone suppression test, urine or plasma metanephrines and, in virilised women, measurement of serum testosterone, DHEAS and androstenedione. Patients with hypertension should be investigated for mineralocorticoid excess, as described below. In bilateral masses consistent with adrenocortical lesions, 17-OH-progesterone should also be measured.

CT and MRI are equally effective in assessing the malignant potential of an adrenal mass, using the following parameters:

- **Size.** The larger the lesion, the greater the malignant potential. Around 90% of adrenocortical carcinomas are over 4cm in diameter, but specificity is poor since only approximately 25% of such lesions are malignant.
- **Configuration.** Homogeneous and smooth lesions are more likely to be benign. The presence of metastatic lesions elsewhere increases the risk of malignancy, but as many as two-thirds of adrenal incidentalomas in patients with cancer are benign.
- **Presence of lipid.** Adenomas are usually lipid-rich, resulting in an attenuation of below 10 Hounsfield units (HU) on an unenhanced CT, and in signal dropout on chemical shift MRI.
- **Enhancement.** Benign lesions demonstrate rapid washout of contrast, whereas malignant lesions tend to retain contrast.

Histology in a sample obtained by CT-guided biopsy is rarely indicated, and is not useful in distinguishing an adrenal adenoma from an adrenocortical carcinoma. Biopsy is occasionally helpful in confirming adrenal metastases from other cancers, but should be avoided if either pheochromocytoma or primary adrenal cancer is suspected in order to avoid precipitation of a hypertensive crisis or seeding of tumour cells, respectively. An endocrine opinion must be sought before any biopsy.

### Management

In patients with radiologically benign, non-functioning lesions of less than 4 cm in diameter, surgery is not usually indicated. Functional lesions and tumours of more than 4 cm in diameter with indeterminate or concerning features, should be considered for surgery, and many centres will not

## 20.45 Causes of mineralocorticoid excess

### With renin high and aldosterone high (secondary hyperaldosteronism)

- Inadequate renal perfusion (diuretic therapy, cardiac failure, liver failure, nephrotic syndrome, renal artery stenosis)
- Renin-secreting renal tumour (very rare)

### With renin low and aldosterone high (primary hyperaldosteronism)

- Adrenal adenoma secreting aldosterone (Conn syndrome)
- Idiopathic bilateral adrenal hyperplasia
- Glucocorticoid-suppressible hyperaldosteronism (rare)

### With renin low and aldosterone low (non-aldosterone-dependent activation of mineralocorticoid pathway)

- Ectopic ACTH syndrome
- Licorice misuse (inhibition of 11 $\beta$ -HSD2)
- Liddle syndrome
- 11-deoxycorticosterone-secreting adrenal tumour
- Rare forms of congenital adrenal hyperplasia and 11 $\beta$ -HSD2 deficiency

(11 $\beta$ -HSD2 = 11 $\beta$ -hydroxysteroid dehydrogenase type 2; ACTH = adrenocorticotrophic hormone)

operate on tumours >4 cm if all other characteristics suggest benign disease. Optimal management of patients with low-grade cortisol secretion, as demonstrated by the dexamethasone suppression test, remains to be established.

## Primary hyperaldosteronism

Estimates of the prevalence of primary hyperaldosteronism vary according to the screening tests employed, but it may occur in as many as 10% of people with hypertension. Indications to test for mineralocorticoid excess in hypertensive patients include hypokalaemia (including hypokalaemia induced by thiazide diuretics), poor control of blood pressure with conventional therapy, a family history of early-onset hypertension, or presentation at a young age.

Causes of excessive activation of mineralocorticoid receptors are shown in Box 20.45. It is important to differentiate primary hyperaldosteronism, caused by an intrinsic abnormality of the adrenal glands resulting in aldosterone excess, from secondary hyperaldosteronism, which is usually a consequence of enhanced activity of renin in response to inadequate renal perfusion and hypotension. Most individuals with primary hyperaldosteronism have bilateral adrenal hyperplasia (idiopathic hyperaldosteronism), while only a minority have an aldosterone-producing adenoma (APA; Conn syndrome). Glucocorticoid-suppressible hyperaldosteronism is a rare autosomal dominant condition in which aldosterone is secreted 'ectopically' from the adrenal zona fasciculata/reticularis in response to ACTH. Rarely, the mineralocorticoid receptor pathway in the distal nephron is activated, even though aldosterone concentrations are low.

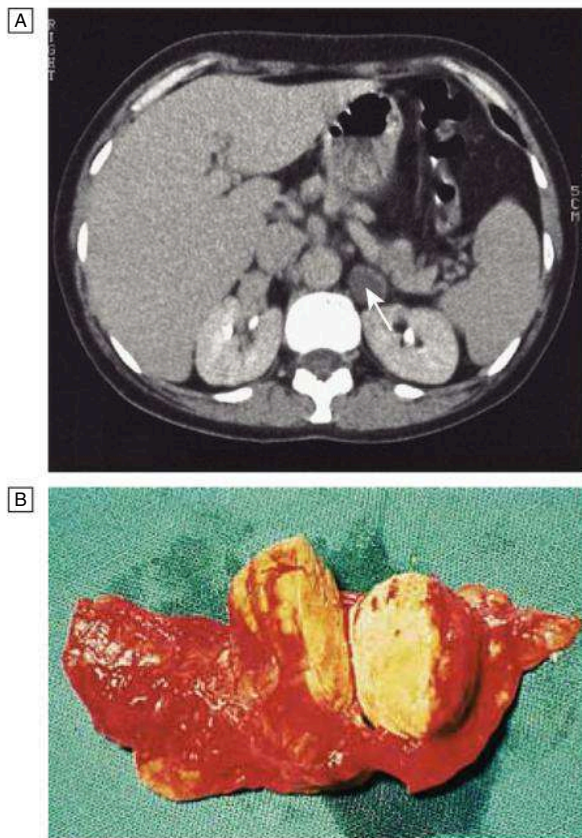

### Clinical features

Individuals with primary hyperaldosteronism are usually asymptomatic but may have features of sodium retention or potassium loss. Sodium retention may cause oedema, while hypokalaemia may cause muscle weakness (or even paralysis, especially in South-east Asian populations), polyuria (secondary to renal tubular damage, which produces nephrogenic diabetes insipidus) and occasionally tetany (because of associated metabolic alkalosis and low ionised calcium). Blood pressure is elevated but accelerated phase hypertension is rare.

### Investigations

#### Biochemical

Routine blood tests may show a hypokalaemic alkalosis. Sodium is usually at the upper end of the reference range in primary hyperaldosteronism, but is characteristically low in secondary hyperaldosteronism (because low

**Fig. 20.24** Aldosterone-producing adenoma causing Conn syndrome. **A** CT scan of left adrenal adenoma (arrow). **B** The tumour is 'canary yellow' because of intracellular lipid accumulation.

plasma volume stimulates vasopressin (antidiuretic hormone, ADH) release and high angiotensin II levels stimulate thirst). The key measurements are plasma renin and aldosterone (Box 20.45), and in many centres the aldosterone:renin ratio (ARR) is employed as a screening test for primary hyperaldosteronism in hypertensive patients. Almost all antihypertensive drugs interfere with this ratio ( $\beta$ -blockers inhibit while diuretics stimulate renin secretion). Thus, individuals with an elevated ARR require further testing after stopping many antihypertensive drugs for at least 4 weeks (although if the ratio is still high despite a patient taking ACE inhibitors or angiotensin receptor-blocking drugs then this need not be done as these agents would normally cause a lowering of the ratio). If necessary, antihypertensive agents that have minimal effects on the renin–angiotensin system, such as calcium antagonists and  $\alpha$ -blockers, may be substituted. Oral potassium supplementation may also be required, as hypokalaemia itself suppresses renin activity. If, on repeat testing, plasma renin is low and aldosterone concentrations are elevated, then further investigation under specialist supervision may include saline or fludrocortisone suppression tests.

#### Imaging and localisation

Imaging with CT or MRI will identify most APAs (Fig. 20.24A) but it is important to recognise the risk of false positives (non-functioning adrenal adenomas are common) and false negatives (imaging may have insufficient resolution to identify adenomas with a diameter of less than 0.5 cm). If the imaging is inconclusive and there is an intention to proceed with surgery on the basis of strong biochemical evidence of an APA, then adrenal vein catheterisation with measurement of aldosterone (and cortisol to confirm positioning of the catheters) is usually required. In some centres, this is performed even in the presence of a unilateral 'adenoma', to avoid inadvertent removal of an incidental non-functioning adenoma contralateral to a radiologically inapparent cause of aldosterone excess.

#### 20.46 Clinical features of pheochromocytoma

- Hypertension (usually paroxysmal; often postural drop of blood pressure)
- Paroxysms of:
  - Pallor (occasionally flushing)
  - Palpitations, sweating
  - Headache
  - Anxiety (angor animi)
- Abdominal pain, vomiting
- Constipation
- Weight loss
- Glucose intolerance

#### Management

Mineralocorticoid receptor antagonists (spironolactone and eplerenone) are valuable in treating both hypokalaemia and hypertension in all forms of mineralocorticoid excess. Up to 20% of males develop gynaecomastia on spironolactone. Amiloride (10–40 mg/day), which blocks the epithelial sodium channel regulated by aldosterone, is an alternative.

In patients with an APA, medical therapy is usually given for a few weeks to normalise whole-body electrolyte balance before unilateral adrenalectomy. Laparoscopic surgery cures the biochemical abnormality but, depending on the pre-operative duration, hypertension remains in as many as 70% of cases, probably because of irreversible damage to the systemic microcirculation.

#### Pheochromocytoma and paraganglioma

These are rare neuro-endocrine tumours that may secrete catecholamines (adrenaline/epinephrine, noradrenaline/norepinephrine). Approximately 80% of these tumours occur in the adrenal medulla (pheochromocytomas), while 20% arise elsewhere in the body in sympathetic ganglia (paragangliomas). Most are benign but approximately 15% show malignant features. Around 40% are associated with inherited disorders, including neurofibromatosis, von Hippel–Lindau syndrome, MEN 2a and MEN 2b. Paragangliomas are particularly associated with mutations in the succinate dehydrogenase A, B, C and D genes. Other genetic causes include mutations in *SDHA*, *SDHAF2*, *TMEN127* and *MAX*.

#### Clinical features

These depend on the pattern of catecholamine secretion and are listed in Box 20.46.

Some patients present with hypertension, although it has been estimated that pheochromocytoma accounts for less than 0.1% of cases of hypertension. The presentation may be with a complication of hypertension, such as stroke, myocardial infarction, left ventricular failure, hypertensive retinopathy or accelerated phase hypertension. The apparent paradox of postural hypotension between episodes is explained by 'pressure natriuresis' during hypertensive episodes so that intravascular volume is reduced. There may also be features of the familial syndromes associated with pheochromocytoma. Paragangliomas are often non-functioning.

#### Investigations

Excessive secretion of catecholamines can be confirmed by measuring metabolites in plasma and/or urine (metanephrine and normetanephrine). There is a high 'false-positive' rate, as misleading metanephrine concentrations may be seen in stressed patients (during acute illness, following vigorous exercise or severe pain) and following ingestion of some drugs such as tricyclic antidepressants. For this reason, a repeat sample should usually be requested if elevated levels are found, although, as a rule, the higher the concentration of metanephrines, the more likely the diagnosis of pheochromocytoma/paraganglioma. Serum chromogranin A is often elevated and may be a useful tumour marker in patients with non-secretory tumours and/or metastatic disease. Genetic testing should be considered in individuals with other features of a

**Fig. 20.25** CT scan of abdomen showing large left adrenal phaeochromocytoma. The normal right adrenal (white arrow) contrasts with the large heterogeneous phaeochromocytoma arising from the left adrenal gland (black arrow).

genetic syndrome, in those with a family history of phaeochromocytoma/paraganglioma, and in those presenting under the age of 50 years.

#### Localisation

Phaeochromocytomas are usually identified by abdominal CT or MRI (Fig. 20.25). Localisation of paragangliomas may be more difficult. Scintigraphy using meta-iodobenzyl guanidine (MIBG) can be useful, particularly if combined with CT, for adrenal phaeochromocytoma but is often negative in paraganglioma.  $^{18}\text{F}$ -deoxyglucose PET or  $^{68}\text{Ga}$ -DOTANOC or DOTATATE-PET CT are especially useful for detection of malignant disease and for confirming an imaging abnormality as a paraganglioma in an individual with underlying risk due to genetic mutation.

#### Management

In functioning tumours, medical therapy is required to prepare the patient for surgery, preferably for a minimum of 6 weeks, to allow restoration of normal plasma volume. The most useful drug in the face of very high circulating catecholamines is the  $\alpha$ -blocker phenoxybenzamine (10–20 mg orally 3–4 times daily) because it is a non-competitive antagonist, unlike prazosin or doxazosin. If  $\alpha$ -blockade produces a marked tachycardia, then a  $\beta$ -blocker such as propranolol can be added. On no account should a  $\beta$ -blocker be given before an  $\alpha$ -blocker, as this may cause a paradoxical rise in blood pressure due to unopposed  $\alpha$ -mediated vasoconstriction.

During surgery, sodium nitroprusside and the short-acting  $\alpha$ -antagonist phentolamine are useful in controlling hypertensive episodes, which may result from anaesthetic induction or tumour mobilisation. Post-operative hypotension may occur and require volume expansion and, very occasionally, noradrenaline (norepinephrine) infusion, but is uncommon if the patient has been prepared with phenoxybenzamine.

Metastatic tumours may behave in an aggressive or a very indolent fashion. Management options include debulking surgery, radionuclide therapy with  $^{131}\text{I}$ -MIBG or  $^{177}\text{Lu}$ DOTATATE, chemotherapy and (chemo)embolisation of hepatic metastases; some may respond to tyrosine kinase and angiogenesis inhibitors.

### Congenital adrenal hyperplasia

#### Pathophysiology and clinical features

Inherited defects in enzymes of the cortisol biosynthetic pathway (see Fig. 20.20) result in insufficiency of hormones downstream of the block, with impaired negative feedback and increased ACTH secretion. ACTH then stimulates the production of steroids upstream of the enzyme block. This produces adrenal hyperplasia and a combination of clinical features

that depend on the severity and site of the defect in biosynthesis. All of these enzyme abnormalities are inherited as autosomal recessive traits.

The most common enzyme defect is 21-hydroxylase deficiency. This results in impaired synthesis of cortisol and aldosterone, and accumulation of 17-OH-progesterone, which is then diverted to form adrenal androgens. In about one-third of cases, this defect is severe and presents in infancy with features of glucocorticoid and mineralocorticoid deficiency (see Box 20.41) and androgen excess, such as ambiguous genitalia in girls. In the other two-thirds, mineralocorticoid secretion is adequate but there may be features of cortisol insufficiency and/or ACTH and androgen excess, including precocious pseudo-puberty, which is distinguished from 'true' precocious puberty by low gonadotrophins. Sometimes the mildest enzyme defects are not apparent until adult life, when females may present with amenorrhoea and/or hirsutism. This is called 'non-classical' or 'late-onset' congenital adrenal hyperplasia.

Defects of all the other enzymes in Figure 20.20 are rare. Both 17-hydroxylase and 11 $\beta$ -hydroxylase deficiency may produce hypertension due to excess production of 11-deoxycorticosterone, which has mineralocorticoid activity.

#### Investigations

Circulating 17-OH-progesterone levels are raised in 21-hydroxylase deficiency but this may be demonstrated only after ACTH administration in late-onset cases. To avoid salt-wasting crises in infancy, 17-OH-progesterone can be routinely measured in heelprick blood spot samples taken from all infants in the first week of life. Assessment is otherwise as described earlier for adrenal insufficiency.

In siblings of affected children, antenatal genetic diagnosis can be made by amniocentesis or chorionic villus sampling. This allows prevention of virilisation of affected female fetuses by administration of dexamethasone to the mother to suppress ACTH levels.

#### Management

The aim is to replace deficient corticosteroids and to suppress ACTH-driven adrenal androgen production. A careful balance is required between adequate suppression of adrenal androgen excess and excessive glucocorticoid replacement resulting in features of Cushing's syndrome. In children, growth velocity is an important measurement, since either under- or over-replacement with glucocorticoids suppresses growth. In adults, there is no uniformly agreed adrenal replacement regimen, and clinical features (menstrual cycle, hirsutism, weight gain, blood pressure) and biochemical profiles (plasma renin, 17-OH-progesterone and testosterone levels) provide a guide.

Women with late-onset 21-hydroxylase deficiency may not require corticosteroid replacement. If hirsutism is the main problem, anti-androgen therapy may be just as effective.

### The endocrine pancreas and gastrointestinal tract

A series of hormones are secreted from cells distributed throughout the gastrointestinal tract and pancreas. Functional anatomy and physiology are described in Chapter 23 and 24. Diseases associated with abnormalities of these hormones are listed in Box 20.47. Most are rare, with the exception of diabetes mellitus (Ch. 21).

### Presenting problems in endocrine pancreas disease

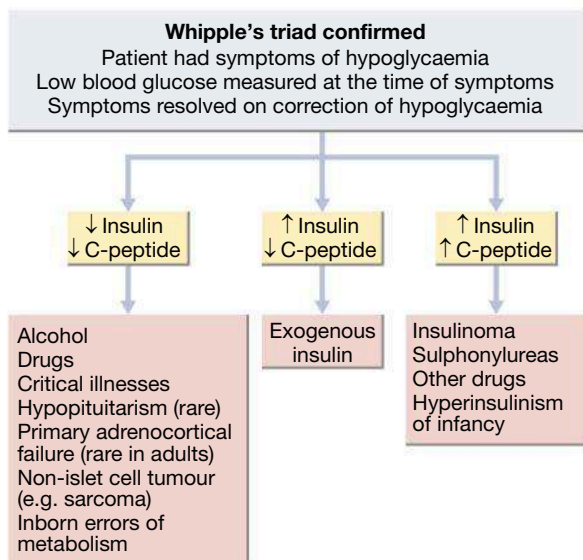

#### Spontaneous hypoglycaemia

Hypoglycaemia most commonly occurs as a side-effect of treatment with insulin or sulphonylurea drugs in people with diabetes mellitus. In non-diabetic individuals, symptomatic hypoglycaemia is rare, but it is not uncommon to detect venous blood glucose concentrations below 3.0 mmol/L

### 20.47 Classification of endocrine diseases of the pancreas and gastrointestinal tract

	Primary	Secondary
<b>Hormone excess</b>	Insulinoma Gastrinoma (Zollinger–Ellison syndrome) Carcinoid syndrome (secretion of 5-HT) Glucagonoma VIPoma Somatostatinoma	Hypergastrinaemia of achlorhydria Hyperinsulinaemia after bariatric surgery
<b>Hormone deficiency</b>	Diabetes mellitus	
<b>Hormone resistance</b>	Insulin resistance syndromes (e.g. type 2 diabetes mellitus, lipodystrophy, Donohue syndrome)	
<b>Non-functioning tumours</b>	Pancreatic carcinoma Pancreatic neuro-endocrine tumour	

(5-HT = 5-hydroxytryptamine, serotonin)

**Fig. 20.26** Differential diagnosis of spontaneous hypoglycaemia. Measurement of insulin and C-peptide concentrations during an episode is helpful in determining the underlying cause.

(54 mg/dL) in asymptomatic patients. For this reason, and because the symptoms of hypoglycaemia are non-specific, a hypoglycaemic disorder should be diagnosed only if all three conditions of Whipple's triad are met (Fig. 20.26). There is no specific blood glucose concentration at which spontaneous hypoglycaemia can be said to occur, although the lower the blood glucose concentration, the more likely it is to have pathological significance. Investigations are unlikely to be needed unless glucose concentrations below 3.0 mmol/L are observed, many patients with true hypoglycaemia demonstrating glucose levels below 2.2 mmol/L (40 mg/dL).

With the increasing use of bariatric surgery, and more specifically gastric bypass surgery, more patients are presenting with post-prandial hypoglycaemia due to excess stimulated insulin secretion due to the rapid carbohydrate loads being delivered directly to the small intestine. Careful history-taking is needed to distinguish between post-prandial and spontaneous hypoglycaemia, and oral glucose tolerance or mixed meal testing may invoke observed hypoglycaemia in the former.

### Clinical assessment

The clinical features of hypoglycaemia are described in the section on insulin-induced hypoglycaemia in Chapter 21. Individuals with chronic spontaneous hypoglycaemia often have attenuated autonomic responses and 'hypoglycaemia unawareness', and may present with a wide variety of features of neuroglycopenia, including odd behaviour and convulsions. The symptoms are usually episodic and relieved by consumption of carbohydrate. Symptoms occurring while fasting (such as before breakfast) or following exercise are much more likely to be representative of pathological hypoglycaemia than those that develop after food (post-prandial or 'reactive' symptoms). Hypoglycaemia should be considered in all comatose patients, even if there is an apparently obvious cause, such as hemiplegic stroke or alcohol intoxication.

### Investigations

#### Does the patient have a hypoglycaemic disorder?

Patients who present acutely with delirium, coma, convulsions or stroke should be tested for hypoglycaemia at the bedside with a capillary blood sample and an automated meter. While this is sufficient to exclude hypoglycaemia, blood glucose meters are relatively inaccurate in the hypoglycaemic range and the diagnosis should always be confirmed by a laboratory-based glucose measurement. At the same time, a sample should be taken for later measurement of alcohol, insulin, C-peptide, cortisol and sulphonylurea levels, if hypoglycaemia is confirmed. Taking these samples during an acute presentation prevents subsequent unnecessary dynamic tests and is of medico-legal importance in cases where poisoning is suspected.

Patients who attend the outpatient clinic with episodic symptoms suggestive of hypoglycaemia present a more challenging problem. The main diagnostic test is the prolonged (72-hour) fast. If symptoms of hypoglycaemia develop during the fast, then blood samples should be taken to confirm hypoglycaemia and for later measurement of insulin and C-peptide. Hypoglycaemia is then corrected with oral or intravenous glucose and Whipple's triad is completed by confirmation of the resolution of symptoms. The absence of clinical and biochemical evidence of hypoglycaemia during a prolonged fast effectively excludes the diagnosis of a hypoglycaemic disorder.

#### What is the cause of the hypoglycaemia?

In the acute setting, the underlying diagnosis is often obvious. In non-diabetic individuals, alcohol excess is the most common cause of hypoglycaemia in the UK, but other drugs – e.g. salicylates, quinine and pentamidine – may also be implicated. Hypoglycaemia is one of many metabolic derangements that occur in patients with hepatic failure, renal failure, adrenal insufficiency, sepsis or malaria.

Hypoglycaemia in the absence of insulin, or any insulin-like factor, in the blood indicates impaired gluconeogenesis and/or availability of glucose from glycogen in the liver. Hypoglycaemia associated with high insulin and low C-peptide concentrations is indicative of administration of exogenous insulin, either factitiously or feloniously. Adults with high insulin and C-peptide concentrations during an episode of hypoglycaemia are most likely to have an insulinoma but sulphonylurea ingestion should also be considered (particularly in individuals with access to such medication, such as health-care professionals or family members of someone with type 2 diabetes). Suppressed plasma  $\beta$ -hydroxybutyrate helps confirm inappropriate insulin secretion during fasting. Usually, insulinomas in the pancreas are small (<5 mm diameter) but can be identified by CT, MRI or ultrasound (endoscopic or laparoscopic). Imaging should include the liver since around 10% of insulinomas are malignant and may metastasise to the liver. Rarely, large non-pancreatic tumours, such as sarcomas, may cause recurrent hypoglycaemia because of their ability to produce excess pro-insulin-like growth factor-2 (pro-IGF-2), which has considerable structural homology to insulin.

### Management

Treatment of acute hypoglycaemia should be initiated as soon as laboratory blood samples have been taken and should *not* be deferred until

formal laboratory confirmation has been obtained. Intravenous dextrose (5% or 10%) is effective in the short term in the obtunded patient and should be followed on recovery with oral unrefined carbohydrate (starch). Continuous dextrose infusion may be necessary, especially in sulphonylurea poisoning. Intramuscular glucagon (1 mg) stimulates hepatic glucose release but is ineffective in patients with depleted glycogen reserves, such as in alcohol excess or liver disease.

Chronic recurrent hypoglycaemia in insulin-secreting tumours can be treated by regular consumption of oral carbohydrate combined with agents that inhibit insulin secretion (diazoxide or somatostatin analogues). Insulinomas are resected when benign, providing the individual is fit enough to undergo surgery. Metastatic malignant insulinomas may be incurable and are managed along the same lines as other metastatic neuro-endocrine tumours (see below).

## Gastroenteropancreatic neuro-endocrine tumours

Neuro-endocrine tumours (NETs) are a heterogeneous group derived from neuro-endocrine cells in many organs, including the gastrointestinal tract, lung, adrenals (phaeochromocytoma) and thyroid (medullary carcinoma). Most NETs occur sporadically but a proportion are associated with genetic cancer syndromes, such as MEN 1, 2a and 2b, and neurofibromatosis type 1. NETs may secrete hormones into the circulation.

Gastroenteropancreatic NETs arise in organs that are derived embryologically from the gastrointestinal tract. Most commonly, they occur in the small bowel but they can also arise elsewhere in the bowel, pancreas, thymus and bronchi. The term 'carcinoid' is often used when referring to non-pancreatic gastroenteropancreatic NETs because, when initially described, they were thought to behave in an indolent fashion compared with conventional cancers. It is now recognised that there is a wide spectrum of malignant potential for all NETs; some are more usually benign (most insulinomas and appendiceal carcinoid tumours), while others have an aggressive clinical course with widespread metastases (small-cell carcinoma of the lung). The majority of gastroenteropancreatic NETs behave in an intermediate manner, with relatively slow growth but a propensity to invade and metastasise to remote organs, especially the liver.

### Clinical features

Patients with gastroenteropancreatic NETs often have a history of abdominal pain over many years prior to diagnosis and usually present with local mass effects, such as small-bowel obstruction, appendicitis and pain from hepatic metastases. Thymic and bronchial carcinoids occasionally present with ectopic ACTH syndrome. Pancreatic NETs can also cause hormone excess (Box 20.48) but most are non-functional.

20.48 Pancreatic neuro-endocrine tumours		
Tumour	Hormone	Effects
Gastrinoma	Gastrin	Peptic ulcer and steatorrhoea (Zollinger–Ellison syndrome)
Insulinoma	Insulin	Recurrent hypoglycaemia (see above)
VIPoma	Vasoactive intestinal peptide (VIP)	Watery diarrhoea and hypokalaemia
Glucagonoma	Glucagon	Diabetes mellitus, necrolytic migratory erythema
Somatostatinoma	Somatostatin	Diabetes mellitus and steatorrhoea

## 20.49 Clinical features of the carcinoid syndrome

- Episodic flushing, wheezing and diarrhoea
- Facial telangiectasia
- Cardiac involvement (tricuspid regurgitation, pulmonary stenosis, right ventricular endocardial plaques) leading to heart failure

The classic 'carcinoid syndrome' (Box 20.49) occurs when vasoactive hormones reach the systemic circulation. In the case of gastrointestinal carcinoids, this invariably means that the tumour has metastasised to the liver or there are peritoneal deposits, which allow secreted hormones to gain access to the systemic circulation; hormones secreted by the primary tumour into the portal vein are metabolised and inactivated in the liver. The features of Zollinger–Ellison syndrome are described on page 816.

### Investigations

A combination of imaging with ultrasound, CT, MRI and/or radio-labelled somatostatin analogue (Fig. 20.27) will usually identify the primary tumour and allow staging, which is crucial for determining prognosis. Biopsy of the primary tumour or a metastatic deposit is required to confirm the histological type. NETs demonstrate immunohistochemical staining for the proteins chromogranin A and synaptophysin, and the histological grade provides important prognostic information: the higher the Ki67 proliferation index, the worse the prognosis.

Carcinoid syndrome is confirmed by measuring elevated concentrations of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, in a 24-hour urine collection. False positives can occur, particularly if the individual has been eating serotonin-rich foods, such as avocado and pineapple. Plasma chromogranin A can be measured in a fasting blood sample, along with the hormones listed in Box 20.48. All of these can be useful as tumour markers.

### Management

Treatment of solitary tumours is by surgical resection. If metastatic or multifocal primary disease is present, then surgery is usually not indicated, unless there is a complication such as gastrointestinal obstruction, but debulking surgery may be performed. Diazoxide can reduce insulin secretion in insulinomas, and high doses of proton pump inhibitors suppress acid production in gastrinomas. Somatostatin analogues are effective in reducing the symptoms of carcinoid syndrome and of excess glucagon and vasoactive intestinal peptide (VIP) production. The slow-growing nature of NETs means that conventional cancer therapies, such as chemotherapy and radiotherapy, have limited efficacy, but use of somatostatin analogues is associated with improved progression-free survival, and <sup>177</sup>Lutetium DOTATATE is indicated for many patients with further disease progression. Other treatments, such as interferon, targeted radionuclide therapy with <sup>131</sup>I-MIBG and resection/embolisation/ablation of hepatic metastases, may have a role in the palliation of symptoms but debate exists as to whether this prolongs life. The tyrosine kinase inhibitor sunitinib and the mammalian target of rapamycin (mTOR) inhibitor everolimus have shown significant improvements in progression-free survival in patients with advanced and progressive pancreatic and lung NETs that are not poorly differentiated.

## The hypothalamus and the pituitary gland

Diseases of the hypothalamus and pituitary have an annual incidence of approximately 3:100 000 and a prevalence of 30–70 per 100 000. The pituitary plays a central role in several major endocrine axes, so that investigation and treatment invariably involve several other endocrine glands.

**Fig. 20.27** Ocreotide scintigraphy in a metastatic neuro-endocrine tumour. **A** Coronal CT scan showing hepatomegaly and a mass inferior to the liver (at the intersection of the horizontal and vertical red lines). **B** Ocreotide scintigram showing patches of increased uptake in the upper abdomen. **C** When the ocreotide and CT scans are superimposed, it shows that the areas of increased uptake are in hepatic metastases and in the tissue mass, which may be lymph nodes or a primary tumour.

**Fig. 20.28** Anatomical relationships of the normal pituitary gland and hypothalamus. See also Fig. 20.2. **A** Sagittal MRI. **B** Coronal MRI. (AP = anterior pituitary; CS = cavernous sinus; H = hypothalamus; IC = internal carotid artery; OC = optic chiasm; PP = posterior pituitary; PS = pituitary stalk; SS = sphenoid sinus; TV = third ventricle)

## Functional anatomy, physiology and investigations

The anatomical relationships of the pituitary are shown in Figure 20.28 and its numerous functions are shown in Figure 20.2. The pituitary gland is enclosed in the sella turcica and bridged over by a fold of dura mater called the diaphragma sellae, with the sphenoidal air sinuses below and the optic chiasm above. The cavernous sinuses are lateral to the pituitary fossa and contain the 3rd, 4th and 6th cranial nerves and the internal

## 20.50 Classification of diseases of the pituitary and hypothalamus

	Primary	Secondary
<b>Non-functioning tumours</b>	Pituitary adenoma Craniopharyngioma Metastatic tumours	
<b>Hormone excess</b>		
Anterior pituitary Hypothalamus and posterior pituitary	Prolactinoma Acromegaly Cushing's disease Rare TSH-, LH- and FSH-secreting adenomas Syndrome of inappropriate antidiuretic hormone (SIADH, p. 624)	Disconnection hyperprolactinaemia
<b>Hormone deficiency</b>		
Anterior pituitary Hypothalamus and posterior pituitary	Hypopituitarism Cranial diabetes insipidus	GnRH deficiency (Kallmann syndrome)
<b>Hormone resistance</b>		
	Growth hormone resistance (Laron dwarfism) Nephrogenic diabetes insipidus	
(FSH = follicle-stimulating hormone; GnRH = gonadotrophin-releasing hormone; LH = luteinising hormone; TSH = thyroid-stimulating hormone)		

carotid arteries. The gland is composed of two lobes, anterior and posterior, and is connected to the hypothalamus by the infundibular stalk, which has portal vessels carrying blood from the median eminence of the hypothalamus to the anterior lobe and nerve fibres to the posterior lobe.

Diseases of the hypothalamus and pituitary are classified in Box 20.50. By far the most common disorder is an adenoma of the anterior pituitary gland.

### Investigation of patients with pituitary disease

Although pituitary disease presents with diverse clinical manifestations (see below), the approach to investigation is similar in all cases (Box 20.51).

The approach to testing for hormone deficiency is outlined in Box 20.51. Details are given in the sections on individual glands elsewhere in this chapter. Tests for hormone excess vary according to the hormone in question. For example, prolactin is not secreted in pulsatile fashion, although it rises with significant psychological stress. Assuming that the patient was not distressed by venepuncture, a random measurement of

**20.51 How to investigate patients with suspected pituitary hypothalamic disease**

**Identify pituitary hormone deficiency**

**ACTH deficiency**

- Short ACTH stimulation test (see Box 20.42)
- Insulin tolerance test (see Box 20.55): only if there is uncertainty in interpretation of short ACTH stimulation test (e.g. acute presentation)

**LH/FSH deficiency**

- In the male, measure random serum testosterone, LH and FSH
- In the pre-menopausal female, ask if the menses are regular
- In the post-menopausal female, measure random serum LH and FSH (FSH normally >30 IU/L and LH >20 IU/L)

**TSH deficiency**

- Measure random serum T<sub>4</sub>
- Note that TSH is often detectable in secondary hypothyroidism

**Growth hormone deficiency**

Only investigate if growth hormone replacement therapy is being contemplated

- Measure immediately after exercise
- Consider other stimulatory tests (see Box 20.54)

**Cranial diabetes insipidus**

Only investigate if patient complains of polyuria/polydipsia, which may be masked by ACTH or TSH deficiency

- Exclude other causes of polyuria with blood glucose, potassium and calcium measurements
- Water deprivation test (see Box 20.60) or 5% saline infusion test

**Identify hormone excess**

- Measure random serum prolactin
- Investigate for acromegaly (glucose tolerance test) or Cushing's syndrome if there are clinical features

**Establish the anatomy and diagnosis**

- Consider visual field testing
- Image the pituitary and hypothalamus by MRI or CT

(ACTH = adrenocorticotrophic hormone; CT = computed tomography; FSH = follicle-stimulating hormone; LH = luteinising hormone; MRI = magnetic resonance imaging; TSH = thyroid-stimulating hormone)

serum prolactin is sufficient to diagnose hyperprolactinaemia. In contrast, growth hormone is secreted in a pulsatile fashion. A high random level does not confirm acromegaly; the diagnosis is confirmed only by failure of growth hormone to be suppressed during an oral glucose tolerance test, and a high serum insulin-like growth factor-1 (IGF-1). Similarly, in suspected ACTH-dependent Cushing's disease, random measurement of plasma cortisol is unreliable and the diagnosis is usually made by a dexamethasone suppression, and other tests.

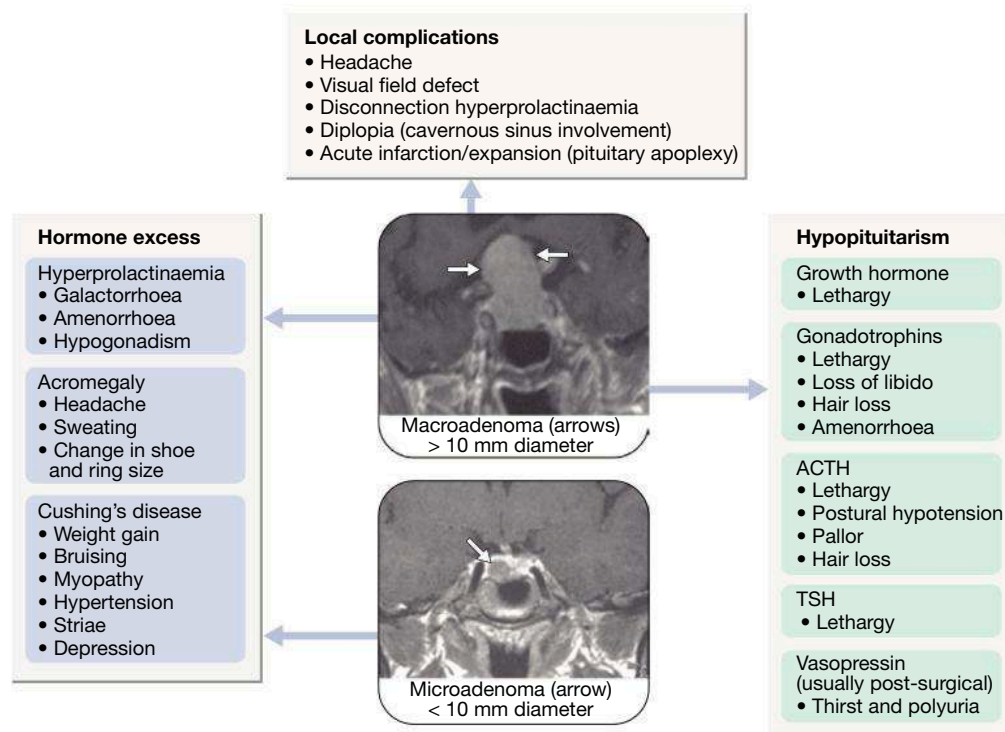

The most common local complication of a large pituitary tumour is compression of the optic pathway. The resulting visual field defect can be documented using a Goldmann perimetry chart or with an automated perimetry method (see p. 1222).

MRI reveals 'abnormalities' of the pituitary gland in as many as 10% of 'healthy' middle-aged people. It should therefore be performed only if there is a clear biochemical abnormality or if a patient presents with clinical features of pituitary tumour (see below). A pituitary tumour may be classified as either a macroadenoma (>10 mm diameter) or a microadenoma (<10 mm diameter).

Surgical biopsy is usually only performed as part of a therapeutic operation. Conventional histology identifies tumours as chromophobe (usually non-functioning), acidophil (typically prolactin- or growth hormone-secreting) or basophil (typically ACTH-secreting); immunohistochemistry may confirm their secretory capacity but is poorly predictive of growth potential of the tumour.

## Presenting problems in hypothalamic and pituitary disease

The clinical features of pituitary disease are shown in Figure 20.29. Younger women with pituitary disease most commonly present with secondary amenorrhoea or galactorrhoea (in hyperprolactinaemia). Post-menopausal women and men of any age are less likely to report symptoms of hypogonadism and so are more likely to present late with larger tumours causing visual field defects. The presentation and management of pituitary and hypothalamic disease may be affected by old age (Box 20.52). Nowadays, many patients present with the incidental finding of a pituitary tumour on a CT or MRI scan.

**Fig. 20.29** Common symptoms and signs to consider in a patient with suspected pituitary disease. (ACTH = adrenocorticotrophic hormone; TSH = thyroid-stimulating hormone)

**20.52 The pituitary and hypothalamus in old age**

- **Late presentation:** often with large tumours causing visual disturbance, because early symptoms such as amenorrhoea and sexual dysfunction do not occur or are not recognised.
- **Coincidentally discovered pituitary tumours:** may not require surgical intervention if the visual apparatus is not involved, because of slow growth.
- **Hyperprolactinaemia:** less impact in post-menopausal women who are already 'physiologically' hypogonadal. Macroprolactinomas, however, require treatment because of their potential to cause mass effects.

**20.53 Causes of anterior pituitary hormone deficiency****Structural**

- Primary pituitary tumour
- Adenoma\*
- Carcinoma (exceptionally rare)
- Craniopharyngioma\*
- Meningioma\*
- Secondary tumour (including leukaemia and lymphoma)
- Chordoma
- Germinoma (pinealoma)
- Arachnoid cyst
- Rathke's cleft cyst
- Haemorrhage (apoplexy)

**Inflammatory/infiltrative**

- Sarcoidosis
- Infections, e.g. pituitary abscess, tuberculosis, syphilis, encephalitis
- Lymphocytic hypophysitis
- Haemochromatosis
- Langerhans cell histiocytosis

**Congenital deficiencies**

- GnRH (Kallmann syndrome)\*
- GHRH\*
- TRH
- CRH

**Functional\***

- Chronic systemic illness
- Anorexia nervosa
- Excessive exercise

**Other**

- Head injury\*
- (Para)sellar surgery\*
- (Para)sellar radiotherapy\*
- Post-partum necrosis (Sheehan syndrome)
- Opiate analgesia

\*The most common causes of pituitary hormone deficiency.

(CRH = corticotrophin-releasing hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotrophin-releasing hormone; TRH = thyrotrophin-releasing hormone)

**Hypopituitarism**

Hypopituitarism describes combined deficiency of any of the anterior pituitary hormones. The clinical presentation is variable and depends on the underlying lesion and the pattern of resulting hormone deficiency. The most common cause is a pituitary macroadenoma but other causes are listed in [Box 20.53](#).

**Clinical assessment**

The presentation is highly variable. For example, following radiotherapy to the pituitary region, there is a characteristic sequence of loss of pituitary hormone secretion. Growth hormone secretion is often the earliest to be lost. In adults, this produces lethargy, muscle weakness and increased fat mass but these features are not obvious in isolation. Next, gonadotrophin (LH and FSH) secretion becomes impaired with loss of libido in the male and oligomenorrhoea or amenorrhoea in the female. Later, in the male there may be gynaecomastia and decreased frequency of shaving. In both sexes, axillary and pubic hair eventually become sparse or even absent and the skin becomes characteristically finer and wrinkled. Chronic anaemia may also occur. The next hormone to be lost is usually ACTH, resulting in symptoms of cortisol insufficiency (including postural hypotension and a *dilutional* hyponatraemia). In contrast to primary adrenal insufficiency, angiotensin II-dependent zona glomerulosa function is not lost and hence aldosterone secretion maintains normal

plasma potassium. In contrast to the pigmentation of Addison's disease due to high levels of circulating ACTH acting on the skin melanocytes, a striking degree of pallor is usually present. Finally, TSH secretion is lost with consequent secondary hypothyroidism. This contributes further to apathy and cold intolerance. In contrast to primary hypothyroidism, frank myxoedema is rare, presumably because the thyroid retains some autonomous function. The onset of all of the above symptoms is notoriously insidious. However, patients sometimes present acutely unwell with glucocorticoid deficiency. This may be precipitated by a mild infection or injury, or may occur secondary to pituitary apoplexy.

Other features of pituitary disease may be present ([Fig. 20.29](#)).

**Investigations**

The strategy for investigation of pituitary disease is described in [Box 20.51](#). In acutely unwell patients, the priority is to diagnose and treat cortisol deficiency. Other tests can be undertaken later. Specific dynamic tests for diagnosing hormone deficiency are described in [Box 20.42](#) and [Box 20.54](#). More specialised biochemical tests, such as insulin tolerance tests ([Box 20.55](#)), GnRH and TRH tests, are rarely required. All patients with biochemical evidence of pituitary hormone deficiency should have an MRI or CT scan to identify pituitary or hypothalamic tumours. If a tumour is not identified, then further investigations are indicated to exclude infectious or infiltrative causes.

**20.54 Tests of growth hormone secretion**

GH levels are commonly undetectable, so a choice from the range of 'stimulation' tests is required:

- Insulin-induced hypoglycaemia
- Arginine (may be combined with GHRH)
- Glucagon
- Clonidine (in children)

(GH = growth hormone; GHRH = growth hormone-releasing hormone)

**20.55 How and when to do an insulin tolerance test****Use**

- Assessment of the HPA axis
- Assessment of GH deficiency
- Indicated when there is doubt after the other tests in [Box 20.51](#)
- Usually performed in specialist centres, especially in children
- IV glucose and hydrocortisone must be available for resuscitation

**Contraindications**

- Ischaemic heart disease
- Epilepsy
- Severe hypopituitarism (0800 hrs plasma cortisol <180 nmol/L (6.6 µg/dL))

**Dose**

- 0.15 U/kg body weight soluble insulin IV

**Aim**

- To produce adequate hypoglycaemia (tachycardia and sweating with blood glucose <2.2 mmol/L (40 mg/dL))

**Blood samples**

- 0, 30, 45, 60, 90, 120 mins for blood glucose, plasma cortisol and growth hormone

**Results**

- Normal subjects: GH >6.7 µg/L (20 mIU/L)\*
- Normal subjects: cortisol >500 nmol/L (approximately 20.2 µg/dL)\*

\*The precise cut-off figure for a satisfactory cortisol and GH response depends on the assay used and so varies between centres.  
(GH = growth hormone; HPA = hypothalamic–pituitary–adrenal; IV = intravenous)

## Management

Treatment of acutely ill patients is similar to that described for adrenocortical insufficiency, except that sodium depletion is less likely to be present as there is still mineralocorticoid activity due to the renin–angiotensin–aldosterone system (which is lost in primary adrenal insufficiency). Chronic hormone replacement therapies are described below. Once the cause of hypopituitarism is established, specific treatment – of a pituitary macroadenoma, for example (see below) – may be required.

### Cortisol replacement

Hydrocortisone should be given if there is ACTH deficiency. Suitable doses are described in the section on adrenal disease on page 679. Mineralocorticoid replacement is not required.

### Thyroid hormone replacement

Levothyroxine 50–150 µg once daily should be given as described on page 657. Unlike in primary hypothyroidism, measuring TSH is not helpful in adjusting the replacement dose because patients with hypopituitarism often secrete glycoproteins that are measured in the TSH assays but are not bioactive. The aim is to maintain serum  $T_4$  in the upper part of the reference range. It is dangerous to give thyroid replacement in adrenal insufficiency without first giving glucocorticoid therapy, since this may precipitate adrenal crisis.

### Sex hormone replacement

This is indicated if there is gonadotrophin deficiency in women under the age of 50 and in men to restore normal sexual function and to prevent osteoporosis.

### Growth hormone replacement

Growth hormone (GH) is administered by daily subcutaneous self-injection to children and adolescents with GH deficiency and, until recently, was discontinued once the epiphyses had fused. However, although hypopituitary adults receiving ‘full’ replacement with hydrocortisone, levothyroxine and sex steroids are usually much improved by these therapies, some individuals remain lethargic and unwell compared with a healthy population. Some of these patients feel better, and have objective improvements in their fat:muscle mass ratio and other metabolic parameters, if they are also given GH replacement. Treatment with GH may also help young adults to achieve a higher peak bone mineral density. The principal side-effect is sodium retention, manifest as peripheral oedema or carpal tunnel syndrome if given in excess. For this reason, GH replacement should be started at a low dose, with monitoring of the response by measurement of serum IGF-1.

## Pituitary tumour

Pituitary tumours produce a variety of mass effects, depending on their size and location, but also present as incidental findings on CT or MRI, or with hypopituitarism, as described above. A wide variety of disorders can present as mass lesions in or around the pituitary gland (see Box 20.53). Most intrasellar tumours are pituitary macroadenomas (most commonly non-functioning adenomas; see Fig. 20.29), whereas suprasellar masses may be craniopharyngiomas (see Fig. 20.32). The most common cause of a parasellar mass is a meningioma.

### Clinical assessment

Clinical features are shown in Figure 20.29. A common but non-specific presentation is with headache, which may be the consequence of stretching of the diaphragma sellae. Although the classical abnormalities associated with compression of the optic chiasm are bitemporal hemianopia (see Fig. 20.30) or upper quadrantanopia, any type of visual field defect can result from suprasellar extension of a tumour because it may compress the optic nerve (unilateral loss of acuity or scotoma) or the optic tract (homonymous hemianopia). Optic atrophy may be apparent on ophthalmoscopy. Lateral extension of a sellar mass into the

**Fig. 20.30** Shrinkage of a macroprolactinoma following treatment with a dopamine agonist. **A** MRI scan showing a pituitary macroadenoma (T) compressing the optic chiasm (C). **B** MRI scan of the same tumour following treatment with a dopamine agonist. The macroadenoma, which was a prolactinoma, has decreased in size substantially and is no longer compressing the optic chiasm.

cavernous sinus with subsequent compression of the 3rd, 4th or 6th cranial nerve may cause diplopia and strabismus, but in anterior pituitary tumours this is an unusual presentation.

Occasionally, pituitary tumours infarct or there is bleeding into cystic lesions. This is termed ‘pituitary apoplexy’ and may result in sudden expansion with local compression symptoms and acute-onset hypopituitarism. Non-haemorrhagic infarction can also occur in a normal pituitary gland; predisposing factors include catastrophic obstetric haemorrhage (Sheehan syndrome), diabetes mellitus and raised intracranial pressure.

### Investigations

Patients suspected of having a pituitary tumour should undergo MRI. If MRI is not available CT may be used but is inferior for assessment of pituitary disease and will not show the majority of small pituitary tumours. For patients intolerant of MRI this investigation may be performed under general anaesthesia if needed, or imaging performed by CT. While some lesions have distinctive neuro-radiological features, the definitive diagnosis is made on histology after surgery. All patients with (para)sellar space-occupying lesions should have pituitary function assessed as described in Box 20.51.

### Management

Modalities of treatment of common pituitary and hypothalamic tumours are shown in Box 20.56. Associated hypopituitarism should be treated as described above.

Urgent treatment is required if there is evidence of pressure on visual pathways. The chances of recovery of a visual field defect are proportional to the duration of symptoms, with full recovery unlikely if the defect has been present for longer than 4 months. In the presence of a sellar mass lesion, it is crucial that serum prolactin is measured before emergency surgery is performed. If the prolactin is over 5000 mIU/L (236 ng/mL), then the lesion is likely to be a macroprolactinoma and should respond to a dopamine agonist with shrinkage of the lesion, making surgery unnecessary (see Fig. 20.30).

20.56 Therapeutic modalities for functioning and non-functioning hypothalamic and pituitary tumours				
	Surgery	Radiotherapy	Medical	Comment
<b>Non-functioning pituitary macroadenoma</b>	1st line	2nd line	–	
<b>Prolactinoma</b>	2nd line	2nd line	1st line Dopamine agonists	Dopamine agonists usually cause macroadenomas to shrink
<b>Acromegaly</b>	1st line	2nd line	2nd line Somatostatin analogues Dopamine agonists GH receptor antagonists	Medical therapy does not reliably cause macroadenomas to shrink Radiotherapy and medical therapy are used in combination for inoperable tumours
<b>Cushing's disease</b>	1st line	2nd line	2nd line Steroidogenesis inhibitors Pasireotide	Radiotherapy may take many years to reduce ACTH excess and medical therapies may be used as a bridge. Bilateral adrenalectomy may also be considered if the pituitary tumour is not completely resectable
<b>Craniopharyngioma</b>	1st line	2nd line	–	

(ACTH = adrenocorticotrophic hormone; GH = growth hormone)

Most operations on the pituitary are performed using the trans-sphenoidal approach via the nostrils, while transfrontal surgery via a craniotomy is occasionally needed for suprasellar tumours. It is uncommon to be able to resect lateral extensions into the cavernous sinuses, although with modern endoscopic techniques this is more feasible. All operations on the pituitary carry a risk of damaging normal endocrine function; this risk increases with the size of the primary lesion.

Pituitary function (see Box 20.51) should be retested 4–6 weeks following surgery, primarily to detect the development of any new hormone deficits. Rarely, the surgical treatment of a sellar lesion can result in recovery of hormone secretion that was deficient pre-operatively.

Following surgery, usually after 3–6 months, imaging should be repeated. If there is a significant residual mass and the histology confirms an anterior pituitary tumour, external radiotherapy may be given to reduce the risk of recurrence but the risk:benefit ratio needs careful individualised discussion. Radiotherapy is not useful in patients requiring urgent therapy because it takes many months or years to be effective and there is a risk of acute swelling of the mass. Fractionated radiotherapy carries a life-long risk of hypopituitarism (50%–100% in the first 10 years) and annual pituitary function tests are obligatory. There is also concern that radiotherapy might impair cognitive function, cause vascular changes and even induce primary brain tumours, but these side-effects have not been quantified reliably and are likely to be rare. Stereotactic radiosurgery allows specific targeting of residual disease in a more focused fashion.

Non-functioning tumours should be followed up by repeated imaging at intervals that depend on the size of the lesion and on whether or not radiotherapy has been administered. For smaller lesions that are not causing mass effects, therapeutic surgery may not be indicated and the lesion may simply be monitored by serial neuroimaging without a clear-cut diagnosis having been established.

## Hyperprolactinaemia/galactorrhoea

Hyperprolactinaemia is a common abnormality that usually presents with hypogonadism and/or galactorrhoea (lactation in the absence of breastfeeding). Since prolactin stimulates milk secretion but not breast development, galactorrhoea rarely occurs in men and only does so if gynaecomastia has been induced by hypogonadism. The differential diagnosis of hyperprolactinaemia is shown in Box 20.57. Many drugs, especially dopamine antagonists, elevate prolactin concentrations. Pituitary tumours can cause hyperprolactinaemia by directly secreting prolactin (prolactinomas, see below), or by compressing the infundibular stalk and thus interrupting the tonic inhibitory effect

of hypothalamic dopamine on prolactin secretion ('disconnection' hyperprolactinaemia).

Prolactin usually circulates as a free (monomeric) hormone in plasma but, in some individuals, prolactin becomes bound to an IgG antibody. This complex is known as macroprolactin and such patients have macroprolactinaemia (not to be confused with macroprolactinoma, a prolactin-secreting pituitary tumour of more than 1 cm in diameter). Since macroprolactin cannot cross blood-vessel walls to reach prolactin receptors in target tissues, it is of no pathological significance. Some

commercial prolactin assays do not distinguish prolactin from macroprolactin and so macroprolactinaemia is a cause of spurious hyperprolactinaemia. Identification of macroprolactin requires gel filtration chromatography or polyethylene glycol precipitation techniques, and one of these tests should be performed in all patients with hyperprolactinaemia if the prolactin assay is known to cross-react.

### Clinical assessment

In women, in addition to galactorrhoea, hypogonadism associated with hyperprolactinaemia causes secondary amenorrhoea and anovulation with infertility. Important points in the history include drug use, recent pregnancy and menstrual history. The quantity of milk produced is variable and it may be observed only by manual expression. In men there is decreased libido, reduced shaving frequency and lethargy. Unilateral galactorrhoea may be confused with nipple discharge, and breast examination to exclude malignancy or fibrocystic disease is important. Further assessment should address the features in [Figure 20.29](#).

### Investigations

Pregnancy should first be excluded before further investigations are performed in women of child-bearing potential. The upper limit of normal for many assays of serum prolactin is approximately 500 mIU/L (24 ng/mL). In non-pregnant and non-lactating patients, monomeric prolactin concentrations of 500–1000 mIU/L (24–47 ng/mL) are likely to be induced by stress or drugs, and a repeat measurement is indicated. Levels between 1000 and 5000 mIU/L (47–236 ng/mL) are likely to be due to drugs, a microprolactinoma or 'disconnection' hyperprolactinaemia. Levels above 5000 mIU/L (236 ng/mL) are highly suggestive of a macroprolactinoma.

Patients with prolactin excess should have tests of gonadal function (p. 667), and  $T_4$  and TSH should be measured to exclude primary

hypothyroidism causing TRH-induced prolactin excess. Unless the prolactin falls after withdrawal of relevant drug therapy, a serum prolactin consistently above the reference range is an indication for MRI or CT scan of the hypothalamus and pituitary. Patients with a macroadenoma also need tests for hypopituitarism (see [Box 20.51](#)).

### Management

If possible, the underlying cause should be corrected (e.g. cessation of offending drugs and giving levothyroxine replacement in primary hypothyroidism). If dopamine antagonists are the cause, then dopamine agonist therapy is contraindicated; if gonadal dysfunction is the primary concern, sex steroid replacement therapy may be indicated. Troublesome physiological galactorrhoea can also be treated with dopamine agonists (see [Box 20.58](#)). Management of prolactinomas is described below.

## Prolactinoma

Most prolactinomas in pre-menopausal women are microadenomas because the symptoms of prolactin excess usually result in early presentation. Prolactin-secreting cells of the anterior pituitary share a common lineage with GH-secreting cells, so occasionally prolactinomas can secrete excess GH and cause acromegaly. In prolactinomas there is a relationship between prolactin concentration and tumour size: the higher the level, the bigger the tumour. Some macroprolactinomas can elevate prolactin concentrations above 100 000 mIU/L (4700 ng/mL). The investigation of prolactinomas is the same as for other pituitary tumours (see above).

### Management

As shown in [Box 20.56](#), several therapeutic modalities can be employed in the management of prolactinomas.

### Medical

Dopamine agonist drugs are first-line therapy for the majority of patients ([Box 20.58](#)). They usually reduce serum prolactin concentrations and cause significant tumour shrinkage after several months of therapy ([Fig. 20.30](#)), but visual field defects, if present, may improve within days of first administration. It is possible to withdraw dopamine agonist therapy without recurrence of hyperprolactinaemia after a few years of treatment in some patients with a microadenoma. Also, after the menopause, suppression of prolactin is required in microadenomas only if galactorrhoea is troublesome, since hypogonadism is then physiological and tumour growth unlikely. In patients with macroadenomas, drugs can be withdrawn only after curative surgery or radiotherapy and under close supervision.

Ergot-derived dopamine agonists (bromocriptine and cabergoline) can bind to 5-HT<sub>2B</sub> receptors in the heart and elsewhere and have been associated with fibrotic reactions, particularly tricuspid valve regurgitation, when used in high doses in patients with Parkinson's disease. At the relatively low doses used in prolactinomas most data suggest that systematic screening for cardiac fibrosis is unnecessary, but if dopamine agonist therapy is prolonged, periodic screening by echocardiography or use of non-ergot agents (quinagolide) may be indicated. Dopamine agonists can affect mood and behaviour, including depression, psychosis and risk-taking behaviour (e.g. gambling), and patients should be warned about these potential side-effects.

### Surgery and radiotherapy

Surgical decompression is usually necessary only when a macroprolactinoma has failed to shrink sufficiently with dopamine agonist therapy, and this may be because the tumour has a significant cystic component. Surgery may also be performed in patients who are intolerant of dopamine agonists. Microadenomas can be removed selectively by trans-sphenoidal surgery with a cure rate of about 80%, but recurrence is possible; the cure rate for surgery in macroadenomas is substantially lower.

External irradiation may be required for some macroadenomas to prevent regrowth if dopamine agonists are stopped.

### 20.58 Dopamine agonist therapy: drugs used to treat prolactinomas

Drug	Oral dose*	Advantages	Disadvantages
<b>Bromocriptine</b>	2.5–15 mg/day 2–3 times daily	Available for parenteral use Short half-life; useful in treating infertility Proven long-term efficacy	Ergotamine-like side-effects (nausea, headache, postural hypotension, constipation) Frequent dosing so poor adherence Rare reports of fibrotic reactions in various tissues
<b>Cabergoline</b>	250–1000 µg/week 2 doses/week	Long-acting, so missed doses less important Reported to have fewer ergotamine-like side-effects	Limited data on safety in pregnancy Associated with cardiac valvular fibrosis in Parkinson's disease
<b>Quinagolide</b>	50–150 µg/day Once daily	A non-ergot with few side-effects in patients intolerant of the above	Limited data on safety in pregnancy

\*Tolerance develops for the side-effects. All of these agents, especially bromocriptine, must be introduced at low dose and increased slowly. If several doses of bromocriptine are missed, the process must start again.

**Fig. 20.31** Clinical features of acromegaly. (IGT = impaired glucose tolerance)

### Pregnancy

Hyperprolactinaemia often presents with infertility, so dopamine agonist therapy may be followed by pregnancy. Patients with microadenomas should be advised to withdraw dopamine agonist therapy as soon as pregnancy is confirmed. In contrast, macroprolactinomas may enlarge rapidly under oestrogen stimulation and these patients should continue dopamine agonist therapy and need measurement of prolactin levels and visual fields during pregnancy. All patients should be advised to report headache or visual disturbance promptly.

## Acromegaly

Acromegaly is caused by growth hormone (GH) secretion from a pituitary tumour, usually a macroadenoma, and carries an approximate twofold excess mortality when untreated.

### Clinical features

If GH hypersecretion occurs before puberty, then the presentation is with gigantism. More commonly, GH excess occurs in adult life and presents with acromegaly. If hypersecretion starts in adolescence and persists into adult life, then the two conditions may be combined. The clinical features are shown in [Figure 20.31](#). The most common complaints are headache and sweating. Additional features include those of any pituitary tumour (see [Fig. 20.29](#)).

### Investigations

The clinical diagnosis must be confirmed by measuring GH levels during an oral glucose tolerance test and measuring serum IGF-1.

In normal subjects, plasma GH suppresses to below  $0.5 \mu\text{g/L}$  (approximately  $2 \text{ mIU/L}$ ). In acromegaly, GH does not suppress and in about 30% of patients there is a paradoxical rise; IGF-1 is also elevated. The rest of pituitary function should be investigated as described in [Box 20.51](#). Prolactin concentrations are elevated in about 30% of patients due to co-secretion of prolactin from the tumour. Additional tests in acromegaly may include screening for colonic neoplasms with colonoscopy.

### Management

The main aims are to improve symptoms and to normalise serum GH and IGF-1 to reduce morbidity and mortality. Treatment is summarised in [Box 20.56](#).

#### Surgical

Trans-sphenoidal surgery is usually the first line of treatment and may result in cure of GH excess, especially in patients with microadenomas. More often, surgery serves to debulk the tumour and further second-line therapy is required, according to post-operative imaging and glucose tolerance test results.

#### Medical

If acromegaly persists after surgery, medical therapy is usually employed to lower GH levels to below  $1.0 \mu\text{g/L}$  (approximately  $3 \text{ mIU/L}$ ) and to normalise IGF-1 concentrations. Medical therapy may be discontinued after several years in patients who have received radiotherapy once the latter has been effective. Somatostatin analogues (such as octreotide, lanreotide or pasireotide) can be administered as slow-release injections every few weeks. Somatostatin

**Fig. 20.32 Craniopharyngioma.** **A** This developmental tumour characteristically presents in younger patients; it is often cystic and calcified, as shown in this MRI scan (arrows). **B** Pathology specimen.

analogues can also be used as primary therapy for acromegaly either as an alternative or in advance of surgery, given evidence that they can induce modest tumour shrinkage in some patients. Dopamine agonists are less effective at lowering GH but may sometimes be helpful, especially with associated prolactin excess. Pegvisomant is a peptide GH receptor antagonist administered by daily self-injection and may be indicated in some patients whose GH and IGF-1 concentrations fail to suppress sufficiently following somatostatin analogue therapy.

#### Radiotherapy

External radiotherapy is increasingly employed as third-line treatment if acromegaly persists after surgery, to stop tumour growth and lower GH levels. However, GH levels fall slowly (over many years) and there is a risk of hypopituitarism.

### Craniopharyngioma

Craniopharyngiomas are benign tumours that develop in cell rests of Rathke's pouch, and may be located within the sella turcica, or commonly in the suprasellar space. They are often cystic, with a solid component that may or may not be calcified (Fig. 20.32). In young people, they are diagnosed more commonly than pituitary adenomas. They may present with pressure effects on adjacent structures, hypopituitarism

### 20.59 Causes of diabetes insipidus

#### Cranial

##### Structural hypothalamic or high stalk lesion

- See Box 20.53

#### Idiopathic

##### Genetic defect

- Dominant (AVP gene mutation)
- Recessive (DIDMOAD syndrome – association of diabetes insipidus with diabetes mellitus, optic atrophy, deafness)

#### Nephrogenic

##### Genetic defect

- V2 receptor mutation
- Aquaporin-2 mutation
- Cystinosis

##### Metabolic abnormality

- Hypokalaemia
- Hypercalcaemia

##### Drug therapy

- Lithium
- Demeclocycline

##### Poisoning

- Heavy metals

##### Chronic kidney disease

- Polycystic kidney disease
- Sickle-cell anaemia
- Infiltrative disease

and/or cranial diabetes insipidus. Other clinical features directly related to hypothalamic damage may also occur. These include hyperphagia and obesity, loss of the sensation of thirst and disturbance of temperature regulation, and these features can be significant clinical challenges to manage.

Craniopharyngiomas can be treated by the trans-sphenoidal route but surgery may also involve a craniotomy, with a relatively high risk of hypothalamic damage and other complications. If the tumour has a large cystic component, it may be safer to place in the cyst cavity a drain that is attached to a subcutaneous access device, rather than attempt a resection. Whatever form it takes, surgery is unlikely to be curative and radiotherapy may often be given to reduce the risk of relapse. Unfortunately, craniopharyngiomas often recur, requiring repeated surgery. They often cause considerable morbidity, usually from hypothalamic obesity, water balance problems and/or visual failure.

### Diabetes insipidus

This uncommon disorder is characterised by the persistent excretion of excessive quantities of dilute urine and by thirst. It is classified into two types:

- cranial diabetes insipidus, in which there is deficient production of vasopressin by the hypothalamus
- nephrogenic diabetes insipidus, in which the renal tubules are unresponsive to vasopressin.

The underlying causes are listed in Box 20.59.

#### Clinical features

The most marked symptoms are polyuria (>3L per 24 hours) and polydipsia. The patient may pass 5–20L or more of urine in 24 hours. This

20.60 How and when to do a water deprivation test
<p><b>Use</b></p> <ul style="list-style-type: none"> <li>To establish a diagnosis of diabetes insipidus and to differentiate cranial from nephrogenic causes</li> </ul>
<p><b>Protocol</b></p> <ul style="list-style-type: none"> <li>No coffee, tea or smoking on the test day</li> <li>Free fluids until 0730 hrs on the morning of the test, but discourage patients from 'stocking up' with extra fluid in anticipation of fluid deprivation</li> <li>No fluids from 0730 hrs</li> <li>Attend at 0830 hrs for measurement of body weight and plasma and urine osmolality</li> <li>Record body weight, urine volume, urine and plasma osmolality and thirst score on a visual analogue scale every 2 hrs for up to 8 hrs</li> <li>Stop the test if the patient loses 3% of body weight</li> <li>If plasma osmolality reaches &gt;300 mOsmol/kg and urine osmolality &lt;600 mOsmol/kg, then administer DDAVP (see text) 2 µg IM</li> </ul>
<p><b>Interpretation</b></p> <ul style="list-style-type: none"> <li>Diabetes insipidus is confirmed by a plasma osmolality &gt;300 mOsmol/kg with a urine osmolality &lt;600 mOsmol/kg</li> <li>Cranial diabetes insipidus is confirmed if urine osmolality rises by at least 50% after DDAVP</li> <li>Nephrogenic diabetes insipidus is confirmed if DDAVP does not concentrate the urine</li> <li>Primary polydipsia is suggested by low plasma osmolality at the start of the test</li> </ul>

is of low specific gravity and osmolality. If the patient has an intact thirst mechanism, is conscious and has access to oral fluids, then he or she can maintain adequate fluid intake. However, in an unconscious patient or a patient with damage to the hypothalamic thirst centre, diabetes insipidus is potentially lethal. If there is associated cortisol deficiency, then diabetes insipidus may not be manifest until glucocorticoid replacement therapy is given. The most common differential diagnosis is primary polydipsia, caused by drinking excessive amounts of fluid in the absence of a defect in vasopressin or thirst control.

### Investigations

Diabetes insipidus can be confirmed if serum vasopressin is undetectable (although the assay for this is not widely available) or the urine is not maximally concentrated (i.e. <600 mOsmol/kg) in the presence of increased plasma osmolality (i.e. >300 mOsmol/kg). Sometimes, the diagnosis can be confirmed or refuted by random simultaneous samples of blood and urine, but more often a dynamic test is required. The water deprivation test described in [Box 20.60](#) is widely used, but an alternative is to infuse hypertonic (5%) saline and measure vasopressin or better still co-peptin secretion in response to increasing plasma osmolality. Thirst can also be assessed during these tests on a visual analogue scale. Anterior pituitary function and suprasellar anatomy should be assessed in patients with cranial diabetes insipidus (see [Box 20.51](#)).

In primary polydipsia, the urine may be excessively dilute because of chronic diuresis, which 'washes out' the solute gradient across the loop of Henle, but plasma osmolality is low rather than high. DDAVP (see below) should not be administered to patients with primary polydipsia, since it will prevent excretion of water and there is a risk of severe water intoxication if the patient continues to drink fluid to excess.

In nephrogenic diabetes insipidus, appropriate further tests may include plasma electrolytes, calcium, ultrasound of the kidneys and urinalysis.

### Management

Treatment of cranial diabetes insipidus is with des-amino-des-aspartate-arginine vasopressin (desmopressin, DDAVP), an analogue of vasopressin that has a longer half-life. For chronic replacement therapy

20.61 Multiple endocrine neoplasia (MEN) syndromes
<p><b>MEN 1 (Wermer syndrome)</b></p> <ul style="list-style-type: none"> <li>Primary hyperparathyroidism</li> <li>Pituitary tumours</li> <li>Pancreatic neuro-endocrine tumours (e.g. non-functioning, insulinoma, gastrinoma)</li> <li>Bronchial and thymic carcinoids</li> <li>Adrenal tumours</li> <li>Cutaneous lesions (e.g. lipomas, collagenomas, angiofibromas)</li> </ul>
<p><b>MEN 2a (Sipple syndrome, and formerly known as MEN 2)</b></p> <ul style="list-style-type: none"> <li>Primary hyperparathyroidism</li> <li>Medullary carcinoma of thyroid</li> <li>Phaeochromocytoma</li> </ul>
<p><b>MEN 2b (formerly MEN 3)</b></p> <ul style="list-style-type: none"> <li>As for MEN 2a above (though medullary thyroid cancer occurs earlier, even within the first year of life)</li> <li>Marfanoid habitus</li> <li>Skeletal abnormalities (e.g. craniosynostosis)</li> <li>Abnormal dental enamel</li> <li>Multiple mucosal neuromas</li> </ul>
<p><b>MEN 4</b></p> <ul style="list-style-type: none"> <li>Primary hyperparathyroidism</li> <li>Pituitary tumours</li> <li>Possible tumours in the adrenals, reproductive organs, kidneys</li> <li>Possible pancreatic, gastric, bronchial and cervical neuro-endocrine tumours</li> </ul>

DDAVP may be administered intranasally and orally, although the latter formulation has variable bioavailability. In sick patients, DDAVP should be given by intramuscular injection. The dose of DDAVP should be adjusted on the basis of serum sodium concentrations and/or osmolality. The principal hazard is excessive treatment, resulting in water intoxication and hyponatraemia. Conversely, inadequate treatment results in thirst and polyuria. The ideal dose prevents nocturia but allows a degree of polyuria from time to time before the next dose (e.g. DDAVP nasal dose 5 µg in the morning and 10 µg at night).

The polyuria in nephrogenic diabetes insipidus is improved by thiazide diuretics (e.g. bendroflumethiazide 5–10 mg/day), amiloride (5–10 mg/day) and NSAIDs (e.g. indometacin 50 mg 3 times daily), although the last of these carries a risk of reducing glomerular filtration rate.

## Disorders affecting multiple endocrine glands

### Multiple endocrine neoplasia

Multiple endocrine neoplasias (MEN) are rare autosomal dominant syndromes characterised by hyperplasia and formation of adenomas or malignant tumours in multiple glands. They fall into four groups, as shown in [Box 20.61](#). Some other genetic diseases also have an increased risk of endocrine tumours; for example, phaeochromocytoma is associated with von Hippel–Lindau syndrome and neurofibromatosis type 1.

The MEN syndromes should be considered in all patients with two or more endocrine tumours and in patients with solitary tumours who report other endocrine tumours in their family. Inactivating mutations in *MEN1* (*MENIN*), a tumour suppressor gene on chromosome 11, cause MEN 1, whereas MEN 2a and 2b are caused by gain-of-function mutations in the *RET* proto-oncogene on chromosome 10. These cause constitutive activation of the membrane-associated tyrosine kinase RET, which controls the development of cells that migrate from the neural crest. In contrast, loss-of-function mutations of the RET kinase cause Hirschsprung's disease. MEN 4 is extremely rare and is associated with loss-of-function mutations in the *CDNK1B* gene on chromosome 12;

## 20.62 Autoimmune polyendocrine syndromes (APS)\*

### Type 1 (APECED)

- Addison's disease
- Hypoparathyroidism
- Type 1 diabetes
- Primary hypothyroidism
- Chronic mucocutaneous candidiasis
- Nail dystrophy
- Dental enamel hypoplasia

### Type 2 (Schmidt syndrome)

- Addison's disease
- Primary hypothyroidism
- Graves' disease
- Pernicious anaemia
- Primary hypogonadism
- Type 1 diabetes
- Vitiligo
- Coeliac disease
- Myasthenia gravis

\*In both types of APS, the precise pattern of disease varies between affected individuals. (APECED = autoimmune poly-endocrinopathy-candidiasis-ectodermal dystrophy)

this gene codes for the protein p27, which has putative tumour suppressor activity. Predictive genetic testing can be performed on relatives of individuals with MEN syndromes, after appropriate counselling.

Individuals who carry mutations associated with MEN should be entered into a surveillance programme. In MEN 1, this typically involves annual history, examination and measurements of serum calcium and prolactin, and MRI of the pituitary and pancreas every 2 years; some centres also perform regular CT or MRI scans of the chest. In individuals with MEN 2a and 2b, annual history, examination and measurement of serum calcium, calcitonin and urinary or plasma catecholamine metabolites should be performed. Because the penetrance of medullary carcinoma of the thyroid approaches 100% in individuals with a *RET* mutation, prophylactic thyroidectomy should be performed in early childhood in most patients. The precise timing of surgery in childhood should be guided by the specific mutation in the *RET* gene.

## Autoimmune polyendocrine syndromes

Two distinct autoimmune polyendocrine syndromes are known: APS types 1 and 2.

The most common is APS type 2 (Schmidt syndrome), which typically presents in women between the ages of 20 and 60. It is usually defined as the occurrence in the same individual of two or more autoimmune endocrine disorders, some of which are listed in Box 20.62. The mode of inheritance is autosomal dominant with incomplete penetrance and there is a strong association with HLA-DR3 and CTLA-4.

Much less common is APS type 1, which is also termed autoimmune poly-endocrinopathy-candidiasis-ectodermal dystrophy (APECED). This is inherited in an autosomal recessive fashion and is caused by loss-of-function mutations in the autoimmune regulator gene *AIRE*, which is

responsible for the presentation of self-antigens to thymocytes in utero. This is essential for the deletion of thymocyte clones that react against self-antigens and hence for the development of immune tolerance. The most common clinical features are described in Box 20.62, although the pattern of presentation is variable and other autoimmune disorders are often observed.

## Endocrine effects of cancer immunotherapy

Modern cancer treatment increasingly uses immunotherapy, including immune check-point inhibitors. Whilst highly effective anti-cancer agents, these may cause endocrine dysfunction, most commonly hypopituitarism and hypothyroidism. It is crucial that these axes are monitored during therapy and that there is a high index of suspicion for potential secondary hypoadrenalism in patients presenting with fatigue and tiredness, especially in those on the anti-CTLA-4 antibody ipilimumab, and a low threshold for glucocorticoid replacement.

## Late effects of childhood cancer therapy

The therapies used to treat cancers in children and adolescents, including radiotherapy and chemotherapy, may cause long-term endocrine dysfunction. These complications are discussed in detail in Chapter 33.

## Opioid-induced endocrine dysfunction

Opioids may cause secondary hypoadrenalism and hypogonadism. With the increasingly widespread use of these analgesics more patients will present with vague features of lethargy that may represent secondary adrenal insufficiency, which needs to be investigated and treated as described on p. 685.

## Multiple Choice Questions

- 20.1. A 28-year-old man presents to his general practitioner with recent onset of weight loss, heat intolerance and palpitations. On examination a small goitre with a 2 cm discrete nodule is noted. TFTs show TSH  $<0.01$  mIU/L (RR 0.2–4.5 mIU/L), and free  $T_4$  25 pmol/L (RR 9–21 pmol/L). TSH receptor antibody (TRAb) is 1.1 IU/L (RR 0–1.6 IU/L). Prior to attendance at the endocrine clinic, a thyroid ultrasound is performed which confirms a benign-looking 2 cm nodule in the context of a multinodular goitre. What would be the most appropriate next step?
- Fine needle aspiration (FNA) of the nodule
  - Hemi-thyroidectomy
  - Carbimazole
  - Scintigraphy
  - Radioiodine (400 MBq)

Answer: D.

The patient has thyrotoxicosis with an equivocal TRAb, no discriminatory clinical features of Graves' disease and evidence of nodular thyroid disease. In this context, it is useful to perform scintigraphy to determine whether this is a 'hot' nodule (i.e. autonomously producing thyroid hormone). This has important implications as 'hot' nodules are almost never malignant and treatment with radioiodine has a high likelihood of restoring euthyroidism (as opposed to Graves' disease where the likeliest outcome is permanent hypothyroidism).

- 20.2. A 42-year-old male presented to his family doctor with a 6-month history of weight gain, fatigue and muscle weakness. The doctor noticed that he had centripetal obesity and abdominal striae and referred him to your endocrine clinic. The patient has no history of recent or current use of oral or inhaled steroids. You carry out some tests and find the following results:
- Low-dose dexamethasone suppression test (LDDST): serum cortisol measured after 48 hours is 125 nmol/L (a normal response is a serum cortisol of  $<50$  nmol/L [1.8  $\mu\text{g/dL}$ ])
- Late night (2300 hours) salivary cortisol: 18.4 nmol/L on the first occasion and 16.8 nmol/L on repeat testing (local RR  $<3.6$  nmol/L)
- Plasma adrenocorticotrophic hormone (ACTH) at 0900 hours: undetectable (RR 1.5–13.9 pmol/L)
- What would be the next most appropriate next investigation to request in this patient?

- Computerised tomography (CT) of the adrenal glands
- Corticotrophin-releasing hormone (CRH) stimulation test
- High-dose dexamethasone suppression test (HDDST)
- Magnetic resonance imaging (MRI) scan of the pituitary gland
- Measurement of 24-hour urine free cortisol production

Answer: A.

The clinical features suggest Cushing's syndrome, which is confirmed by the failure of cortisol suppression in the LDDST and the (repeated) high late-night cortisol level. The absence of detectable ACTH indicates an adrenal cause, with pituitary ACTH secretion being suppressed by high levels of cortisol. The most likely causes at this stage are a cortisol-secreting adrenal tumour (adenoma or more rarely carcinoma), so the most appropriate test is a CT scan of the adrenal glands.

There is no indication to carry out either a CRH stimulation test or an HDDST, as these tests are used to help to distinguish between pituitary-dependent Cushing's syndrome and Cushing's syndrome caused by ectopic ACTH secretion. Similarly, there is no indication for an MRI of the pituitary gland as the undetectable ACTH indicates an adrenal cause. 24-hour urine free cortisol production would be expected to be decreased, but this test is not necessary, as the diagnosis of Cushing's syndrome has already been confirmed.

- 20.3. A 45-year-old man is incidentally found to have an elevated plasma calcium (2.7 mmol/l) on two separate occasions. Which of the following would make a diagnosis of familial hypocalcaemic hypercalcaemia (FHH) more likely?
- Normal plasma calcium recorded 5 years previously
  - PTH concentration within the reference range
  - Previous history of nephrolithiasis
  - Family history of hypercalcaemia in a first-degree relative
  - Previous history of osteoporosis

Answer: D.

FHH is an autosomal dominant condition caused by mutations in the calcium-sensing receptor (*CASR*) gene. It is typically associated with relatively modest hypercalcaemia and an absence of the end-organ damage associated with primary hyperparathyroidism. Previously normal calcium levels would be more consistent with the onset of primary hyperparathyroidism. PTH concentration in the upper half of the reference range is commonly encountered in primary hyperparathyroidism and does not help discriminate between this condition and FHH.

▲ Necrobiosis lipoidica

### 11 Feet (see opposite)

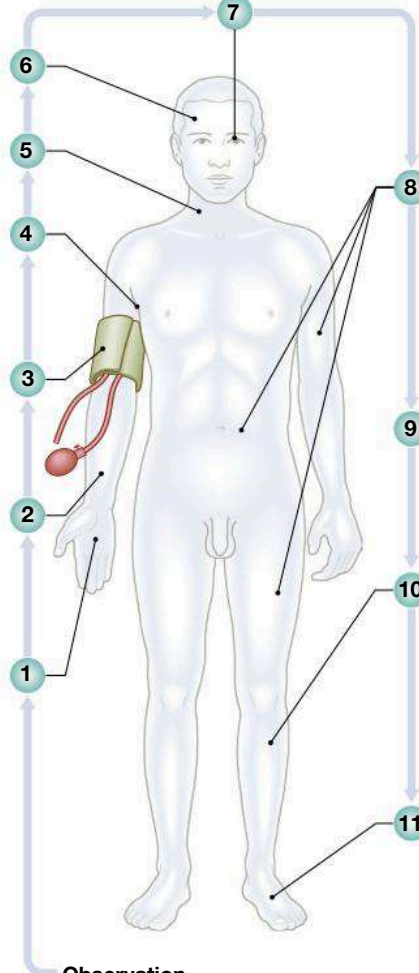

Inspection  
Peripheral pulses  
Sensation

▲ Neuropathic foot ulcer

▲ Charcot neuroarthropathy

#### Observation

- Weight loss in insulin deficiency
- Obesity in type 2 diabetes
- Mucosal candidiasis
- Dehydration – dry mouth,  
↓ tissue turgor
- Air hunger – Kussmaul breathing  
in ketoacidosis

Insets (Acanthosis nigricans) From Lim E (ed.). *Medicine and surgery: an integrated textbook*. Edinburgh: Elsevier Ltd; 2007. (Exudative maculopathy) Courtesy of Dr A.W. Patrick and Dr I.W. Campbell.

Diabetes affects every system in the body. Clinical assessment is dominated by history and investigation rather than clinical examination. In routine clinical practice, the most important aspects of clinical examination relate to complication screening:

- Blood pressure measurement
- Foot examination (for pulses and sensation) to determine risk of (or presence of) ulceration (p. 752)
- Insulin injection sites (if applicable): inspect to check they are not over-used as this leads to impaired or unpredictable insulin absorption (lipohypertrophy, see Box 8)
- Retinal screening (see Box 7): check this has been performed according to local guidelines

## 7 Examination of the eyes

### Visual acuity<sup>1</sup>

- Check distance vision using Snellen chart at 6 m
- Check near vision using standard reading chart

### Lens opacification

- Look for a normal red reflex using the ophthalmoscope held 30 cm from the eye

### Fundal examination

- Use digital retinal photography (where available)<sup>2</sup>
- Where not available (or in an emergency), dilate pupils with mydriatic drops (unless contraindicated) and examine using direct ophthalmoscopy in a darkened room
- Note features of diabetic retinopathy (p. 1230), including photocoagulation scars from previous laser treatment

<sup>1</sup>Note that visual acuity can alter reversibly with acute hyperglycaemia due to osmotic changes affecting the lens. Most patients with retinopathy do not have altered visual acuity, except after a vitreous haemorrhage or in some cases of maculopathy. <sup>2</sup>The number of fields captured, the use of mydriatic drops (e.g. tropicamide) and how images are read depends on the setting and technology available.

Proliferative retinopathy. Courtesy of Dr A.W. Patrick and Dr I.W. Campbell.

Other clinically useful information:

- Technology: clinical inspection of the arm and abdomen may reveal the use of a continuous glucose monitoring (CGM) device and/or insulin pump delivering a continuous subcutaneous insulin infusion (CSII)

Other relevant clinical signs:

- Hands: there may be thickening of the skin and tendons (due to non-enzymatic glycation of collagen from long-term hyperglycaemia, see Box 1)
- Skin (uncommon):
  - Acanthosis nigricans (axilla and neck): associated with forms of diabetes involving severe insulin resistance (see Box 4)
  - Necrobiosis lipoidica diabetorum: rash with scarred central yellow area (red margin when active) over the shins (see Box 10)

## 1 Examination of the hands\*

Several abnormalities are more common in diabetes than in the general population:

- Limited joint mobility ('cheiroarthropathy') causes painless stiffness. The inability to extend (to 180°) the metacarpophalangeal or interphalangeal joints of at least one finger bilaterally can be demonstrated in the 'prayer sign' (see Box 1)
- Dupuytren's contracture (p. 1061) causes nodules or thickening of the skin and knuckle pads
- Carpal tunnel syndrome (p. 1193) presents with wrist pain radiating into the hand
- Trigger finger (flexor tenosynovitis) may be present
- Muscle-wasting/sensory changes may be present in peripheral sensorimotor neuropathy (more common in the lower limbs)

\*Usually only examined if symptoms reported

## 8 Insulin injection sites\*

### Main areas used

- Anterior abdominal wall
- Upper thighs
- Upper outer arms

### Inspection

- Bruising
- Subcutaneous fat deposition (lipohypertrophy)
- Erythema, infection (rare)

\*if applicable should be checked at all consultations

Lipohypertrophy of the upper arm.

## 11 Annual examination of the feet

Focus on detecting abnormal sensation and circulation to determine appropriate level of care required and prevent future ulceration/amputation.

### Inspection

- Ulcers or skin breaks (require urgent referral for podiatry assessment and treatment)
- Localised bacterial or fungal infection (may require antibiotic/antifungal treatment)
- Discoloration (dusky colour) of the skin indicating critical ischaemia (if confirmed requires urgent vascular assessment)
- Callus (hard skin) formation on weight-bearing areas, ingrowing toenails (these require routine referral for podiatry to prevent ulceration)
- Fungal infection may affect skin between toes, and nails (topical or systemic antifungal treatment may be appropriate)
- Clawing of the toes/loss of the plantar arch (may reflect neuropathy)
- Severe deformity may reflect Charcot neuroarthropathy (see p. 752)

### Circulation

- Peripheral pulses – dorsalis pedis and posterior tibial (**document at least annually**). If neither is palpable, the foot is at 'moderate' risk of ulceration, even if sensation is normal
- Assess capillary refill in nail-beds if pulses absent
- Skin temperature is raised in Charcot neuroarthropathy

### Sensation

- 'Stocking' distribution in typical peripheral sensorimotor neuropathy
- Test light touch with a 10 gram monofilament on the dorsal surfaces of the toes and metatarsals. If absent in one or more of five places, the risk of foot ulceration is increased 5–10-fold ('moderate'), even if pulses are present (**document at least annually**)
- Testing of other sensation modalities (vibration, pain, proprioception) is not routine unless neuropathy is being fully evaluated

### Reflexes (not routinely performed)

- Ankle reflexes are lost in severe sensorimotor neuropathy

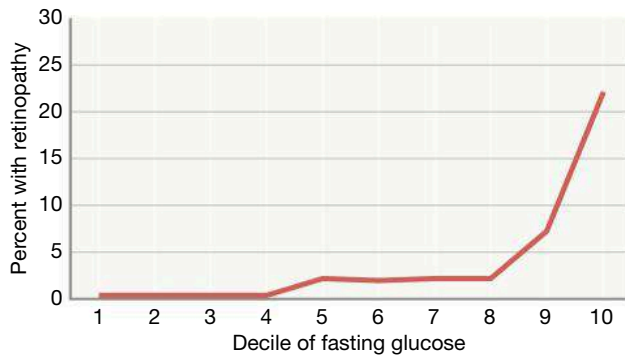

People with diabetes who have: (i) normal pulses and sensation, (ii) good footcare (nail cutting, lack of callus) and (iii) well-fitting footwear can be reassured and reviewed annually without regular podiatry.

**Monofilament.** This is applied gently until it bends at each of five points on both feet. Areas of callus should be avoided as sensation is reduced.

Diabetes mellitus is a clinical syndrome with many causes (see [Box 21.6](#)), which is characterised by the presence of hyperglycaemia (*mellitus* being Latin for 'sweet'). Type 2 diabetes accounts for around 90% of cases, while type 1 diabetes accounts for most of the remainder. In the United States, more than 20% of adults over the age of 65 years have type 2 diabetes, while in the UK people with diabetes occupy almost 20% of acute hospital beds.

All forms of diabetes are ultimately a consequence of *absolute* or *relative* insulin deficiency. Although type 1 and type 2 diabetes share the clinical phenotype of hyperglycaemia and carry risks of similar complications, their aetiology and pathophysiology are very different. In type 1 diabetes, there is an *absolute* deficiency of insulin because

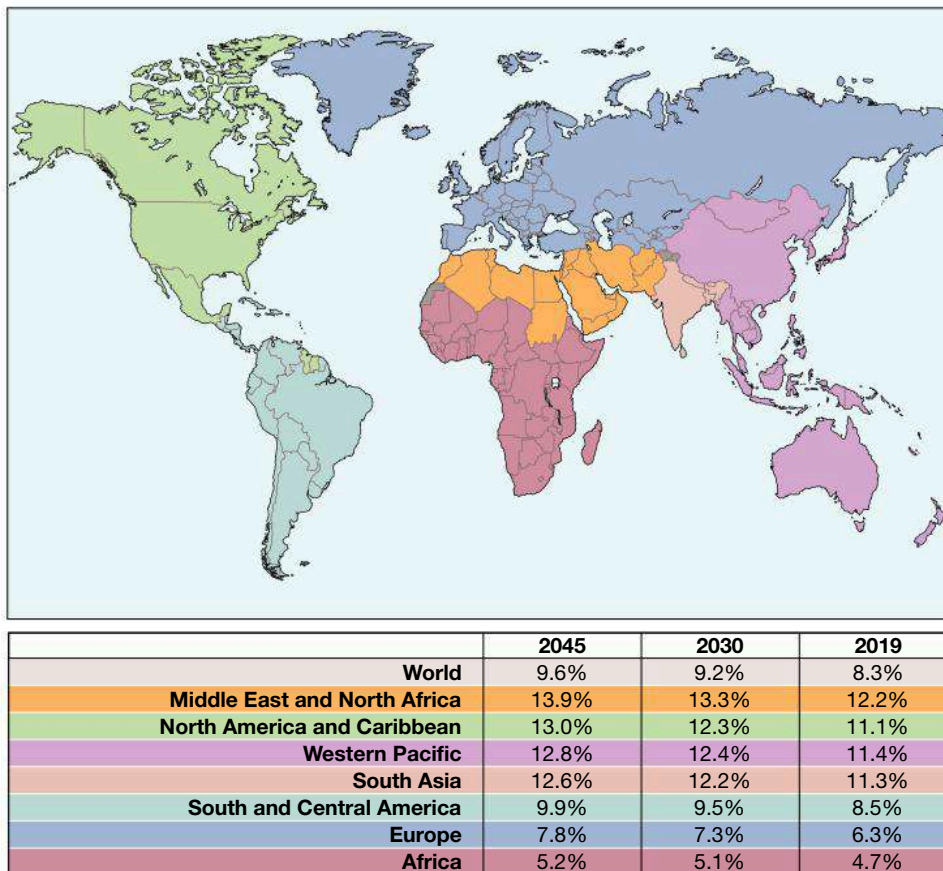

**Fig. 21.1** Prevalence of retinopathy by decile of fasting glucose. There is a small inflection point at 4 mmol/L, but a major inflection at 8 mmol/L. Adapted from World Health Organization and International Diabetes Federation. *Definition and diagnosis of diabetes mellitus and intermediate hyperglycaemia: report of a WHO/IDF consultation*. Geneva: World Health Organization; 2006. <https://apps.who.int/iris/handle/10665/43588>

of an immune-mediated destruction of insulin-producing  $\beta$  cells in the pancreatic islets of Langerhans. In contrast, in type 2 diabetes, concentrations of circulating insulin are typically elevated, but there is a *relative* deficiency of insulin because there is reduced sensitivity to insulin in peripheral tissues (due to obesity) and the  $\beta$  cells cannot make sufficient insulin to overcome this 'insulin resistance'.

Diabetes carries a heavy personal burden for those affected as well as high financial costs to health-care systems and society at large. In 2017, diabetes caused 4 million deaths globally, and health-care expenditure attributed to diabetes was estimated to be at least 727 billion US dollars, or 10% of total health-care expenditure. Acutely, high glucose results in marked symptoms of thirst, polydipsia and polyuria. If left untreated, it can lead to life-threatening metabolic decompensation requiring hospitalisation, especially in type 1 diabetes. Long-term hyperglycaemia is responsible for diabetes-specific 'microvascular' complications, particularly affecting the eyes (retinopathy), kidneys (nephropathy) and feet (neuropathy). These occur at a younger age in type 1 diabetes due to its earlier average age of onset.

Although the onset of clinical diabetes is often experienced as sudden in individual cases, there may have been a pre-clinical phase of months or even years when abnormal glucose values were not identified. Scientifically, there is no clear 'cut off' between normal and abnormal glucose levels, so international bodies have derived diagnostic criteria for diabetes ([Box 21.2](#)) based on blood glucose concentrations above which there is an appreciable risk of developing diabetic retinopathy, the most common microvascular complication ([Fig. 21.1](#)). Lower levels of hyperglycaemia (above normal) are classified as 'pre-diabetes' ([Box 21.2](#)).

The prevalence of diabetes is rising. Globally, it is estimated that 463 million people had diabetes in 2019 (9.3% of the world adult population), approximately 90% with type 2 diabetes. This figure is expected to reach 700 million by 2045. Prevalence is highest in the Middle East and lowest in parts of Africa, varying around the world ([Fig. 21.2](#)) according to

**Fig. 21.2** Current and projected diabetes prevalence in adults by region (2019–2045). Adapted from International Diabetes Federation. *IDF Diabetes Atlas, 9th edn*. Brussels; 2019. Available at <https://www.diabetesatlas.org>.

ethnicity as well as environmental factors (obesity, diet, habitual physical activity, urbanisation and economic development). A pronounced rise in the prevalence of type 2 diabetes occurs in migrant populations from low-income to industrialised countries. In many high-income countries, type 2 diabetes is no longer rare in children and adolescents, particularly in people of Hispanic, non-Hispanic Black and South Asian ethnicity. In some of these countries, increased survival is a factor underlying rising prevalence.

Type 1 diabetes is also subject to geographical variation and is generally more prevalent in countries closer to the polar regions. Finland, for instance, has the highest rate of type 1 diagnosis per year at >60 per 100 000 of the population, whereas in China, India and Venezuela the incidence is only 0.1 per 100 000. The incidence of type 1 diabetes is also increasing: between 1989 and 2013, 3.4 % more children were diagnosed worldwide each year. Type 1 diabetes is more common in people of European descent than in other ethnic groups and, for reasons that are not understood, more people are diagnosed in the winter months.

## Functional anatomy and physiology

As a supply (and uptake) of glucose is essential for the functioning of all organs and tissues, a host of metabolic and physiological processes are involved in precise regulation of its levels in blood.

### Insulin

Insulin is synthesised in the  $\beta$  cells of the pancreatic islets of Langerhans as a pro-hormone (pro-insulin), consisting of A- and B-chains, linked by C-peptide (see Fig. 21.23). C-peptide is cleaved by  $\beta$ -cell peptidases to create insulin (the A- and B-chains are joined by two disulfide bonds) and free C-peptide. In a healthy individual, around 10 days' supply of insulin is stored (~200–250 units). There are around one thousand  $\beta$  cells (approximately 70% of the islet cell population) in each of around one million islets scattered diffusely throughout the pancreas. The islets also contain  $\alpha$  and  $\delta$  cells, which synthesise respectively glucagon and somatostatin; F cells (also known as PP cells) synthesise pancreatic polypeptide. The islets are highly metabolically active, but each individual has a total mass of less than 1 g (see Fig. 21.3B). They are highly vascularised, to allow synthesised hormones to enter the portal circulation; despite making up only 1%–2% of total pancreatic mass, they receive 10%–15% of pancreatic blood flow.

### Regulation of insulin secretion

The pancreatic  $\beta$  cell is designed to regulate blood glucose concentrations tightly by coupling glucose and other nutrient stimuli with insulin secretion (Fig. 21.3). Entry of glucose into the pancreatic  $\beta$  cell is by facilitated diffusion down its concentration gradient through insulin-independent cell membrane glucose transporters (GLUT1 or GLUT2). Glucose is metabolised by glycolysis and oxidative phosphorylation. The first step of the glycolytic pathway, the conversion of glucose to glucose-6-phosphate, is catalysed by the enzyme glucokinase (GK). The generation of glucose-6-phosphate is directly proportional to the concentration of glucose, thus making GK a very effective physiological glucose sensor in the  $\beta$  cell. When glucose is metabolised, adenosine triphosphate (ATP) is generated, closing an ATP-sensitive potassium channel ( $K_{ATP}$ ). This depolarises the cell membrane, triggering release of calcium, which in turn activates voltage-sensitive calcium channels resulting in secretion of

**Fig. 21.3** Pancreatic structure and endocrine function. **A** The normal adult pancreas contains about 1 million islets, which are scattered throughout the exocrine parenchyma. Histology is shown in Figure 21.8. **B** The core of each islet consists of  $\beta$  cells that produce insulin and is surrounded by a cortex of endocrine cells that produce other hormones, including glucagon ( $\alpha$  cells), somatostatin ( $\delta$  cells) and pancreatic polypeptide (F or PP cells). **C** Schematic representation of the pancreatic  $\beta$  cell. (1) Glucose enters the cell via a glucose transporter (GLUT1 or GLUT2). (2) Glucose then enters glycolysis, and subsequent oxidative phosphorylation in the mitochondria results in a rise in intracellular adenosine triphosphate (ATP). (3) This ATP acts to close the  $K_{ATP}$  channel (which consists of four  $KIR6.2$  subunits and four  $SUR1$  subunits). This leads to membrane depolarisation. (4) The rise in membrane potential results in calcium influx due to opening of a voltage-gated calcium channel. This rise in intracellular calcium causes insulin secretory vesicles to fuse with the cell membrane, leading to insulin secretion. (5) Other stimuli, such as glucagon-like peptide-1 (GLP-1) or gastric inhibitory polypeptide (GIP), act on G-protein-coupled receptors to increase cyclic adenosine monophosphate (cAMP) and amplify the insulin secretion. Genetic defects in the  $\beta$  cell result in diabetes. The primary genes are glucokinase (the initial step in glycolysis) and  $HNF1\alpha$ ,  $HNF4\alpha$  and  $HNF1\beta$  (nuclear transcription factors). Two groups of drugs act on the  $\beta$  cell to promote insulin secretion. Sulphonylureas act to close the  $K_{ATP}$  channel, causing membrane depolarisation, calcium influx and insulin secretion. Incretin-acting drugs either increase the concentration of endogenous GLP-1 and GIP (the dipeptidyl peptidase 4, or DPP-4, inhibitors) or act as directly on the GLP-1 receptor (GLP-1 receptor agonists). Both of these drug groups act to augment insulin secretion, but only following an initial stimulus to insulin secretion through closure of  $\beta$  cell  $K_{ATP}$  channels by glucose (or sulphonylureas).

**Fig. 21.4** Insulin secretion in response to elevated glucose. **A** The incretin effect describes the observation that insulin secretion is greater when glucose is given by mouth than when glucose is administered intravenously to achieve the same rise in blood glucose concentrations. The additional stimulus to insulin secretion is mediated by release of peptides from the gut and these actions are exploited in incretin-based therapies (p. 735). **B** An acute first phase of insulin secretion occurs in response to an elevated blood glucose, followed by a sustained second phase.

insulin. Therefore, the amount of insulin released in response to this simple pathway at any given time is intrinsically linked to the blood glucose concentration at that moment.

Insulin release can be potentiated by other nutrients and peptides and by neuronal control via the sympathetic and parasympathetic nervous system. Two peptides that potentiate insulin release from  $\beta$  cells following ingestion of food are glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide (GIP), which are released from gastrointestinal L cells and K cells respectively when nutrients reach the duodenum and upper jejunum. Thus, for a given ambient concentration of glucose sensed by the  $\beta$  cell, more insulin is secreted when the glucose has been ingested orally (when gut peptides are released) than when glucose was administered intravenously. This is termed the ‘incretin effect’ (Fig. 21.4A) and GLP-1 and GIP are known as ‘incretin hormones’. The incretin effect is diminished in type 2 diabetes.

Insulin is secreted from  $\beta$  cells into the portal circulation (see Fig. 21.3) and classically this occurs in two phases (see Fig. 21.4B). The rapid first phase represents release of pre-formed insulin from granules within the  $\beta$  cells, starting almost immediately following a rise in blood glucose and is completed within 15 minutes. The second phase is more prolonged (occurring over the following 2–3 hours) and is a consequence of de novo insulin synthesis.

### Actions of insulin

Insulin is an anabolic hormone (i.e. it promotes the storage of nutrients) and has pleiotropic effects on glucose, fat and protein metabolism (Box 21.1). It also stimulates cell proliferation and reduces apoptosis. The actions of insulin are mediated through the cell membrane insulin receptor. The receptor belongs to the tyrosine kinase superfamily and is coupled to an extremely complicated intracellular signalling network. A key action of

## 21.1 Metabolic actions of insulin

Increase	Decrease
<b>Carbohydrate metabolism</b> Glucose transport (muscle, adipose tissue) Glycogen synthesis Glycolysis	Gluconeogenesis Glycogenolysis
<b>Lipid metabolism</b> Triglyceride synthesis Fatty acid synthesis (liver) Lipoprotein lipase activity (adipose tissue)	Lipolysis Lipoprotein lipase (muscle) Ketogenesis Fatty acid oxidation (liver)
<b>Protein metabolism</b> Amino acid transport Protein synthesis	Protein degradation

**Fig. 21.5** Insulin receptor signalling. Insulin (i) binds to the insulin receptor (IR) triggering a complex signalling cascade including phosphorylation (P) of insulin receptor substrate (IRS) by tyrosine kinase. IRS associates with and activates phosphoinositide 3-kinase (PI3K). PI3K stimulates Akt, which phosphorylates and inactivates AS160. This leads ultimately to translocation of glucose transporter 4 (GLUT4) from GLUT4 storage vesicles (GSVs) to the cell surface, allowing cells to take up interstitial glucose (g). Note that there are many other elements of insulin receptor signalling (not shown) that mediate the other aspects of insulin’s pleiotropic actions.

insulin is to lower blood glucose and, in part, this is mediated by promoting the uptake of glucose into muscle and adipose tissue; at a cellular level, the binding of insulin to its receptor causes cell membrane glucose transporter GLUT4 to translocate from the cytoplasm to the cell membrane, permitting the uptake of glucose into adipose and muscle cells (Fig. 21.5).

### Glucagon

Alpha cells make up about 20% of the human islet cell population. Glucagon has opposite effects to insulin: for example, it acts on the liver to stimulate glycogenolysis, releasing stored glucose (‘hepatic glucose production’) and causing blood glucose levels to rise. Glucagon is critically important in the defence against hypoglycaemia. Its secretion by  $\alpha$  cells is inhibited locally by  $\beta$ -cell insulin secretion (i.e. a ‘paracrine’ effect) and also by somatostatin from  $\delta$  cells. Glucagon secretion is also inhibited by islet amyloid polypeptide (amylin), which is co-secreted from  $\beta$  cells with insulin. Thus insulin and glucagon are tightly and reciprocally regulated, such that the ratio of insulin to glucagon in the portal vein is a major determinant of hepatic glucose production and other metabolic processes, including lipolysis and ketogenesis.

### Blood glucose homeostasis

Blood glucose is precisely regulated and maintained within a narrow range (between 4.0 and 5.4 mmol/L (72–99 mg/dL)) when fasting. This is essential for ensuring a physiological continuous supply of glucose to

**Fig. 21.6 Major metabolic pathways of fuel metabolism and the actions of insulin.** ⊕ indicates stimulation and ⊖ indicates suppression by insulin. In response to a rise in blood glucose, e.g. after a meal, insulin is released, suppressing gluconeogenesis and promoting glycogen synthesis and storage. Insulin promotes the peripheral uptake of glucose, particularly in skeletal muscle, and encourages storage (as muscle glycogen). It also promotes protein synthesis and lipogenesis, and suppresses lipolysis. The release of intermediate metabolites, including amino acids (glutamine, alanine), 3-carbon intermediates in oxidation (lactate, pyruvate) and free fatty acids (FFAs), is controlled by insulin. In the absence of insulin, e.g. during fasting, these processes are reversed and favour gluconeogenesis in liver from glycogen, glycerol, amino acids and other 3-carbon precursors.

the central nervous system. The brain has little capacity to store energy in the form of glycogen or triglyceride, while the blood–brain barrier is largely impermeable to fatty acids. Therefore, the brain depends on the liver for a constant supply of glucose for oxidation and hence generation of ATP.

Glucose homeostasis is achieved through the coordinated actions of multiple organs, but mainly reflects a balance between the entry of glucose into the circulation from the liver, supplemented by intestinal absorption of glucose after meals, and the uptake of glucose by peripheral tissues, particularly skeletal muscle and brain. After ingestion of a meal containing carbohydrate, a substantial rise in blood glucose levels is prevented by:

- suppression of hepatic glucose production (by gluconeogenesis and glycogenolysis)
- stimulation of hepatic glucose uptake (and its subsequent storage as glycogen, i.e. glycogen synthesis)
- stimulation of glucose uptake by peripheral tissues (muscle and adipose) (Fig. 21.6).

These effects are mediated primarily by a post-prandial rise in portal vein insulin in response to increasing blood glucose, augmented by incretin hormones, together with a fall in portal glucagon concentrations. Depending on the size of the carbohydrate load, around one-quarter to one-third of ingested glucose is taken up in the liver.

When intestinal glucose absorption declines between meals, blood glucose levels are maintained by increased hepatic glucose output via

both gluconeogenesis and glycogenolysis. This is a consequence of falling portal vein insulin concentrations and rising glucagon levels. The main substrates for gluconeogenesis are glycerol and amino acids, as shown in Figure 21.6. At times of substantially increased metabolic demand for energy, such as during exercise or other acute stress, hepatic glucose output can be further transiently increased by activation of the sympathetic nervous system and release of hormones such as adrenaline (epinephrine), noradrenaline (norepinephrine), cortisol and growth hormone, which antagonise the actions of insulin.

### Fat metabolism

Adipocytes (and the liver) synthesise triglyceride from non-esterified ('free') fatty acids (FFAs) and glycerol. High circulating insulin levels after meals promote triglyceride accumulation and storage in adipose tissue. In contrast, in the fasting state, low insulin levels permit lipolysis and the release into the circulation of FFAs, which can be oxidised by many tissues. Their partial oxidation in the liver provides substrate (glycerol) and energy (in the form of ATP) to drive gluconeogenesis, but also ketones (acetoacetate, which can be reduced to 3-hydroxybutyrate or decarboxylated to acetone), which are generated in hepatocyte mitochondria. Ketones (also known as ketone bodies) are organic acids that can be oxidised and utilised as an alternative metabolic fuel for the brain when glucose is not available (e.g. during illness and prolonged fasting). Thus, when insulin levels are low (and glucagon and catecholamine levels are high), increased lipolysis and delivery of FFAs to the liver results in the production of ketones (see Fig. 21.6). However, the rate at which

ketones can be utilised by peripheral tissues is 'capped': blood ketone concentrations therefore rise (hyperketonaemia) when the rate of production by the liver exceeds their removal.

## Investigations

### Urine glucose

While a colorimetric test for glucose is included in all standard urine 'dipsticks', it is no longer used as a screening procedure and is rarely of clinical value. If apparent glycosuria is detected, it will always require further assessment by blood testing (see below), e.g. there can be cross-reaction with  $\beta$ -lactam antibiotics, levodopa and salicylates. Some individuals have a high 'renal threshold' for glucose excretion, i.e. glucose is not detected in their urine despite a high blood glucose concentration. A low renal threshold for glucose (i.e. decreased reabsorption following filtration) is common during pregnancy and in healthy young adults, and is of no consequence.

### Blood glucose

Measurement of blood glucose concentration is the cornerstone of diabetes diagnosis, but varies markedly according to whether taken in the fasted or fed state. Glucose concentrations are slightly lower in venous than in arterial or capillary blood, as tissues extract glucose. Whole-blood glucose concentrations are lower than separated plasma concentrations, because red blood cells contain relatively little glucose. Venous plasma measurements are the most reliable for diagnostic purposes (Boxes 21.2 and 21.3). Laboratory venous plasma glucose testing utilises a simple enzymatic reaction (glucose oxidase) and is cheap, reliable and usually automated.

## i

### 21.2 Diagnostic criteria for diabetes and pre-diabetes

#### Diabetes is confirmed by international consensus as:

- plasma glucose in random sample or 2 hrs after a 75 g glucose load  $\geq 11.1$  mmol/L (200 mg/dL) *or*
- fasting plasma glucose  $\geq 7.0$  mmol/L (126 mg/dL) *or*
- $HbA_{1c} \geq 48$  mmol/mol

In asymptomatic patients, two diagnostic tests are required to confirm diabetes

#### Definitions of 'pre-diabetes' vary between expert bodies:

- impaired fasting glucose:
  - fasting plasma glucose  $\geq 6.1$  mmol/L (110 mg/dL) and  $<7.0$  mmol/L (126 mg/dL) (World Health Organization) *or*
  - fasting plasma glucose  $\geq 5.6$  mmol/L (100 mg/dL) and  $<7.0$  mmol/L (126 mg/dL) (American Diabetes Association)
- impaired glucose tolerance:
  - fasting plasma glucose  $<7.0$  mmol/L (126 mg/dL) and 2-hr glucose after 75 g oral glucose drink  $\geq 7.8$  (140 mg/dL) and  $<11.1$  mmol/L (200 mg/dL)
- $HbA_{1c}$ :
  - 42–47 mmol/mol (National Institute for Health and Care Excellence [NICE] guidelines, UK) *or*
  - 39–47 mmol/mol (American Diabetes Association)

### 21.3 How to perform an oral glucose tolerance test (OGTT)

#### Preparation before the test

- Unrestricted carbohydrate diet for 3 days
- Fasted overnight for at least 8 hours
- Rest for 30 mins
- Remain seated for the duration of the test, with no smoking

#### Sampling

- Measure plasma glucose before and 2 hours after a 75 g oral glucose drink

Glucose can also be measured in capillary blood from a 'fingerprick' sample using test strips read with a portable electronic meter. This has been the traditional method by which people with type 1 diabetes adjust their insulin doses and detect impending hypoglycaemia. The same applies for people with insulin-treated type 2 diabetes and to a lesser extent for those treated with sulphonylureas (in whom hypoglycaemia occurs about 10 times less frequently, but is nevertheless a risk). The main limitation of capillary glucose monitoring (other than the transient pain associated with the fingerprick) is the practical limit on the number of measurements that can be performed over a 24-hour period. Blood glucose can be extremely variable, especially in people with type 1 diabetes, and so intermittent testing (such as 4–6 capillary measurements per day) may miss substantial peaks and troughs in blood glucose, especially overnight when no 'routine' measurements are usually performed.

Capillary blood glucose testing is also used as a 'near-patient test' to monitor glucose levels at the bedside in hospitalised patients with diabetes and in situations where hyperglycaemia or hypoglycaemia is a potential consequence of a medical condition or its treatment, e.g. intravenous insulin therapy (hyper- and hypoglycaemia), high-dose glucocorticoids (hyperglycaemia) and acute liver failure (hypoglycaemia). Arterial blood glucose levels are often reported, along with several other analytes, by 'near-patient' blood gas analysers in critical care and emergency departments. As with capillary testing, the blood glucose data provided can be useful in monitoring patients who are acutely unwell and at risk of hyper- and/or hypoglycaemia.

It is important to note, however, that capillary and arterial whole blood glucose measurements are *less accurate* than laboratory venous plasma glucose measurements. The capillary and arterial glucose measurement devices are designed to give patients and/or clinicians an *approximation* of the prevailing blood glucose. Where high levels of precision are required, e.g. when making a diagnosis of diabetes (which will have substantial implications for the patient) or in the evaluation of spontaneous hypoglycaemia (see Ch. 20), laboratory venous plasma blood glucose concentrations should be measured.

### Interstitial glucose

An increasingly established approach to measure glucose in people with diabetes is continuous glucose monitoring (CGM). CGM systems use a tiny sensor inserted under the skin to measure glucose in interstitial fluid. CGM devices display both the current glucose and trend arrows, by automatically transmitting to a receiver, smartphone or smartwatch application. CGM devices can also be downloaded onto a personal computer. The use of CGM has accelerated in recent years and is becoming a standard of care in type 1 diabetes management in high-income countries. CGM can be intermittently scanned (isCGM or 'flash' CGM) or provide real-time CGM (rtCGM). The sensor can stay in place for up to 2 weeks before being replaced and provides measurements of glucose levels every 5 minutes for rtCGM or every 15 minutes for isCGM. The most recent devices do not require calibration against capillary blood glucose measurements. Less expensive (isCGM) devices require to be scanned at least once every 8 hours or the data stored in the sensor are lost (see Fig. 21.7).

Interstitial glucose correlates well with blood glucose, but has a 10- to-15-minute lag when blood glucose is rapidly changing. This can lead to discrepancies between contemporaneous CGM and capillary blood glucose measurements; these can also occur due to intrinsic inaccuracies (neither is as accurate as a laboratory measurement). Accuracy of CGM devices is constantly improving, with newer devices reporting mean absolute relative difference (MARD) of interstitial fluid and blood glucose of  $<11\%$ .

Daily use of CGM improves glycaemic control in type 1 diabetes, providing useful information on daily glucose profiles and, in particular, nighttime glucose patterns. It can reveal high and low glycaemic excursions that are not identified by capillary glucose testing. Alarms are incorporated into all rtCGM and some isCGM devices to warn about impending low glucose and high glucose events. Alarms are particularly important

**Fig. 21.7** Download from intermittently scanned ('flash') continuous glucose monitor (isCGM). Glucose data from four consecutive days are shown. Each small open circle (o) on the graph represents an occasion when the sensor has been scanned by the patient and there is a corresponding glucose level displayed at the bottom of the graph. The grey section represents the ideal target range of 3.9–10.0 mmol/L. Low glucose episodes are in red. Note the substantial variation in glucose within each 24-hour period (with frequent episodes of low and high glucose) and the variation between comparable time points on different days. Such variation could not be detected by intermittent capillary glucose testing. Each daily graph has a short period when no data are provided; this is because the time between sensor scans exceeded 8 hours.

during the night (when periods of even quite severe biochemical hypoglycaemia may go undetected) and for people with impaired awareness of hypoglycaemia (see p. 725). Early identification of low glucose (by alarm or a trend arrow showing rapidly declining glucose) allows prompt corrective action (i.e. ingesting sugar-containing foods and drinks), and thus may prevent a mild episode of hypoglycaemia becoming a severe episode. Identification of high glucose also allows self-administration, if appropriate, of additional 'correction' doses of insulin.

Initiation of CGM requires education and support to overcome potential information overload and extract meaningful from the extensive data generated. Online resources are provided by the manufacturing companies and also by user forums. The functionality that allows people with diabetes to remotely share their glucose levels with family members (e.g. a child with diabetes can share data with a parent), caregivers and their diabetes specialist team (e.g. facilitating remote consultations) is an important advance. CGM can be linked with continuous subcutaneous insulin infusion (CSII) devices ('insulin pumps') to permit the creation of 'sensor-augmented' systems; such systems can be life-transforming for people with type 1 diabetes and are discussed in detail on p. 741.

## Urine and blood ketones

Ketones can be measured in either urine (using dipsticks) or blood using portable electronic meters (integrated into some capillary glucose

meters). Urine tests detect acetoacetate (by the nitroprusside reaction), while blood testing strips detect beta-hydroxybutyrate ( $\beta$ -OHB), the major ketone found in blood during diabetic ketoacidosis (DKA). Blood testing is particularly useful to guide self-management during 'sick days' as an early warning sign of incipient DKA, but also to guide emergency in-patient management (see p. 721) e.g. monitoring resolution of DKA (Box 21.4).

Ketonuria/ketonaemia is not pathognomonic of diabetes and can be found after exercise in non-diabetic people who have been fasting or exercising strenuously, repeated vomiting, or eating a 'ketogenic' diet (with a macronutrient composition that is both high in fat and low in carbohydrate).

## Glycated haemoglobin

Glycated haemoglobin is accepted as the international standard method for assessing glycaemic control in diabetes as it reflects average blood glucose over a period of weeks or months.

During hyperglycaemia, slow non-enzymatic covalent attachment of glucose to haemoglobin (glycation) increases the proportion in the HbA<sub>1c</sub> (and specifically HbA<sub>1c</sub>) fraction, relative to non-glycated adult haemoglobin (HbA<sub>0</sub>). These fractions can be separated by chromatography although other laboratory methods can also be used. The rate of formation of HbA<sub>1c</sub> is directly proportional to ambient blood glucose

21.4 Interpretation of capillary blood ketone measurements	
Measurement <sup>1</sup>	Interpretation
<0.6 mmol/L	Normal; no action required
0.6–1.5 mmol/L	Suggests metabolic control may be deteriorating; the patient should continue to monitor and seek medical advice if sustained/progressive
1.5–3.0 mmol/L	High risk of diabetic ketoacidosis; seek medical advice
>3.0 mmol/L	Severe ketosis suggests presence of diabetic ketoacidosis; seek urgent medical advice

<sup>1</sup>To convert to mg/dL, multiply values by 18.

21.5 Conversion between DCCT and IFCC units for HbA <sub>1c</sub>	
DCCT units (%)	IFCC units (mmol/mol)
4	20
5	31
6	42
7	53
8	64
9	75
10	86
IFCC HbA <sub>1c</sub> (mmol/mol) = [DCCT HbA <sub>1c</sub> (%) – 2.15] × 10.929	
(DCCT = Diabetes Control and Complications Trial; IFCC = International Federation of Clinical Chemistry and Laboratory Medicine)	

concentration: a rise of 11 mmol/mol in HbA<sub>1c</sub> corresponds to an approximate average increase of 2 mmol/L (36 mg/dL) in blood glucose. Although HbA<sub>1c</sub> concentration reflects the integrated blood glucose control over the lifespan of erythrocytes (typically 120 days), HbA<sub>1c</sub> is most sensitive to changes in glycaemic control occurring in the month before measurement.

Since 2011, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has developed a standard system for reporting HbA<sub>1c</sub> (IFCC-standardised HbA<sub>1c</sub>) reported in mmol/mol. However, it is important to be aware of the 'percentage' units that were previously used as many people with diabetes are more familiar with these (and many specialist publications use dual-reporting) (Box 21.5).

HbA<sub>1c</sub> may be erroneously low (i.e. lower than would be anticipated for the prevailing average blood glucose) in conditions associated with shorter red cell lifespan (e.g., chronic blood loss, sickle cell anaemia, thalassaemia, pregnancy) and after blood transfusion (as transfused red cell concentrate usually comes from non-diabetic donors). Conversely, HbA<sub>1c</sub> may be erroneously high in conditions that increase red cell lifespan (iron, vitamin B<sub>12</sub> or folate deficiency anaemia, splenectomy). It may be difficult to interpret with some assay methods in patients who have uraemia or a haemoglobinopathy. It is particularly important to be aware of this in pregnancy care and also in health-care settings in which red cell disorders and nutritional deficiency are prevalent, especially if HbA<sub>1c</sub> is used in the diagnosis of diabetes (see below).

### Islet autoantibodies

As type 1 diabetes is characterised by inflammatory infiltration of pancreatic β cells, it can be useful when making a diagnosis of diabetes to identify evidence of autoimmunity. Islet antibodies include:

anti-insulin, anti-glutamic acid decarboxylase (GAD), anti-protein tyrosine phosphatase-related proteins (IA-2) and anti-zinc transporter 8 (ZnT8). They are generally measured using specific immunoassays and, as with other such assays, 'false-positive' results can occur due to assay interference. Islet antibodies may also be found in healthy individuals and although some of these may go on and develop type 1 diabetes in the future (particularly if they have first-degree relatives with type 1 diabetes), many will not develop diabetes. The significance of islet antibodies is greater when they are detected at concentrations greater than the 95th centile of the general population (i.e. in 'high titre') and if multiple antibodies are detectable. A single positive autoantibody confers a 5-year risk of type 1 diabetes of 20%–25%, rising to 50%–60% risk with two autoantibodies and 70% with three autoantibodies. Conversely, as autoantibody levels can wane over time, they may be negative in people with established type 1 diabetes. Pragmatically, if anti-GAD and anti-IA-2 antibodies are measured together, either or both will be 'positive' in approximately 85% of newly diagnosed type 1 diabetes; measurement of anti-ZnT8 antibodies at the same time increases sensitivity to over 90% (i.e. fewer than 10% of cases will be antibody negative). Islet autoantibody testing is becoming standard in some high-income countries for people commenced on insulin therapy within 3 years of diagnosis. A negative autoantibody result should prompt consideration of an alternative diagnosis to type 1 diabetes; however, as type 1 diabetes can still occur in people with negative antibodies, the clinical diagnosis of type 1 diabetes should not immediately be rejected.

### C-peptide

C-peptide (see Fig. 21.23) can be readily measured in blood and urine. It is secreted by β cells in equimolar concentrations to insulin, but is not a constituent of synthetic insulin. Therefore C-peptide is a useful marker of *endogenous insulin secretion*, particularly in insulin-treated individuals (in whom a direct measurement of insulin does not distinguish exogenous from endogenous insulin).

Severe endogenous insulin deficiency (typically serum C-peptide < 200 pmol/L) is found in type 1 diabetes, diabetes secondary to other pancreatic disorders and some forms of monogenic diabetes (see p. 719). 'Undetectable' serum C-peptide was traditionally considered pathognomonic of type 1 diabetes; however, the use of modern high-sensitivity C-peptide immunoassays (e.g. with a lower limit of detection of 3 pmol/L) has demonstrated that there is a spectrum of retained endogenous insulin secretion in type 1 diabetes. Persistent endogenous insulin secretion, in any form of diabetes, even though insufficient to maintain normoglycaemia, can have a smoothing effect on blood glucose, i.e. peaks and troughs in glucose are reduced because there is a retained ability to vary insulin secretion (upwards or downwards) in response to prevailing blood glucose.

In type 2 diabetes, C-peptide concentrations are usually significantly elevated (typically > 900 pmol/L) reflecting increased insulin secretion in response to tissue insulin resistance. However, in forms of type 2 diabetes where there is a degree of endogenous insulin deficiency (such as with long diabetes duration), lower levels of C-peptide may occur.

Although there is overlap between C-peptide levels in the different forms of diabetes, a one-off measurement of random (non-fasting) serum C-peptide can be used to identify individuals who have been misclassified, e.g. labelled as type 1 diabetes, when they have type 2 diabetes or vice versa. If C-peptide is used in this way, blood glucose must be checked simultaneously to ensure it is > 4.0 mmol/L (> 72 mg/dL), as hypoglycaemia lowers endogenous insulin secretion and thus C-peptide. C-peptide measurement is also used in the diagnosis of spontaneous hypoglycaemia (p. 689).

### Urine albumin ('microalbuminuria')

Standard urine dipstick testing for albumin detects urinary albumin at concentrations above 300 mg/L, but much lower concentrations can be measured using specific albumin dipsticks or quantitative biochemical

laboratory tests, permitting detection of microalbuminuria ( $\geq 30$  mg/L, see Box 18.11). Microalbuminuria (in the absence of urinary tract infection) has therapeutic implications as it is an important early indicator of diabetic nephropathy and a risk marker for macrovascular complications. Microalbuminuria may progress to overt (dipstick positive) proteinuria.

## Establishing the diagnosis of diabetes

Glycaemia can be classified into three categories: normal, impaired (pre-diabetes) and diabetes (see Box 21.2). The glycaemia cut-off that defines diabetes is based on a level above which there is a significant risk of microvascular complications, particularly retinopathy (see Fig. 21.1). People categorised as having pre-diabetes have blood glucose levels that carry a negligible risk of microvascular complications, but are at increased risk of developing diabetes (5%–10% in this category develop diabetes each year).

Diabetes has traditionally been diagnosed using venous plasma glucose measurements (random or fasting) and (if required) a 75 g oral glucose tolerance test (OGTT; see Box 21.3). When a person has symptoms of diabetes, the diagnosis can be confirmed with either a fasting glucose of  $\geq 7.0$  mmol/L (126 mg/dL) or a random glucose of  $\geq 11.1$  mmol/L (200 mg/dL) (see Box 21.2). Asymptomatic individuals should have a second confirmatory test. Diabetes should not be diagnosed on capillary blood glucose results. In 2011, the World Health Organization (WHO) began to advocate the use of glycated haemoglobin ( $\text{HbA}_{1c}$ ) as a diagnostic test, with an  $\text{HbA}_{1c}$  of  $\geq 48$  mmol/mol indicative of diabetes. This has been adopted in some countries, including the UK where it is recommended by the National Institute for Health and Care Excellence (NICE). However, in part due to the analytical issues raised by prevalent haemoglobinopathies and other factors that affect  $\text{HbA}_{1c}$  independent of average blood glucose (see p. 711), diagnosis by  $\text{HbA}_{1c}$  has not been adopted by the International Diabetes Federation. As  $\text{HbA}_{1c}$  reflects the last 2–3 months of glycaemia, it should not be used to diagnose diabetes when the duration of onset of symptoms has been short; in this context, fasting or random glucose measurements are still required to confirm or rule out a diagnosis.

Pre-diabetes has two forms based on blood glucose criteria, namely 'impaired glucose tolerance' (IGT) and 'impaired fasting glucose' (IFG). In IGT, fasting glucose is normal, but 2-hour glucose is elevated above normal (but not high enough for diabetes). In IFG, fasting glucose is elevated above normal (not high enough for diabetes), but 2-hour glucose is normal. Pre-diabetes may also be diagnosed using  $\text{HbA}_{1c}$ , but criteria vary between international bodies (see Box 21.2). Pre-diabetic states are not associated with a substantial risk of microvascular disease, but with an increased risk of conversion to diabetes (particularly IFG) and an increased risk of macrovascular disease, i.e. myocardial infarction, stroke and peripheral vascular disease (particularly IGT) (see Box 21.3). Individuals in whom pre-diabetes is detected (often when screening for diabetes) should be advised of their risk of progression to diabetes, given advice about lifestyle modification to reduce this risk (as for type 2 diabetes), and be screened for treatable cardiovascular risk factors such as hypertension and dyslipidaemia.

The diagnostic criteria for diabetes in pregnancy (gestational diabetes) are more stringent (see Box 32.12).  $\text{HbA}_{1c}$  should not be used to diagnose diabetes in pregnancy.

## Aetiology and pathogenesis of diabetes

At a fundamental level, diabetes is a consequence of *absolute* or *relative* deficiency of insulin, although the underlying genes, precipitating environmental factors and pathophysiology differ substantially between the various forms. In type 1 diabetes and diabetes secondary to pancreatic pathology there is an *absolute* insulin deficiency that requires treatment with insulin. At the other end of the spectrum, mutations in the insulin

receptor cause diabetes due to severe insulin resistance (e.g. Rabson–Medenhall and Donohue syndromes); such individuals have extremely high levels of insulin, but have a *relative* deficiency because insulin cannot exert a functional effect via an abnormal receptor. In type 2 diabetes, there is usually a combination of both  $\beta$ -cell dysfunction and insulin resistance, although here the insulin resistance is usually a consequence of signalling effects downstream from the insulin receptor (see below). Although it is generally helpful to classify diabetes on an aetiological basis (Box 21.6), many individuals have diabetes due to a combination of factors, e.g. an individual with type 1 diabetes who becomes obese and insulin resistant (sometimes known as 'double diabetes'); an individual with significant obesity *and* a previous distal pancreatectomy; or an individual with a pathogenic monogenic diabetes gene mutation and strongly positive islet autoantibodies.

## Pathogenesis of diabetes

### Insulin resistance and the metabolic syndrome

The precise mechanisms causing insulin resistance are complicated. Abnormalities have been reported in many post-receptor intracellular signalling pathways downstream from the insulin receptor, including phosphoinositide 3-kinase (PI3K), but none of the common abnormalities are sufficient to cause type 2 diabetes in the absence of other abnormalities. A single abnormality can usually be compensated for by other pathways ('redundancy'), so 'multiple hits' may be necessary for significant insulin resistance to occur. The exact combination of abnormalities present differs between individuals (i.e. the condition is 'heterogeneous') and there is a wide range of physiological insulin sensitivity even in non-diabetic individuals. Factors associated with insulin resistance are shown in Box 21.7.

Obesity is a major cause of insulin resistance. Intra-abdominal 'central' adipose tissue is metabolically active and releases large quantities of FFAs, which may induce insulin resistance because they compete with (or inhibit use of) glucose as a fuel supply for oxidation, e.g. in muscle. In addition, adipose tissue releases a number of hormones (including a variety of peptides, called 'adipokines') that act on specific receptors to influence sensitivity to insulin in other tissues. Examples of adipokines include leptin, adiponectin, interleukin-6 and tumour necrosis factor alpha. Venous drainage of visceral adipose tissue is into the portal vein and so central obesity may have a particularly potent influence on hepatic insulin sensitivity and thereby adversely affect hepatic glucose and lipid metabolism.

## 21.6 Aetiological classification of diabetes mellitus

### Type 1 diabetes\*

### Type 2 diabetes\*

### Other specific types

- Genetic defects of  $\beta$ -cell function (see Box 21.8)
- Genetic defects of insulin action (e.g., lipodystrophies)
- Pancreatic disease (e.g. pancreatitis, pancreatectomy, neoplastic disease, cystic fibrosis, haemochromatosis, fibrocalculus pancreatopathy)
- Excess endogenous production of hormonal antagonists to insulin, e.g.:
  - Growth hormone – acromegaly
  - Glucocorticoids – Cushing's syndrome
  - Glucagon – glucagonoma
  - Catecholamines – phaeochromocytoma
  - Thyroid hormones – thyrotoxicosis
- Drug-induced (e.g. glucocorticoids, thiazide diuretics, HIV drugs, immune checkpoint inhibitors)
- Associated with genetic syndromes (e.g. Down syndrome, Klinefelter syndrome, Turner syndrome, DIDMOAD (Wolfram syndrome), Friedreich's ataxia, myotonic dystrophy)
- Gestational diabetes

\*The World Health Organization also recognises 'slowly evolving, immune-mediated diabetes of adults' and 'ketosis-prone type 2 diabetes' as 'hybrid' forms of diabetes. (DIDMOAD = diabetes insipidus, diabetes mellitus, optic atrophy, nerve deafness)

Some ethnic groups, e.g. South Asians and certain indigenous peoples of America and Australasia, have a very high prevalence of insulin resistance. In part this may simply relate to genetic and environmental factors associated with increased obesity in general. However, a common feature in these groups is that for a given body mass index, there is a greater degree of central rather than peripheral adiposity when compared, for example, to people of European descent.

Physical activity is another important determinant of insulin sensitivity. Inactivity is associated with down-regulation of intracellular insulin-sensitive kinases (enzymes that increase the activity of other enzymes by phosphorylation) and may promote accumulation of FFAs within skeletal muscle. Sedentary people are therefore more insulin-resistant than active people with the same degree of obesity. Moreover, physical activity allows non-insulin-dependent glucose uptake into muscle, reducing the 'demand' on pancreatic  $\beta$  cells to produce insulin.

Although the pathogenic mutations in single genes with a large effect (e.g. mutations in the insulin receptor that negatively impact on its function as mentioned above) are extremely rare, genetic factors nevertheless play a very important role in the pathogenesis of insulin resistance. Genome-wide association studies have shown that many common and rare gene variants are associated with increased and decreased sensitivity to insulin. Obesity has a strong genetic element (see p. 764), often relating to impaired hypothalamic mechanisms of appetite and satiety, and so many of the identified gene variants associated with obesity are also associated with insulin resistance. Ethnic differences in adipose deposition are also likely to have a genetic basis, although this has not yet been conclusively proven (many genetic studies to date have had included mainly participants of European descent). Non-obesity related genetic variants associated with insulin resistance are mostly either directly involved in glucose metabolism or in the insulin intracellular signalling cascade.

Increasing age is associated with reduced insulin sensitivity, but this may be a consequence of increased adiposity and reduced lean muscle mass rather than a direct effect of ageing. Drugs (notably glucocorticoids) and excess of hormones such as cortisol and growth hormone (see Box 21.6) can also antagonise the action of insulin.

As well as being associated with hyperglycaemia, insulin resistance is also associated with a cluster of other conditions. These include hypertension, dyslipidaemia (elevated small dense low-density lipoprotein (LDL) cholesterol, elevated triglycerides and low high-density lipoprotein (HDL) cholesterol), non-alcoholic fatty liver disease (Ch. 24) and, in women, polycystic ovarian syndrome. This cluster has been termed the 'insulin resistance syndrome' or 'metabolic syndrome' and is usually associated with central obesity, impaired glucose tolerance and an increased risk of macrovascular disease. Severe insulin resistance is also associated with acanthosis nigricans (see p. 704), i.e. dark pigmentation of body folds and creases, particularly in the axillae, groins and neck.

### $\beta$ -cell dysfunction

Insulin deficiency occurs across a spectrum that ranges from complete deficiency (e.g. following a total pancreatectomy), through the severe insulin deficiency of type 1 diabetes, to more minor degrees of insulin insufficiency that only become important if increased demand is placed upon the pancreas, e.g. by obesity-induced insulin resistance. In this latter situation, insulin deficiency may be more relative than absolute, i.e. the  $\beta$  cells may produce substantial amounts of insulin, but not in sufficient quantities to overcome an insulin-resistant state. Insulin deficiency may be the consequence of a number of different factors, some of which are listed in Box 21.7.

There is wide variation in the capacity of the pancreas to produce insulin, because of natural variation in  $\beta$ -cell mass and the inherent efficiency of the  $\beta$  cells. Single gene mutations with a large effect on  $\beta$ -cell mass and function are uncommon, but form the basis of most forms of monogenic diabetes (Box 21.8). Most of the variation in  $\beta$ -cell mass and function is mediated by multiple genes, each with a very small effect. However, where a large number of adverse genetic variants are

inherited, their cumulative effect can be significant. Individuals with genetically lower  $\beta$ -cell mass and function may not have abnormal blood glucose at birth, but are more susceptible to developing diabetes in later life, particularly if the individual becomes insulin resistant or acquires additional loss of  $\beta$  cells (e.g. through exposure to a toxin or following pancreatic surgery). Genetic variants may also code for proteins that increase susceptibility of  $\beta$  cells to environmental toxins or pro-inflammatory cytokines.

Autoimmune destruction and other disorders of the pancreas leading to loss of  $\beta$ -cell mass are discussed in subsequent sections. Increasing age is associated with a decline in  $\beta$ -cell mass and function and exposure to certain chemicals (notably alcohol) can also be toxic to  $\beta$  cells.

Elevated plasma glucose and FFAs exert toxic (and potentially reversible) effects on pancreatic  $\beta$  cells, respectively known as glucotoxicity and lipotoxicity. These effects are often apparent as severe hyperglycaemia (and even ketoacidosis) and may occur at the time of diagnosis of diabetes.

In type 2 diabetes, deposition of a peptide known as islet amyloid polypeptide may be observed in islets. It is not entirely clear if this contributes to the decline in  $\beta$ -cell function in type 2 diabetes or if it is simply a manifestation of other insults to the pancreas. Obesity is a pro-inflammatory state and cytokines released from adipose tissue (including IL-1 $\beta$ , IFN- $\gamma$ , TNF- $\alpha$ , leptin and resistin) may also contribute to  $\beta$ -cell dysfunction in type 2 diabetes.

21.7 Factors associated with insulin resistance and insulin deficiency	
Insulin resistance	Insulin deficiency
Genetic factors*	Genetic factors*
Single gene mutations	Single gene mutations
Multiple gene variants	Multiple gene variants
Central obesity	Increasing age
Ethnicity	Autoimmune destruction
Reduced physical activity	Pancreatic pathology (see Box 21.6)
Hormone excess (see Box 21.6)	Toxins, e.g. alcohol, cytokines
Drugs, e.g. glucocorticoids	Infections, e.g. SARS-CoV-2
	Glucotoxicity
	Lipotoxicity
	Deposition of islet amyloid polypeptide
*Single gene mutations generally have a large effect size, while gene variants individually have a small effect size, but collectively the effect size can be important.	

21.8 Monogenic diabetes mellitus: maturity-onset diabetes of the young (MODY)		
Functional defect	Main type*	Gene mutated*
$\beta$ -cell glucose sensing	MODY2	<i>GCK</i>
The set point for basal insulin release is altered, causing a high fasting glucose, but sufficient insulin is released after meals. As a result, the HbA <sub>1c</sub> is often normal and microvascular complications are rare. Treatment is rarely required.		
$\beta$ -cell transcriptional regulation	MODY3 MODY5 MODY1	<i>HNF1<math>\alpha</math></i> <i>HNF1<math>\beta</math></i> <i>HNF4<math>\alpha</math></i>
Diabetes develops during adolescence/early adulthood and can be managed with diet and tablets for many years, but ultimately, insulin treatment is required. The <i>HNF1<math>\alpha</math></i> and <i>4<math>\alpha</math></i> forms respond particularly well to sulphonylurea drugs. All types are associated with microvascular complications. <i>HNF1<math>\beta</math></i> mutations also cause renal cysts and renal failure.		
*Other gene mutations have been found in rare cases. For further information, see diabetesgenes.org.		

## Type 1 diabetes

### Pathogenesis

Type 1 diabetes is an immune-mediated disorder involving T-cell destruction of  $\beta$  cells in the pancreatic islets ('insulinitis'). The natural history of type 1 diabetes is classically based on a 'gene-environment interaction' model, i.e. genetically susceptible individuals develop  $\beta$ -cell autoimmunity following exposure to an environmental trigger. This results in a progressive loss of  $\beta$  cells over a period of months or years, until they have little functional capacity (Fig. 21.8). Although insulinitis is a T-cell-mediated response, circulating autoantibodies to islet and/or  $\beta$ -cell antigens can be present long before the clinical presentation of type 1 diabetes (see p. 712).

The histological appearance of insulinitis is of an inflammatory infiltrate of mononuclear cells (activated macrophages, helper cytotoxic and suppressor T lymphocytes, natural killer cells and B lymphocytes) within islets (see Fig. 21.8). The specific mechanisms inducing this process are unknown, but the hypothesis that it is triggered in susceptible individuals by viral infection has been supported by detection of enterovirus-specific mRNA in fresh pancreatic tissue samples from recently diagnosed adults. Even when type 1 diabetes is established, heavily infiltrated islets may be seen adjacent to unaffected lobules. Although the principal metabolic effect of insulinitis is  $\beta$  cell destruction, inflammation can also be detected in adjacent exocrine (acinar) tissue.

### Genetic predisposition

Type 1 diabetes is strongly influenced by genetic factors, but does not follow a simple Mendelian pattern of inheritance. Monozygotic twins have a concordance rate of 30%–50% for the condition, while dizygotic twins have a concordance of 6%–10%. In the United States, the risk of developing type 1 diabetes is 1:20 for those with a first-degree relative, compared with 1:300 in the general population. Children of mothers with type 1 diabetes have a 1%–4% risk of developing type 1 diabetes, but children of fathers with type 1 diabetes have a 10% risk. If both parents have the condition the risk is up to 30%. Notwithstanding this genetic influence, 80%–85% of new cases do not have a family history.

These observations are consistent with polygenic inheritance (see Box 21.6); over 20 different regions of the human genome have an association with type 1 diabetes risk. Most interest has focused on the human leucocyte antigen (HLA) region within the major histocompatibility complex on the short arm of chromosome 6. The HLA haplotypes *DR3* and/or *DR4* are associated with increased susceptibility to type 1

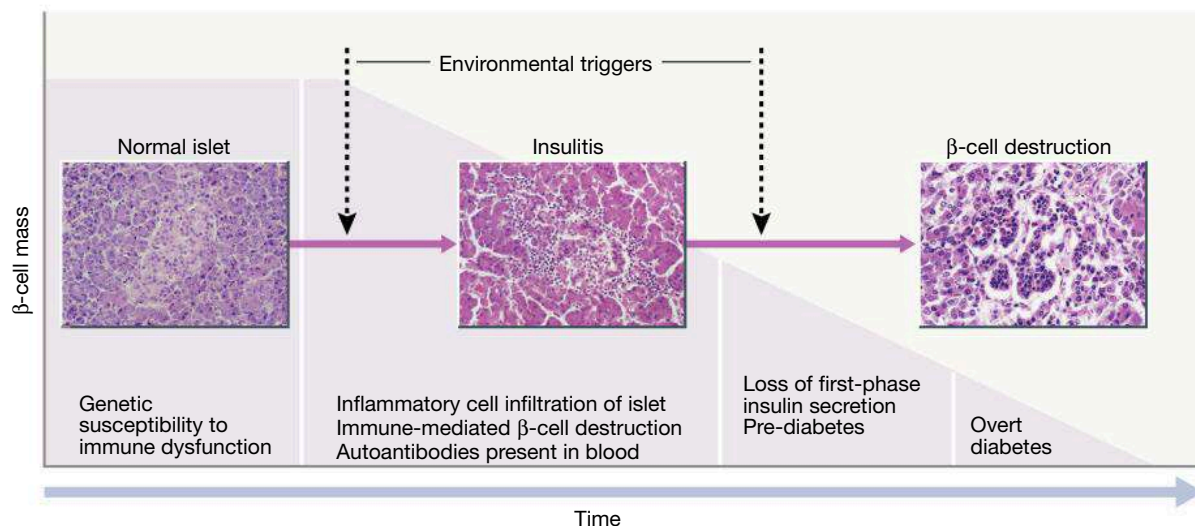

diabetes in people of European descent and are in 'linkage disequilibrium' (i.e. tend to be transmitted together) with the neighbouring alleles of the *HLA-DQA1* and *DQB1* genes. The latter may be the main determinants of genetic susceptibility, since these HLA class II genes code for proteins on the surface of cells that present foreign and self-antigens to T lymphocytes (p. 78). However, candidate gene studies and genome-wide association studies have also implicated other genes, e.g. *CD25*, *PTPN22*, *SH2B3*, *IL2RA* and *IL-10*. The majority of these risk loci are involved in immune responsiveness, such as recognition of pancreatic islet antigens, T cell development and immune regulation. The genes associated with type 1 diabetes overlap with those for coeliac disease and thyroid disease, consistent with clustering of these conditions in individuals or families.

### Environmental predisposition

The wide geographical and seasonal variations in incidence, and the rapid acquisition of local disease incidence rates in migrants from low- to high-incidence countries, suggest that environmental factors have an important role in precipitating the development of type 1 diabetes.

Although there are many hypotheses, the nature of these environmental factors is unknown. They may trigger type 1 diabetes through direct toxicity to  $\beta$  cells or by stimulating an autoimmune reaction directed against  $\beta$  cells. Potential candidates fall into four main categories:

1. Viruses: in addition to enteroviruses (e.g. Coxsackie B4), other viruses including mumps, rubella (in utero), cytomegalovirus, Epstein–Barr virus and most recently retroviruses.
2. Toxins: various dietary nitrosamines (found in smoked and cured meats) and coffee. Bovine serum albumin (BSA), a major constituent of cow's milk, has also been implicated, since children who are given cow's milk early in infancy are more likely to develop type 1 diabetes than those who are breastfed. BSA may cross the neonatal gut wall and raise antibodies that cross-react with a heat-shock protein expressed by  $\beta$  cells.
3. Hygiene hypothesis: it has been proposed that reduced exposure to microorganisms in early childhood limits maturation of the immune system and increases susceptibility to autoimmune disease.
4. Vitamin D: as the highest incidences are in areas where there is less sunlight (including northern Europe), low levels of vitamin D may be important. However, no clear cause–effect relationship has been identified.

**Fig. 21.8 Pathogenesis of type 1 diabetes.** Proposed sequence of events in the development of type 1 diabetes. Environmental triggers are described in the text. *Insets* (normal islet,  $\beta$ -cell destruction) Courtesy of Dr A. Foulis, Department of Pathology, University of Glasgow.

Immune checkpoint inhibitors, increasingly used in oncology, can trigger the development of autoimmune disorders, including type 1 diabetes (see Ch. 7). The natural history of the onset of immune-mediated destruction of the pancreas seems to occur at an accelerated rate compared to the standard trajectory of type 1 diabetes, and there is often very severe insulin deficiency resulting in marked glycaemic variability.

### Metabolic disturbances in type 1 diabetes

Type 1 diabetes presents when progressive  $\beta$ -cell destruction has crossed a threshold at which adequate insulin secretion and normal blood glucose levels can no longer be sustained. Above a certain level, high glucose levels are toxic to the remaining  $\beta$  cells (glucotoxicity) so that profound insulin deficiency rapidly ensues, causing the metabolic sequelae shown in Figure 21.9. Hyperglycaemia leads to glycosuria and dehydration, while glycosuria, lipolysis and proteolysis result in weight loss. Ketoacidosis occurs when generation of ketones exceeds the capacity for their metabolism. Elevated blood  $H^+$  ions drive  $K^+$  out of the intracellular compartment, while secondary hyperaldosteronism encourages urinary loss of  $K^+$ . Thus, new cases of type 1 diabetes usually present with a short history (typically a few weeks) of hyperglycaemic symptoms (see Box 21.9) and weight loss, and in the most severe cases (usually when the diagnosis is delayed) DKA can develop (p. 721).

### Clinical course of type 1 diabetes

The natural course of type 1 diabetes involves initially a loss of first-phase insulin secretion, followed by a period of pre-diabetes and then clinically undiagnosed diabetes, before a diagnosis of diabetes is made (Fig. 21.8). By this point, more than 80%–90% of  $\beta$ -cell mass has usually been destroyed. Following institution of insulin therapy, there may be a 'honeymoon period' lasting several weeks or months, during which there is a partial recovery in  $\beta$ -cell function as the glucotoxic effect is reversed by correction of hyperglycaemia. During the honeymoon period, the

production of significant endogenous insulin means that exogenous insulin requirements may be very low and some individuals may even be able to stop insulin for a few weeks or months. Typically glycaemic control is good during this period, with modest glucose variability and a low risk of hypoglycaemia. In most patients, the immune-mediated process eventually destroys the majority of remaining  $\beta$ -cells, resulting in severe insulin deficiency, increased requirements for exogenous insulin and more marked glycaemic variability.

It is increasingly recognised that a proportion of individuals with type 1 diabetes retain in the long term a subset of viable  $\beta$  cells with a capacity to secrete small amounts of endogenous insulin. The resulting spectrum of retained endogenous insulin production can be identified by measuring C-peptide (see p. 712). A shorter duration of diabetes and a later age at onset are associated with increased likelihood of significant detectable C-peptide. As exemplified by the honeymoon period, higher C-peptide concentrations are associated with reduced glucose variability and hypoglycaemia, and increased time in range (Fig. 21.10). Higher C-peptide concentrations are also associated with reduced  $HbA_{1c}$ , exogenous insulin requirements, frequency of ketoacidosis and microvascular

### 21.9 Symptoms of hyperglycaemia

- Polyuria
- Nocturia
- Thirst, dry mouth
- Polydipsia
- Tiredness, fatigue, lethargy
- Change in weight (usually weight loss)
- Blurring of vision
- Pruritus vulvae, balanitis (genital candidiasis)
- Nausea
- Headache
- Hyperphagia; predilection for sweet foods
- Mood change, irritability, difficulty in concentrating, apathy

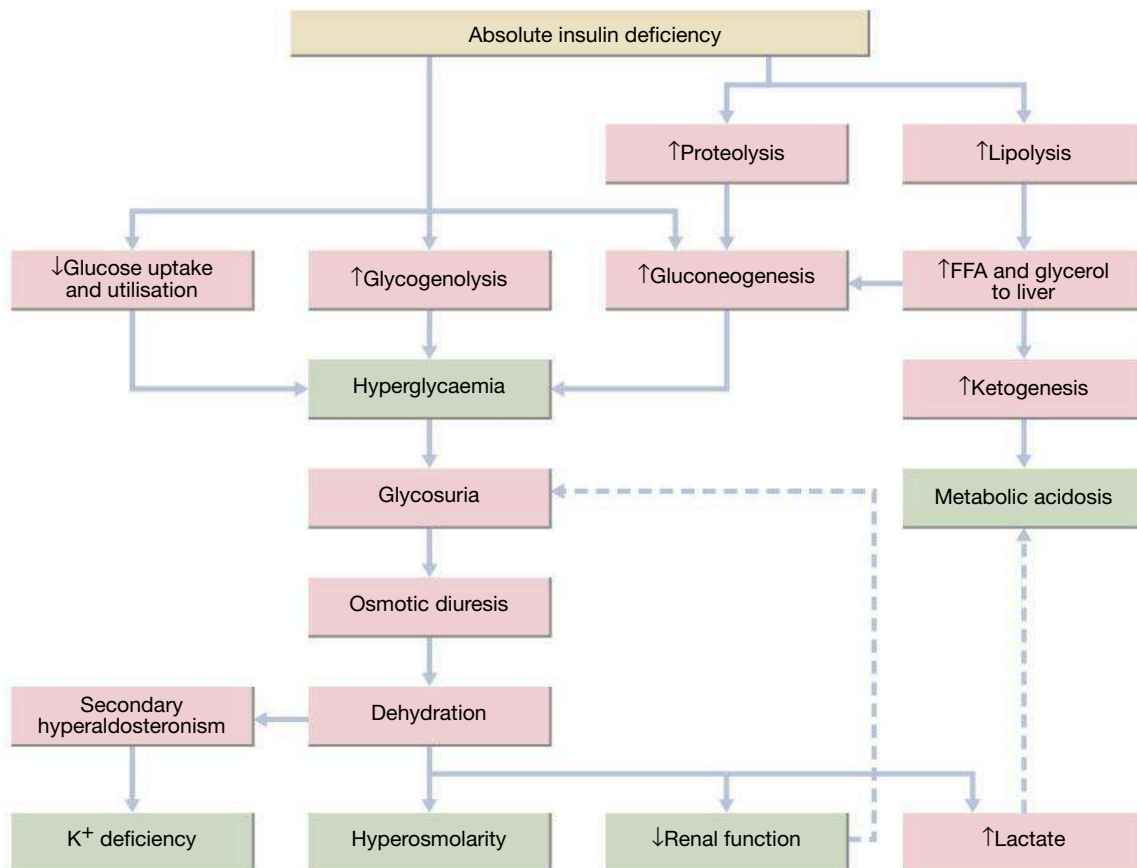

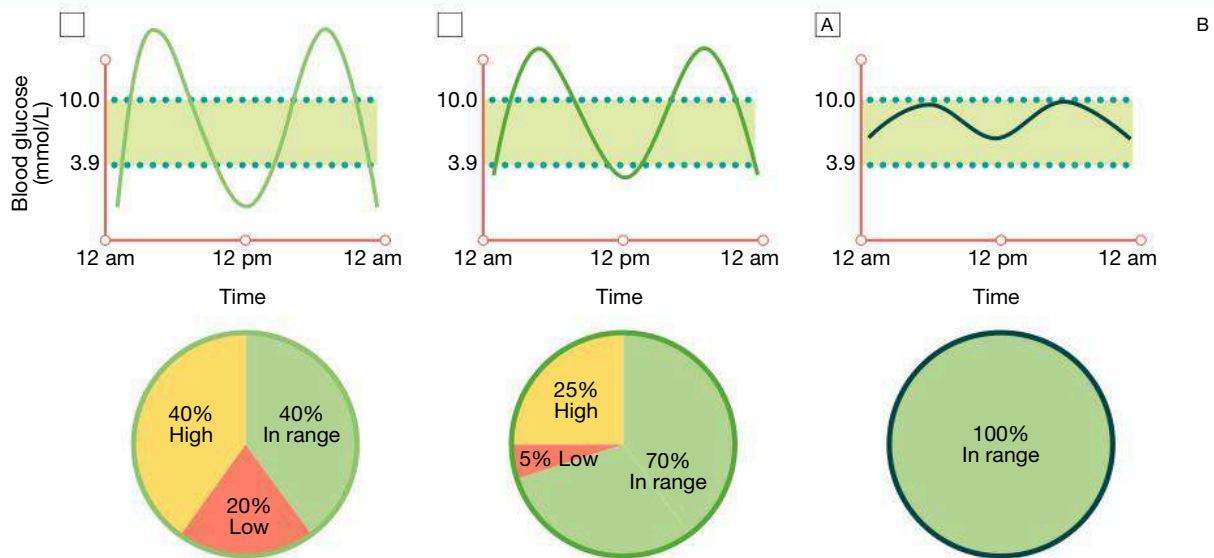

Fig. 21.9 Acute metabolic complications of insulin deficiency. (FFA = free fatty acid)

**Fig. 21.10** Patterns of glycaemic variability in type 1 diabetes. Three patterns of glycaemic variability are shown, all associated with the same average blood glucose (8.6 mmol/L). **A** High variability with only 40% time in range (TIR); **B** Acceptable variability with 70% TIR. **C** Ideal profile with 100% TIR. Glycaemic variability is affected by many factors including individual behaviours (carbohydrate intake, timing and dose of insulin) and C-peptide status (high C-peptide associated with low glycaemic variability).

complications. There is currently much research activity aimed at halting or slowing the decline in endogenous insulin production early in the course of type 1 diabetes ('C-peptide preservation'), using agents such as biologic immunosuppressants.

### Type 1 diabetes presenting in adults

While type 1 diabetes is classically thought of as a disease of children and young adults (most commonly presenting between 5 and 7 years of age and at or near puberty), it can manifest at any age. Over 40% of cases developing in adults over 30 years of age – although some of these diagnoses may be incorrect, with a small proportion actually having unrecognised type 2 diabetes or monogenic diabetes.

Some adults have a more insidious onset of hyperglycaemia and have 'slowly evolving immune-mediated diabetes of adults', previously known as 'latent autoimmune diabetes of adulthood' (LADA). This is essentially a subset of type 1 diabetes with usually a single islet autoantibody present in high titre (usually anti-GAD), greater retention of  $\beta$ -cell function and hyperglycaemia that does not require immediate commencement of insulin therapy. Affected individuals often have features of the metabolic syndrome and are initially managed with a working diagnosis of type 2 diabetes, but recognised retrospectively as having progressed more rapidly to requiring insulin treatment than is typical for type 2 diabetes.

## Type 2 diabetes

### Pathogenesis

Type 2 diabetes is a heterogeneous condition characterised by varying degrees of insulin resistance and  $\beta$ -cell dysfunction, commonly associated with obesity. Approximately 40% of overall type 2 diabetes risk is determined by genetic factors, with the rest due to environmental (acquired) factors. Insulin resistance and  $\beta$ -cell dysfunction have both genetic and environmental determinants (see relevant sections above). The relative contribution of insulin resistance and  $\beta$ -cell dysfunction varies between individuals, with most having an important contribution from both factors, but some having severe insulin resistance with less marked  $\beta$ -cell dysfunction, and others having significant insulin deficiency and minimal insulin resistance. For example, type 2 diabetes is increasingly seen in children and young adults, usually driven by insulin resistance due to extreme obesity (often on a background of an ethnic predisposition to diabetes). By contrast, type 2 diabetes may also occur in non-obese individuals (who have more pronounced  $\beta$ -cell dysfunction), particularly in the elderly. Many of the rarer types of diabetes (see [Box 21.6](#)) were

**Fig. 21.11** Natural history of type 2 diabetes. Individuals predisposed to type 2 diabetes may have insulin levels at the lower end of normal and higher than normal insulin resistance (not shown in this figure), due to genetic factors. As insulin resistance increases (green) there is a compensatory increase in insulin secretion (grey), which initially maintains plasma glucose (blue) in the normal range. Eventually, the  $\beta$  cells are unable to compensate adequately and blood glucose rises, producing hyperglycaemia. Normal ranges are shown by horizontal bars shaded in same colours. Redrawn with permission from the original courtesy of Professor E. Ferrannini, University of Pisa.

previously categorised as type 2 diabetes, and it is likely that this list will expand in time as genetic studies provide more insights into the aetiology of diabetes. The natural history of 'typical' type 2 diabetes is shown in [Figure 21.11](#). Individuals at high risk of type 2 diabetes usually have a degree of genetic predisposition to either pancreatic  $\beta$ -cell dysfunction (measured as  $\beta$ -cell glucose sensitivity), insulin resistance (measured as insulin-mediated glucose uptake) or both. Each of these phenotypes declines with age and the trajectory of decline is particularly determined by weight gain. The resulting rise in glucose levels over time (initially small) is compensated by an increase in insulin secretion rate, which is teleologically a homeostatic attempt to maintain normal blood glucose levels. However, unless weight gain can be reversed at an early stage,  $\beta$ -cell function continues to decline such that a relative state of insulin deficiency in prediabetes and early diabetes becomes absolute. This is mediated by obesity-associated factors such as glucotoxicity, lipotoxicity, pro-inflammatory cytokines and/or the deposition of amyloid polypeptide in pancreatic islets. It has been estimated that at the time of diagnosis of type 2 diabetes, around 50% of  $\beta$ -cell function has been

lost. As  $\beta$ -cell function continues to decline over time, there is an escalating requirement for glucose-lowering therapy. In the most extreme form, there is pancreatic  $\beta$ -cell 'exhaustion' and, as in type 1 diabetes, insulin therapy is required to prevent ketoacidosis.

### Risk factors for type 2 diabetes

#### Genetic predisposition

Genetic factors are important in type 2 diabetes, as shown by marked differences in susceptibility in different ethnic groups and by studies in monozygotic twins in whom concordance rates for type 2 diabetes approach 100%. People with an affected sibling with onset before the age of 40 have a 50% lifetime risk, declining to 30% if the sibling's age is >65 years. Genome-wide association studies have identified >400 gene variants that are associated with type 2 diabetes, each exerting a small effect and together explaining only about 10% of the overall genetic variance. Most code either for proteins involved in  $\beta$ -cell function or in regulation of cell cycling and turnover (i.e.  $\beta$ -cell mass); a smaller proportion affect control of appetite and satiety (i.e. individual susceptibility to weight gain) and insulin resistance. Thus, the major genetic susceptibility to type 2 diabetes relates to how well an individual's pancreas produces insulin. The largest population genetic effect described to date is a variation in *TCF7L2* (a transcription factor involved in glucose metabolism in pancreas and liver); 10% of the population have two copies of the risk variant for this gene and have a nearly two-fold increase in risk of developing type 2 diabetes. Other common variants explain much lower risk than this, with many explaining less than a 10% increase. However, an individual with a high genetic burden (e.g. more than 40 risk variants) compared to one with very few is more than 2.5 times more likely to develop diabetes. Rarer variants tend to have larger effects on type 2 diabetes risk than common variants: e.g. in Greenland 3% of people carry a homozygous variant in an insulin signalling gene, *TBC1D4*, that results in muscle insulin resistance and a 10-fold increased risk of type 2 diabetes.

#### Lifestyle factors and obesity

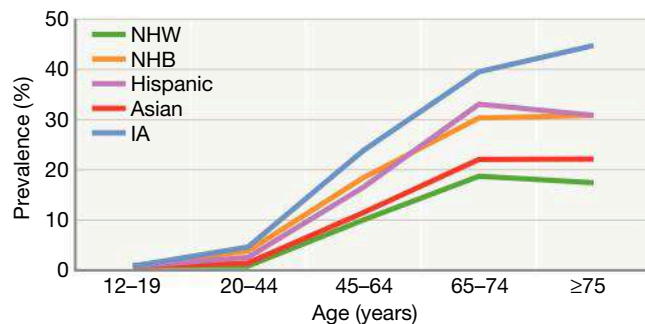

Epidemiological studies show that type 2 diabetes is associated with reduced physical activity and a diet high in saturated fats and refined sugars, and low in fresh fruit and vegetables. Type 2 diabetes is also strongly associated with economic deprivation, social disadvantage, excess alcohol consumption and smoking. These factors are all in turn associated with obesity, which is strongly linked with insulin resistance. The risk of developing type 2 diabetes increases with rising body mass index (BMI), such that risk is increased 10-fold in people with a BMI of more than 30 kg/m<sup>2</sup> (Ch. 22). However, although the majority of individuals with type 2 diabetes are obese, only a minority of obese people develop diabetes, as most obese people are able to increase insulin secretion to compensate for the increased demand resulting from obesity and insulin resistance. Those who develop type 2 diabetes are less able to produce sufficient insulin to overcome insulin resistance because of genetic and/or acquired factors.

#### Age

Type 2 diabetes is more common with increasing age (see Fig. 21.12). In the UK, it now affects approximately 25% of people aged between 60 and 80 years. In 2019, over 80% of all cases of type 2 diabetes in Scotland occurred after the age of 50 years. This association reflects declining  $\beta$ -cell mass and function with increasing age and the increasing tendency to insulin resistance due to greater obesity and reduced lean muscle mass.

#### Ethnicity

The prevalence of type 2 diabetes varies considerably according to ethnicity. For example, Figure 21.12 shows that within the United States the prevalence of diabetes is lowest in those of non-Hispanic White ethnicity and increases across the categories of non-Hispanic Black, Hispanic, Asian and finally Indigenous peoples. Genetic factors are likely to explain some of this variance, but environmental factors are also important, such as cultural practices and socio-economic status, which in turn are reflected in diet, physical activity and levels of obesity.

**Fig. 21.12** Age-specific prevalence of diagnosed type 2 diabetes in the United States by ethnicity. NHW = non-Hispanic White; NHB = non-Hispanic Black; IA = Indigenous American. Adapted from Golden et al. *Racial/ethnic differences in the burden of type 2 diabetes over the life course: a focus on the USA and India*. *Diabetologia* 2019; 62(10):1751–1760. © Springer-Verlag GmbH Germany, part of Springer Nature, 2019.

**Fig. 21.13** Relationship between age of onset of type 2 diabetes and body mass index. On average, type 2 develops at a younger age in people with increased body mass index.

#### Interaction of risk factors for type 2 diabetes

In addition to the risk factors described above, type 2 diabetes is also more common in people with previous 'stress hyperglycaemia', in women with previous gestational diabetes and in those who had a very low birth weight. All the risk factors for type 2 diabetes are inter-related and usually have additive effects. For example, increasing BMI is associated with a younger age of onset of type 2 diabetes (Fig. 21.13), because increased insulin resistance unmasks the genetic inability of the pancreas to produce adequate amounts of insulin. Type 2 diabetes also occurs at a younger age and lower BMI in people whose father and mother are both affected, presumably because they have inherited an increased number of genetic variants associated with  $\beta$ -cell dysfunction and insulin resistance. The threshold of weight gain at which type 2 diabetes occurs is lower for South Asians, who develop the condition on average 5–10 years earlier than people of European descent.

#### Clinical course and metabolic disturbances in type 2 diabetes

In comparison with type 1 diabetes, the risk of acute metabolic decompensation is low in type 2 diabetes due to relative rather than absolute insulin deficiency. Even small amounts of insulin are sufficient to suppress lipolysis and proteolysis, so profound weight loss and DKA are much less common. Hyperglycaemia may therefore be detected incidentally on screening, or even following detection of retinal abnormalities at a routine optician appointment, i.e. before the onset of symptoms. The proportion of cases remaining undetected at any one time varies among health-care systems, but is estimated to be as high as 20%. At diagnosis, there may be a history of fatigue and 'osmotic symptoms' (thirst, polyuria and nocturia) for many months.

However, despite the 'typical' natural history of type 2 diabetes, it is important to remember that some people with type 2 diabetes develop marked and acute osmotic symptoms and weight loss. This may be a

late presentation with advanced  $\beta$ -cell failure (and absolute insulin deficiency), but more often acute decompensation reflects a 'vicious spiral' of decline which is at least in part reversible. In this scenario, severe hyperglycaemia is associated with a craving for sugar, with large volumes of sugary drinks consumed in an effort to quench thirst. This causes glucotoxicity leading to reduced insulin secretion and increased lipolysis with high circulating FFAs aggravating the decompensation (lipotoxicity). Education and dietary intervention can lead to rapid symptomatic improvement, but in the most severe instances, hyperglycaemic hyperosmolar state (p. 723) and even diabetic ketoacidosis (DKA) can occur.

Ketosis and DKA in type 2 diabetes is referred to as 'ketosis-prone' diabetes or 'Flatbush syndrome'. This was named after the Flatbush neighbourhood of New York, which had a large population of African American and African Caribbean origin and in which presentation with DKA was noted in the 1980s to be as common with type 2 diabetes as with type 1 diabetes. It remains unclear whether ketosis-prone diabetes is a unique type or a subset of more severe type 2 diabetes, but it is now recognised to occur in sub-Saharan African, South Asian and Hispanic populations. Importantly in this scenario, insulin treatment is required initially, but as glucose and lipid levels are controlled,  $\beta$  cells recover and oral treatments such as metformin can be effective within 3 months, i.e. insulin treatment can be carefully discontinued.

Intercurrent illness, e.g. infection (including with COVID-19, p. 293) or acute myocardial infarction, increases the production of stress hormones that oppose insulin action. This can precipitate an acute exacerbation of insulin resistance and insulin deficiency, and result in more severe hyperglycaemia and dehydration with ketosis (p. 745). If the hyperglycaemia resolves following successful treatment of the illness, then this is retrospectively termed 'stress hyperglycaemia'. Affected individuals have a significantly increased risk of type 2 diabetes in subsequent years, presumably because they had pre-existing  $\beta$ -cell dysfunction and/or insulin resistance. In some individuals, hyperglycaemia persists, probably because of undiagnosed type 2 diabetes that was exacerbated by the acute illness.

## Other forms of diabetes

Other causes of diabetes are shown in [Box 21.6](#). These can broadly be classified as:

- genetic disorders, which are either monogenic (mutation in or deletion of a single gene) or part of a genetic syndrome
- secondary to endocrine disorders, e.g. excess secretion of counter-regulatory hormones (those that oppose the effects of insulin)
- secondary to more generalised diseases of the pancreas (most commonly pancreatitis and cystic fibrosis)
- drug-induced causes, e.g. glucocorticoid therapy, which may precipitate hyperglycaemia ('steroid-induced diabetes') in susceptible individuals (i.e. with pre-existing insulin-resistance and/or  $\beta$ -cell dysfunction). Affected individuals who recover normal glucose tolerance after cessation of the precipitating drug remain at increased risk of type 2 diabetes.

## Pancreatic diabetes

Diabetes due to more generalised pancreatic disease is a common form of 'secondary diabetes', which is often not accurately distinguished from other forms of diabetes. It may be caused by acute or chronic pancreatitis, either due to alcohol excess or to gall bladder (stone) disease. While chronic pancreatitis may be associated with recurrent abdominal pain, it can also be asymptomatic in many patients. As it may go unrecognised, it is important to be aware of the possibility of pancreatic exocrine deficiency in all cases of diabetes; this can be detected by screening for low faecal enzyme elastase in a stool sample, particularly in the presence of chronic diarrhoea (see p. 850). Adequate oral pancreatic enzyme replacement can reduce abdominal pain, improve absorption of ingested nutrients and enhance well-being. This may facilitate adjustment of insulin doses and reduces risk of hypoglycaemia in affected individuals, who usually require insulin therapy.

In some geographical regions, including South Asia, a form of chronic calcific pancreatitis heralded by chronic abdominal pain can present in adolescence or early adulthood (known as fibrocalculous pancreatic diabetes). It is associated with mutations in the gene *SPINK1*, which codes for an anti-protease enzyme and is therefore now thought to result from slow pancreatic auto-digestion. It is also associated with a high risk of pancreatic cancer.

Diabetes may also be a consequence of other disorders involving the pancreas, including haemochromatosis ('bronze diabetes'), cystic fibrosis and pancreatic carcinoma.

## Monogenic diabetes

Monogenic diabetes accounts for approximately 4% of diabetes in those diagnosed under the age of 30 in the UK. While there are a number of monogenic disorders of insulin action, the most common are caused by defects in insulin secretion. Monogenic disorders of the  $\beta$  cell cause two diabetes subtypes: maturity-onset diabetes of the young (MODY; see [Box 21.8](#)) and neonatal diabetes. The common genes involved in MODY and neonatal diabetes are shown in [Figure 21.3C](#).

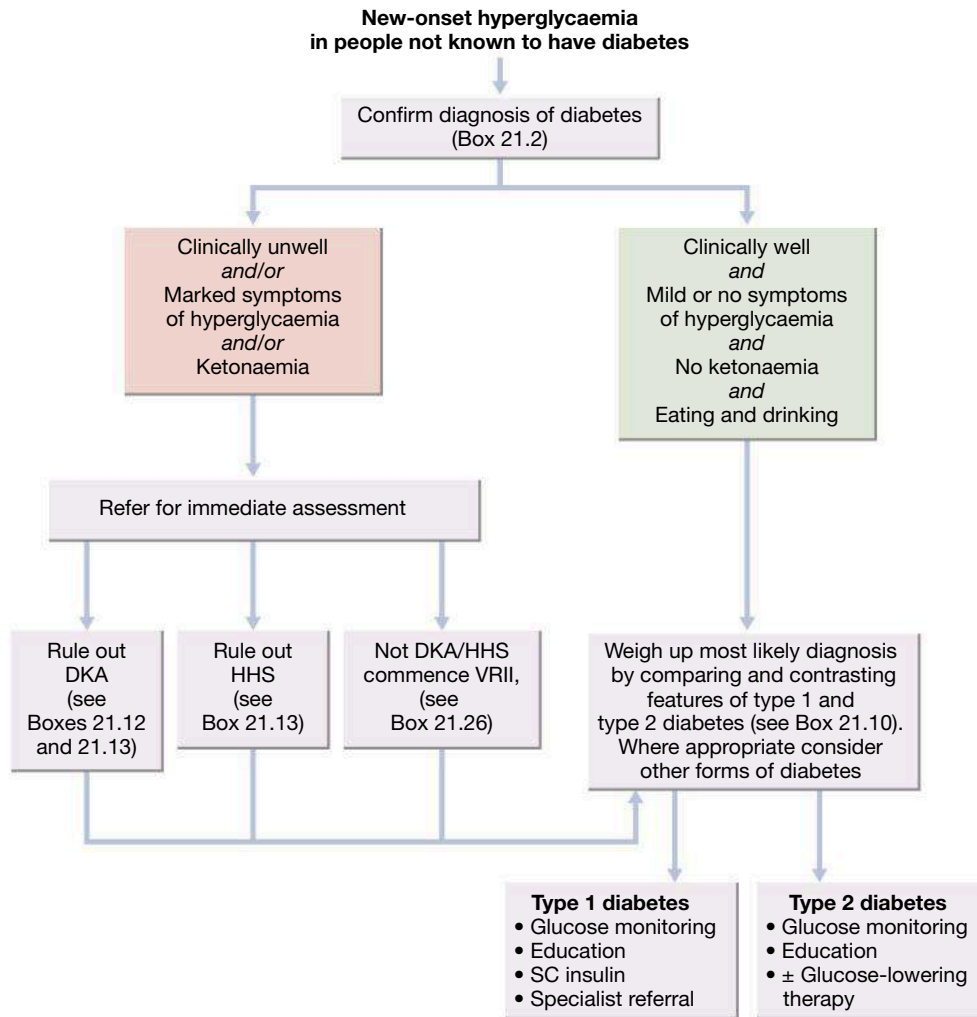

The term MODY was coined in 1974 to signify non-insulin-requiring diabetes developing under the age of 25 years in at least one family member. It is dominantly inherited, which means that many cases have a family history of diabetes spanning three generations or more. MODY has been recognised since the 1990s to be a heterogeneous condition, with multiple single gene subtypes. One form is caused by a mutation in the  $\beta$ -cell glucose sensor enzyme glucokinase (see [Fig. 21.3B](#)) and affected individuals have an altered set-point for glucose. Glucokinase MODY results in a high fasting glucose (usually  $>5.5$  mmol/L (99 mg/dL)), but a normal post-prandial response and slight elevation of HbA<sub>1c</sub>. It is important to identify these individuals as they do not develop diabetes complications and do not require glucose-lowering drug therapy and monitoring. The other forms of MODY are mostly caused by defective transcription factors that play a key role in  $\beta$ -cell development and function (hepatocyte nuclear factor (HNF) 1 $\alpha$ , 1 $\beta$  and 4 $\alpha$ ). Patients with transcription factor MODY develop progressive diabetes in adolescence or early adulthood and the diabetes is progressive, requiring oral glucose-lowering therapy before eventually needing insulin. Patients with HNF1 $\alpha$  and 4 $\alpha$  MODY are extremely sensitive to sulphonylureas, so this is the treatment of choice for these individuals. Many cases have been described in which after genetic diagnosis it has been possible to discontinue long-term insulin therapy. As HNF1 $\beta$  is a critical transcription factor not only in pancreatic development, but also in renal and genital tract development in utero, individuals with *HNF1 $\beta$*  mutations often have renal cystic disease and genital tract malformation including infertility.

Neonatal diabetes is variably defined as diabetes that presents in the first 6 months of life, presenting as profound insulin deficiency with hyperglycaemia and DKA. Approximately half of patients with neonatal diabetes have a transient form that remits by about one year of age, with diabetes recurring in adolescence or early adulthood; the remainder have permanent neonatal diabetes. Approximately two-thirds of individuals with the permanent form have an activating mutation in genes encoding the KIR6.2 and SUR1 subunits of the K<sub>ATP</sub> channel (see [Fig. 21.3C](#)). These cause it to be insensitive to glucose-mediated increase in intracellular ATP; as a result, pancreatic  $\beta$  cells do not secrete insulin and insulin treatment is required from soon after birth. However, as affected individuals respond to sulphonylureas, genetic diagnosis can transform their lives, with over 90% managed with oral sulphonylurea treatment. The K<sub>ATP</sub> channel is found in neurons so mutations can severely affect their function causing developmental delay and epilepsy. Early sulphonylurea treatment can in some cases prevent or improve these neurological consequences.

## Presenting problems in diabetes

### Hyperglycaemia

Although the presence or absence of diabetes is simply based on confirmation of hyperglycaemia above the diagnostic threshold, defining

**Fig. 21.14** Assessment and initial management of new-onset hyperglycaemia. (DKA = diabetic ketoacidosis; HHS = hyperosmotic hyperglycaemic state; VRIL = variable rate insulin infusion)

which type of diabetes has developed can be more complex in some individuals. Initial management involves a careful clinical assessment to decide whether (and if so what type of) immediate treatment is required (Fig. 21.14). Failure to initiate insulin treatment when it is required can result in the development of DKA and even death. Therefore, when the cause of diabetes is in doubt, it may be necessary to start insulin treatment with a view to later withdrawal if it becomes apparent alternative glucose-lowering therapy is sufficient. Such decisions require careful discussion and explanation at a time of high stress.

The classical symptoms of hyperglycaemia and clinical features of type 1 and type 2 diabetes are shown respectively in Box 21.9 and Box 21.10. The classic ‘osmotic symptoms’ of polyuria (including nocturia), thirst and polydipsia are a consequence of the diuretic effect of significant glycosuria. Weight loss is due to dehydration and loss of calories in urine from glycosuria and, in type 1 diabetes, proteolysis and lipolysis. Severe osmotic symptoms and rapid weight loss are classically associated with the onset of type 1 diabetes, but type 2 diabetes may also present with these symptoms. Uncontrolled hyperglycaemia is associated with increased susceptibility to infection, such as skin infection (boils), genital candidiasis (with pruritus) or urine infection (see p. 748).

At the extremes of age, the distinction between type 1 and type 2 diabetes is usually obvious, but uncertainty can occur, particularly between the ages of 25 and 50 years. However, although type 2 diabetes is classically a condition of middle and old age, it is increasingly diagnosed in children and young adults. Type 1 diabetes most

commonly occurs in younger people, but can occur at any age and may develop more insidiously in older individuals (p. 717). Family history of diabetes is common in type 2 diabetes and MODY and there may be a family history of autoimmune conditions in type 1 diabetes. Ethnicity and obesity may point to a diagnosis of type 2 diabetes, but type 1 diabetes can present in any race and at any weight, and it is important not to assign an incorrect diagnostic label at an early stage simply based on stereotypical features. Other causes of diabetes (see Box 21.6), such as pancreatic diabetes, should not be forgotten, particularly if there are suggestive symptoms or signs (e.g. chronic alcohol excess).

All patients presenting with hyperglycaemia should be tested for ketonuria/ketonaemia. The presence of raised ketones implies absolute insulin deficiency and indicates the need for referral to a secondary care centre for further assessment and treatment. This will usually indicate a diagnosis of type 1 diabetes but it should be remembered that 10%–15% of cases of DKA occur in people with type 2 diabetes. Islet autoantibody and C-peptide testing can be helpful in establishing the underlying cause of diabetes (p. 712), although C-peptide is most discriminatory when used at least 3 years after diagnosis (see Box 21.10). Sometimes it may be necessary for clinicians to counsel patients that their diagnosis is provisional and that a definitive diagnosis will only be possible once time has elapsed, the results of supplementary investigations are available and the responsiveness to different therapies can be assessed.

### 21.10 Typical characteristics of type 1 and type 2 diabetes<sup>1</sup>

	Type 1	Type 2
Age at onset	< 40 years	> 50 years
Duration of symptoms	Weeks	Months to years
Body weight	Normal or low	Obese
Ketonuria	Yes	No
Non-fasting serum C-peptide <sup>2</sup>	<200 pmol/L	>900 pmol/l
Rapid ketosis/decompensation without insulin treatment	Yes	No
Autoantibodies	Positive	Negative
Family history of diabetes	Less common	Common
Other autoimmune disease	Common	Uncommon

<sup>1</sup>The data in this table are typical examples; however, none of these are perfect discriminators, e.g. obese people can get type 1 diabetes; young adults can get type 2 diabetes. <sup>2</sup>C-peptide is most discriminatory when used >3 years after diagnosis. C-peptide may be >200 pmol/L in people with type 1 diabetes in the 'honeymoon period' and may be <600 pmol/l in people with type 2 diabetes who have a marked hyperglycaemia (due to glucotoxicity).

### Diabetic ketoacidosis

DKA is an acute metabolic complication of diabetes that is a consequence of *absolute* insulin deficiency. It is a medical emergency with important complications including hypoglycaemia, hypokalaemia, pulmonary oedema, acute respiratory distress syndrome and cerebral oedema. Although mortality rates have fallen in the UK over the past two decades, a single episode of DKA is associated with an approximate 5% risk of death, rising to almost 25% in those with recurrent DKA, particularly in low- and middle-income countries. Death most commonly relates to the underlying precipitating illness rather than direct metabolic complications. DKA most commonly occurs in people with type 1 diabetes and can be the first presentation of the condition (see Box 21.10). It can also occur in type 2 diabetes, particularly if it has been longstanding or in individuals who are ketosis-prone (i.e. have significant  $\beta$ -cell dysfunction) or who have been misclassified as type 2 rather than type 1 diabetes. In established diabetes, DKA may be precipitated by an underlying illness or physiological stress. Infection is the most common of these: pneumonia and urinary tract infection are often implicated. Acute myocardial infarction, cerebrovascular disease and pancreatitis are other common examples of a precipitating illness. Physiological stress such as surgery, trauma and pregnancy can also be implicated. The second most common cause of DKA is insulin deficiency due to discontinuation (accidental or deliberate) or inadequate delivery (error in administration, insulin pump failure, pen malfunction, out of date or inadequate storage) of insulin. Drug and social history may reveal glucocorticoid, sodium-glucose co-transporter 2 (SGLT2) inhibitors or cocaine use, all of which have been associated with DKA. In young people with recurrent episodes of DKA, psychological or personality factors are frequent causes of insulin omission and infrequent or absent monitoring of glucose levels.

### Pathogenesis

A clear understanding of the biochemical basis and pathophysiology of DKA is fundamental for its efficient treatment (see Fig. 21.9). DKA is characterised by the cardinal biochemical triad of:

- hyperglycaemia (blood glucose >11.1 mmol/L (200 mg/dL)) or known diabetes\* and

- hyperketonaemia ( $\geq 3.0$  mmol/L on fingerprick testing) or ketonuria (more than 2+ on urine dipstick testing) and
- metabolic acidosis (venous bicarbonate <15 mmol/L and/or venous pH <7.3 ( $H^+$  > 50 nmol/L)).

\*DKA can occur without hyperglycaemia ('euglycaemic DKA', i.e. glucose <11 mmol/L (<198 mg/dL)), but this occurs in fewer than 5% of cases.

Severe hyperglycaemia (in some cases >100 mmol/L (1800 mg/dL)) causes a profound osmotic diuresis leading to dehydration and electrolyte loss, particularly of sodium and potassium. Ketosis is a consequence of insulin deficiency, exacerbated by elevated catecholamines and other stress hormones, leading to unrestrained lipolysis and supply of free fatty acids (FFAs) for hepatic ketogenesis. When this exceeds the capacity to metabolise acidic ketones, these accumulate in blood. The resulting metabolic acidosis forces hydrogen ions into cells, displacing potassium ions.

There are significant deficits of water and electrolytes in DKA. The average loss of water in moderately severe DKA in an adult is around 100 ml/kg. About half the deficit of total body water is derived from the intracellular compartment and occurs comparatively early in the development of acidosis with few clinical features; the remainder represents loss of extracellular fluid sustained in the later stages, when marked contraction of extracellular fluid volume occurs, with haemoconcentration, a decreased blood volume, and finally a fall in blood pressure and subsequent oliguria (<0.5 ml/kg/hr). There are also deficits in sodium (7–10 mmol/kg), chloride (3–5 mmol/kg) and potassium (3–5 mmol/kg). The plasma concentration of potassium gives very little indication of the total body deficit. Plasma potassium may even be raised initially due to disproportionate loss of water, catabolism of protein and glycogen, and displacement of potassium from the intracellular compartment by  $H^+$  ions. However, soon after treatment is started, there is likely to be a precipitous fall in the plasma potassium due to dilution of extracellular potassium by administration of intravenous fluids, the movement of potassium into cells induced by insulin, and the continuing renal loss of potassium (due to secondary hyperaldosteronism as a result of reduced renal perfusion).

The level of hyperglycaemia does not correlate with the severity of the metabolic acidosis, i.e. moderate elevation of blood glucose may be associated with life-threatening ketoacidosis. Type 1 diabetes in pregnancy and the use of sodium-glucose co-transporter 2 (SGLT2) inhibitors are two situations in which euglycaemic DKA can occur. Conversely, in other situations, hyperglycaemia predominates and acidosis is minimal, resulting in a hyperosmolar state (p. 723).

### Clinical assessment

The clinical features of ketoacidosis are listed in Box 21.11. These usually progress rapidly over the course of several hours. DKA should be considered if there are the typical presenting symptoms of diabetes in association with nausea, vomiting, abdominal pain, hyperventilation, dehydration or reduced consciousness. In a severe and rapidly progressing case, the striking features are volume depletion, sunken eyes, dry mucous membranes (mouth and nose), dry axillae, decreased skin turgor (e.g. at the subclavicular area), reduced jugular venous pressure, tachycardia and hypotension. Breathing may be deep and sighing (Kussmaul's breathing) due to the compensatory hyperventilation of severe metabolic acidosis. The breath may have the sweet smell of acetone, similar to nail polish remover or pear drops. Acute confusion, a reduced conscious level, or even coma may be present. In infected patients, including those with sepsis, pyrexia may not be present initially because of vasodilatation secondary to acidosis, indeed mild hypothermia may be present. Abdominal pain and vomiting are common features of DKA and may mimic an acute abdomen (see Ch. 9). It is important to examine for signs of a precipitant; auscultation of the chest for signs of consolidation, examination of the abdomen for peritonism or obstruction and inspection of the skin for cellulitis or wounds. Careful examination of the feet for new ulceration or ischaemia is imperative.

21.11 Clinical features of diabetic ketoacidosis	
<b>Symptoms</b>	
<ul style="list-style-type: none"> <li>• Polyuria, thirst</li> <li>• Weight loss</li> <li>• Weakness</li> <li>• Nausea, vomiting</li> </ul>	<ul style="list-style-type: none"> <li>• Leg cramps</li> <li>• Blurred vision</li> <li>• Abdominal pain</li> </ul>
<b>Signs</b>	
<ul style="list-style-type: none"> <li>• Dehydration</li> <li>• Hypotension (postural or supine)</li> <li>• Cold extremities/peripheral cyanosis</li> <li>• Tachycardia</li> </ul>	<ul style="list-style-type: none"> <li>• Air hunger (Kussmaul's breathing)</li> <li>• Smell of acetone</li> <li>• Hypothermia</li> <li>• Delirium, drowsiness, coma (10%)</li> </ul>

### Investigations

Initial assessment should include the following:

- **Venous blood:** for urea and electrolytes, glucose, bicarbonate and acid–base status to confirm the presence of hyperglycaemia and acidosis. Hyponatraemia and hyperkalaemia are common. Serum amylase is usually elevated in DKA, but rarely indicates coexisting pancreatitis.
- **Blood (or urine if unavailable) analysis for ketones** (p. 710).
- **Electrocardiogram (ECG)** to look for evidence of acute myocardial infarction or electrolyte abnormalities.
- **Chest X-ray** to look for evidence of lung consolidation or pulmonary oedema.
- **Infection screen:** full blood count, blood and urine culture, C-reactive protein, COVID-19 swab if at risk. (N.B. leucocytosis occurs commonly in DKA, but generally represents a stress response rather than infection.)
- **Pregnancy test:** in all women of childbearing age.

### Assessment of severity

The presence of one or more of the features listed in [Box 21.12](#) is indicative of severe DKA.

### Management

DKA is a medical emergency that should be treated in hospital, preferably in a high-dependency area. The aims of DKA management are to correct circulating volume and electrolyte imbalance while halting lipolysis and suppressing ketogenesis. It is important to identify and treat precipitating causes as well as to prevent complications. The central tenets of the management of DKA include intravenous insulin, intravenous fluid and potassium replacement. An agreed evidence-based protocol should be in place. A referral to the diabetes specialist team should be made as early as possible with review within 24 hours. Regular clinical and biochemical review is essential, particularly during the first 24 hours of treatment. Monitoring for complications is paramount during management. Vital signs including cardiac monitoring should be regularly assessed per protocol: low oxygen saturations may suggest the development of pulmonary oedema and acute respiratory distress syndrome (ARDS). In children and adolescents, the Glasgow Coma Scale (GCS) should be monitored hourly for cerebral oedema. Supportive measures may include nasogastric tube insertion for persistent vomiting or reduced level of consciousness and urinary catheter insertion to assess urine output and monitor treatment of oliguria (<0.5 ml urine/kg/hr). An example of the implementation of a UK guideline for the management of DKA is shown in [Figure 21.15](#).

### Fluid replacement

In adults, rapid fluid replacement should be commenced as soon as a diagnosis of DKA is confirmed (see [Fig. 21.15](#)). A rapid fluid bolus over 10–15 minutes may be required if systolic blood pressure is <90 mmHg. A more cautious approach is advised in young adults, in pregnancy, in older adults and those with a history of kidney or heart failure. Most guidelines favour correction of the extracellular fluid deficit with isotonic

21.12 Indicators of severe diabetic ketoacidosis	
<ul style="list-style-type: none"> <li>• Blood ketones &gt;6 mmol/L</li> <li>• Bicarbonate &lt;5 mmol/L</li> <li>• Venous/arterial pH &lt;7.0 (H<sup>+</sup> &gt;100 nmol/L)</li> </ul>	
May also be:	
<ul style="list-style-type: none"> <li>• Persistent hypotension or oliguria</li> <li>• Hypokalaemia (&lt;3.5 mmol/L)</li> <li>• Glasgow Coma Scale score &lt;12</li> <li>• O<sub>2</sub> saturation &lt;92% on air</li> <li>• Systolic blood pressure &lt;90 mmHg</li> <li>• Heart rate &gt;100 or &lt;60 beats per minute</li> <li>• Anion gap &gt;16 mmol/L</li> </ul>	
(pH 7.0–7.25 = moderate DKA; pH 7.26–7.30 = 'mild' DKA)	

saline (0.9% sodium chloride). Introduction of 10% glucose is recommended when the blood glucose falls below 14 mmol/L (252 mg/dL). The 0.9% saline infusion should be continued to correct circulating volume, with glucose infusion concurrently to prevent hypoglycaemia during rapid uptake of circulating glucose into cells.

### Insulin replacement

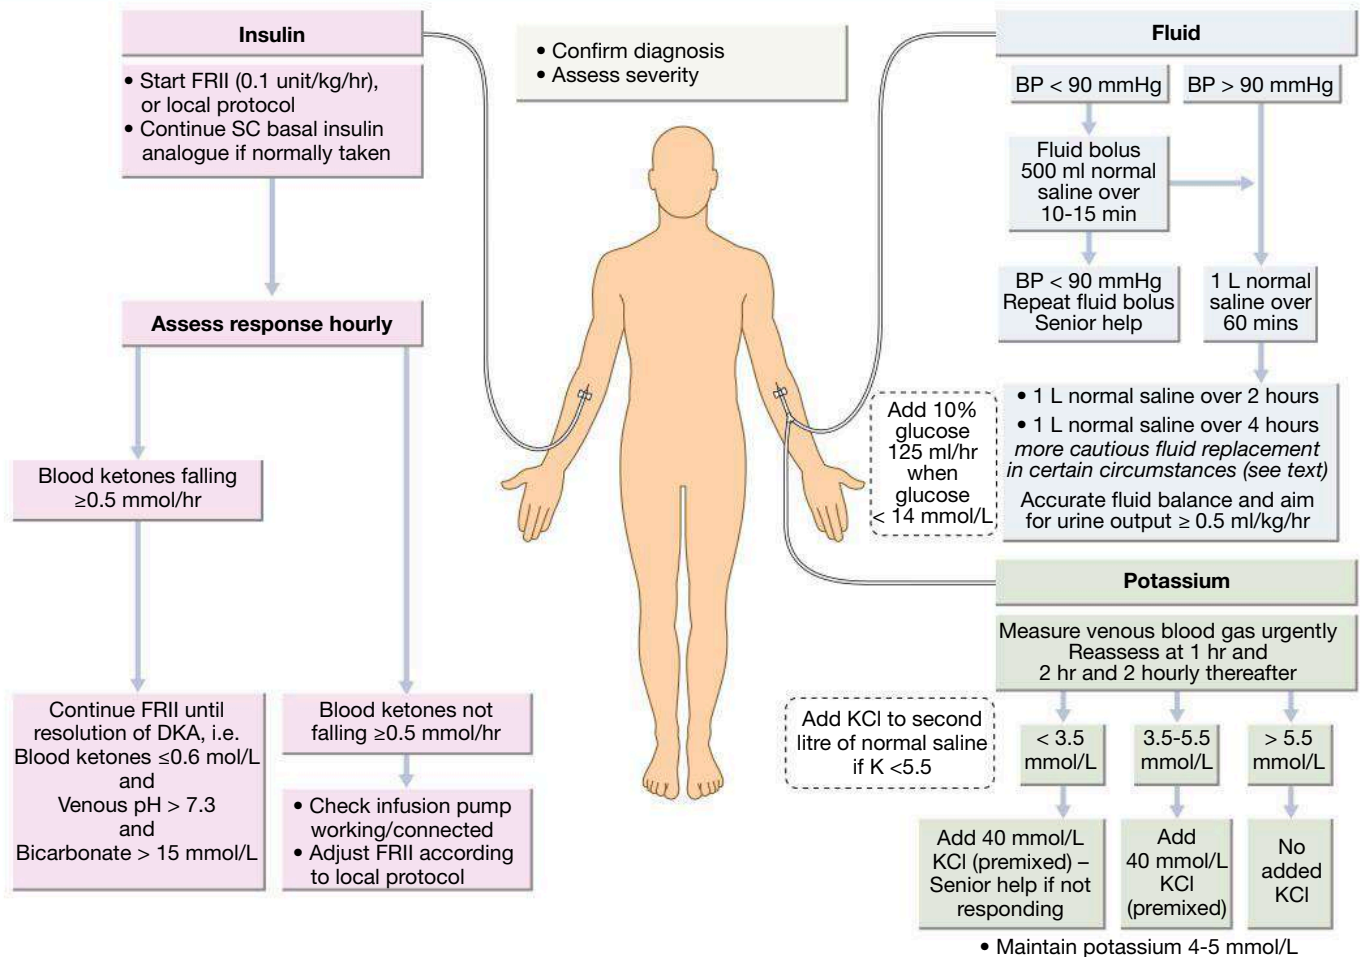

A fixed-rate intravenous insulin infusion should be commenced according to local protocols (for example a UK guideline recommends 0.1 U/kg body weight/hr (see [Fig. 21.15](#)). Blood glucose and blood ketones should be monitored hourly. Response to treatment should be assessed by a blood ketone concentration falling by at least 0.5 mmol/L/hr. Venous bicarbonate or glucose can be used if blood ketone testing is unavailable (aiming for an increase or decrease by 3.0 mmol/L/hr respectively). If blood ketones are not falling by at least 0.5 mmol/L/hr then the insulin infusion should be increased according to local protocols, after checking for malfunction of the insulin infusion. A long-acting insulin analogue in a dose equivalent to the individual's usual regimen should continue to be administered subcutaneously during the initial management of DKA. This provides basal insulin for when the intravenous insulin is discontinued and reduces the risk of rebound hyperglycaemia (or even DKA) recurring in hospital due to insulin interruption or omission – this should be a 'never event'. The fixed rate insulin infusion should be continued until DKA has resolved, defined as blood ketone <0.6 mmol/L, bicarbonate >15 mmol/L and venous pH >7.3.

### Potassium replacement

Careful monitoring of potassium is essential to the management of DKA as both hypo- and hyperkalaemia can occur (see above) and are life-threatening. Potassium is not usually recommended with the initial 1 litre of 0.9% sodium chloride as the primary focus at this stage is on restoring circulating volume and renal failure may be present. Potassium should be measured urgently on a venous blood gas sample and then reassessed after 1 hour, 2 hours and then 2 hourly thereafter. Treatment with 0.9% sodium chloride with potassium chloride 40 mmol/L is recommended if the serum potassium is between 3.5 and 5.5 mmol/L and there is no evidence of oliguria (see [Fig. 21.15](#)). If potassium is >5.5 mmol/L then potassium is not added to fluid replacement. If potassium is <3.5 mmol/L at presentation then begin cardiac monitoring and involve the critical care team as additional potassium will be required. Most guidelines aim to maintain potassium between 4.0 and 5.0 mmol/L.

### Intravenous bicarbonate and phosphate

Adequate fluid and insulin replacement should resolve the acidosis. The use of intravenous bicarbonate therapy is not generally recommended (due to lack of evidence of benefit), but may be considered in the context of a pH of <6.9 following discussion with a senior specialist clinician. Acidosis may reflect an adaptive response, improving oxygen delivery to the tissues, and so excessive bicarbonate may induce a paradoxical fall

**Fig. 21.15** Emergency management of diabetic ketoacidosis. (BP = blood pressure; FRII = fixed rate insulin infusion; KCl = potassium chloride; SC = subcutaneous)

in cerebrospinal fluid pH; this has been implicated in the pathogenesis of cerebral oedema in children and young adults. There is little evidence for intravenous phosphate replacement, but levels of  $< 0.6$  mmol/L are often corrected, particularly in the presence of respiratory or muscle weakness.

#### Ongoing management

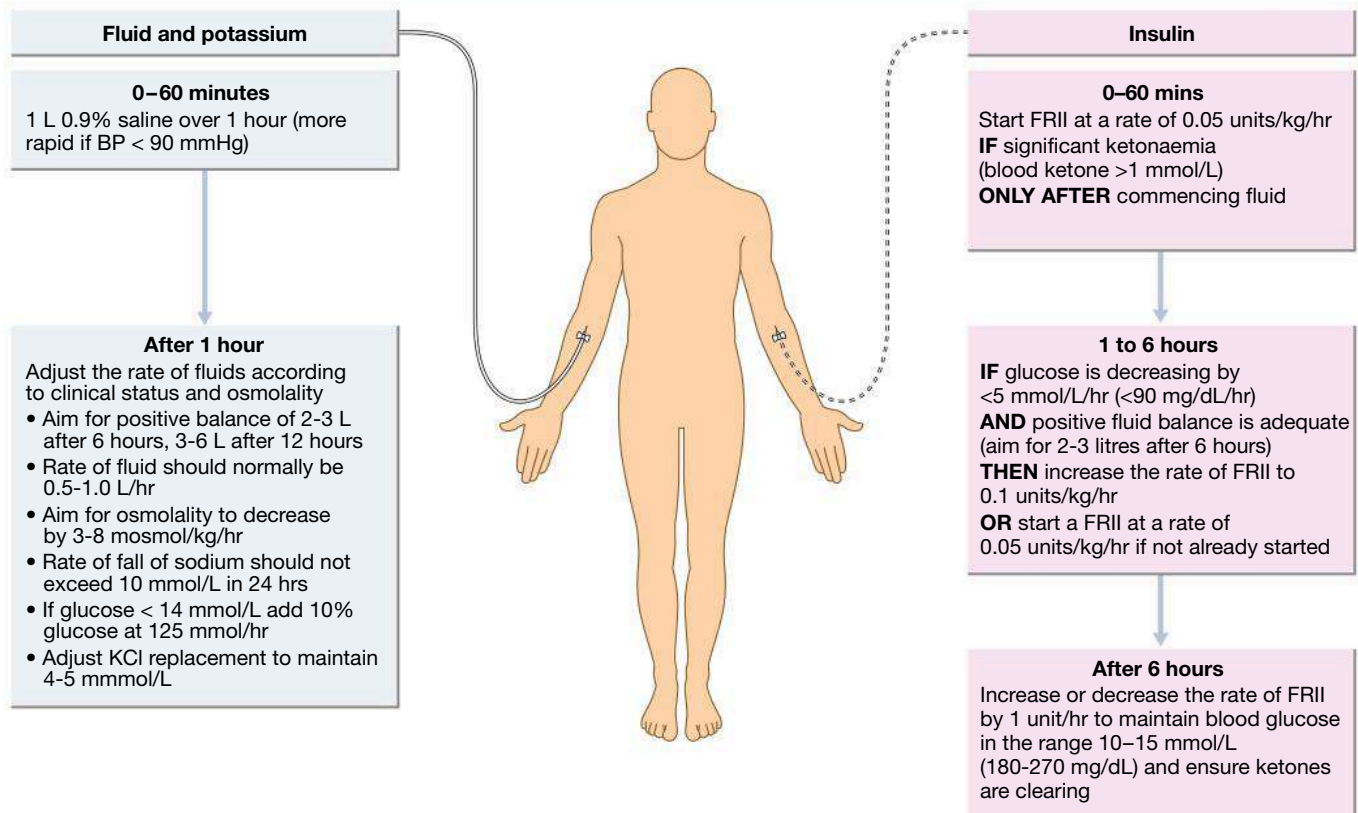

Restoration of the usual insulin regimen, by subcutaneous injection, should not be instituted until the patient is: (i) biochemically stable and (ii) able to eat and drink normally. The fixed rate insulin infusion should be continued for 30 minutes after short-acting (or premixed) insulin is given at a mealtime. If using an insulin pump, then the infusion should be started during the daytime at the usual basal rate (commencement overnight is not recommended as ward staff may be unfamiliar with this method of insulin delivery) and the fixed insulin rate infusion should be continued until the next meal bolus is given.

It is important to review the precipitating factors that led to DKA. Glycaemic control, glucose monitoring, insulin injection technique and injection sites should all be considered. If insulin pump therapy is used then it is important to ensure that there is an adequate supply of equipment, the insulin pump is working (for example not out of warranty) and that there is access to 'back up' insulin within expiry date via pen injector devices. DKA prevention should be discussed and written guidance on 'sick day rules' provided or reinforced. A blood ketone meter should be provided. A telephone number for the diabetes specialist team should be made available at the point of discharge from hospital. Given the mortality rates associated with DKA, early educational assessment and the provision of a personalised management plan are critical. Specialist psychological support may also be necessary.

#### Hyperglycaemic hyperosmolar state

Hyperglycaemic hyperosmolar state (HHS) is a medical emergency that is a consequence of prolonged *relative* insulin deficiency and so requires a different management approach from DKA. There is no precise definition of HHS, but it is characterised by hypovolaemia, severe hyperglycaemia ( $> 30$  mmol/L ( $> 540$  mg/dL)) and hyperosmolality (serum osmolality  $> 320$  mOsmol/kg), without significant ketonaemia ( $< 3$  mmol/L) or acidosis (pH  $> 7.3$  ( $H^+$   $< 50$  nmol/L), bicarbonate  $> 15$  mmol/L). It most often occurs in older people (often in long-term care) who may have impaired thirst perception, cognitive impairment or reduced ability to drink water. Conscious level is often impaired, particularly when osmolality is  $> 340$  mOsmol/L. Mortality rates are higher than DKA (up to 20%) reflecting the age and frailty of the population, but it is increasingly seen in younger adults particularly at the time of diagnosis of type 2 diabetes.

The pathogenesis of HHS is incompletely understood. As with DKA, there is glycosuria, leading to an osmotic diuresis, but renal loss of water is in excess to that of sodium and potassium (hypernatraemia is a common finding). In HHS, hyperglycaemia usually develops over a longer period than in DKA (a few days to weeks), causing more profound hyperglycaemia and dehydration (fluid loss may be 10–22L in a person weighing 100 kg). The reason that people with HHS do not develop significant ketoacidosis is unclear, although it has been speculated that insulin levels, although too low to stimulate glucose uptake in insulin-sensitive tissues, are still sufficient to prevent lipolysis and subsequent ketogenesis. Differentiating HHS and DKA in individual cases can be challenging, particularly in the setting of severe intercurrent illness that can be complicated by starvation ketosis, non-ketotic acidosis (acute kidney injury, lactic acidosis) and the increased prescription of SGLT2 inhibitors.

**Fig. 21.16** Emergency management of hyperglycaemic hyperosmolar state. Dashed intravenous infusion line represents 'if required'. (FRIL = fixed rate insulin infusion; KCl = potassium chloride)

21.13 Typical characteristics of HHS and DKA		
	HHS	DKA
<b>Age</b>	Older	Younger
<b>Classification</b>	Established pre-diabetes/type 2 diabetes or first presentation	Established type 1 diabetes or first presentation
<b>Duration of onset</b>	Days to weeks	Hours to days
<b>Abdominal pain</b>	Uncommon	Common
<b>Volume depletion</b>	10%–20%	5%–10%
<b>Insulin deficiency</b>	Relative	Absolute
<b>Glucose</b>	Usually >30 mmol/L	Usually >11.1 mmol/L
<b>Ketonaemia</b>	<3.0 mmol/L	>3.0 mmol/L
<b>Acidosis</b>	Bicarbonate >15 pH >7.3	Bicarbonate <15 pH 7.0–7.3

(DKA = diabetic ketoacidosis; HHS = hyperglycaemic hyperosmolar state)

The clinical features of HHS and DKA are compared and contrasted in Box 21.13. A mixed picture of HHS and DKA can occur in up to one-third of hyperglycaemic crises. If the predominant diagnosis is unclear then early specialist input is required to guide management and if necessary adjust local protocols.

HHS is more likely to occur when high glucose levels are sustained over many weeks or months. Common precipitating factors include infection (such as pneumonia or urinary tract infection) and other acute illness (such as acute myocardial infarction, cerebrovascular events), leading to an increase in counter-regulatory hormones. HHS can also occur in the context of drug therapy, such as glucocorticoids, and post-operatively in

hospital. Poor prognostic signs include hypothermia, hypotension (systolic blood pressure <90 mmHg), tachy- or bradycardia, severe hypernatraemia (sodium >160 mmol/L), serum osmolality >360 mOsmol/kg, and the presence of multiple comorbidities.

The principles of therapy are shown in Figure 21.16. The aims are to normalise osmolality and blood glucose, replace fluid and electrolyte losses, and prevent complications such as arterial or venous thrombosis (via subcutaneous thromboprophylaxis), foot ulceration (with careful protection of feet – see p. 751), cerebral oedema and central pontine myelinolysis (see Ch. 19). Co-morbidities also need to be taken into account; for example, rapid fluid replacement may precipitate cardiac failure in patients with coronary artery disease, while delirium commonly occurs in older patients. Historically, management of HHS was modelled on DKA protocols, but there is increasing recognition of better outcomes using a slower approach to correction of the electrolyte and other metabolic abnormalities (in contrast to DKA there is no urgent need to correct ketoacidosis). As HHS occurs in people whose brains are at higher risk of injury, rapid shifts in osmolality should be avoided with less aggressive fluid replacement and rate of glucose lowering guided by serial calculations of serum osmolality and glucose. Key recommendations are that 0.9% sodium chloride solution alone is used for initial treatment and that insulin is introduced only when the rate of fall in blood glucose has plateaued.

If osmolality cannot be measured frequently, osmolality can be calculated using the following equation from measurements of plasma electrolytes and glucose (in mmol/L) and used as a surrogate (the normal range is 280–296 mOsmol/L):

$$\text{Plasma osmolality} = 2[\text{Na}^+] + [\text{glucose}] + [\text{urea}]$$

A limitation of this approach is that hyperglycaemia, by increasing serum osmolality, causes the movement of water out of cells into plasma, reducing  $\text{Na}^+$  levels by dilution. Therefore, in the presence of hyperglycaemia, a corrected  $[\text{Na}^+]$  can be calculated for use in this formula by

### 21.14 Levels of hypoglycaemia

- Level 1 hypoglycaemia (*alert value*) as  $<3.9$  mmol/L but  $\geq 3.0$  mmol/L ( $<70$  mg/dL but  $\geq 54$  mg/dL)
- Level 2 hypoglycaemia (*clinically significant*) is defined as  $<3.0$  mmol/L ( $<54$  mg/dL). This level is unequivocally low and suggests clinically important biochemical hypoglycaemia
- Level 3 hypoglycaemia (*severe*) is defined as any low blood glucose level leading to cognitive impairment and the need for external assistance to provide glucose, glucagon or other corrective activity

adding 1.6 mmol/L to the measured  $[Na^+]$  for every 5.55 mmol/L (100 mg/dL) increment of serum glucose above normal.

## Hypoglycaemia

Hypoglycaemia has been defined by the American Diabetes Association in three distinct levels (see [Box 21.14](#)) – level 1 (alert value), level 2 (clinically significant) and level 3 (severe). When hypoglycaemia develops in people without diabetes, it is called ‘spontaneous’ hypoglycaemia: definition, causes and investigation are described on page 689. Hypoglycaemia seldom occurs in people without diabetes, but is very common in people with diabetes, mainly due to insulin and (to a lesser extent) sulphonylurea therapy. Unlike endogenous insulin, secretion of which is down-regulated when blood glucose falls, these therapies continue to act even when blood glucose is low.

More than 10% of people with type 1 diabetes report an episode of level 3 hypoglycaemia per year. CGM devices show more frequent episodes of level 2 hypoglycaemia – up to every 2 days in some studies. Importantly this is more frequent than hypoglycaemia measured by self-reported events or blood glucose monitoring. This finding is likely related to the improved detection by CGM. There may be an element of over-reporting at lower levels of interstitial fluid glucose, owing to lower reliability of some CGM devices, but accuracy of CGM devices is constantly improving.

The critical importance of glucose as a fuel source for the brain means that, in health, a number of mechanisms are in place to ensure that glucose homeostasis is maintained. If blood glucose falls, three primary physiological defence mechanisms operate:

- endogenous insulin release from pancreatic  $\beta$  cells is suppressed
- release of glucagon from pancreatic  $\alpha$  cells is increased
- the autonomic nervous system is activated, with release of catecholamines both systemically and within tissues.

In addition, stress hormones, such as cortisol and growth hormone, are released into the blood. These actions reduce peripheral glucose uptake and increase hepatic glucose production, maintaining a glucose supply to the brain. Retained endogenous insulin secretion in people with type 1 diabetes (measured using C-peptide) has a glucose smoothing effect that reduces the frequency of hypoglycaemia, as insulin secretion is inhibited by falling blood glucose levels. However, in most individuals with type 1 diabetes endogenous insulin production falls to minimal amounts within a few years of diagnosis, increasing glucose variability and the risk of hypoglycaemia. In addition, within 5 years of diagnosis, many people with type 1 diabetes lose their ability to release glucagon during hypoglycaemia. The reasons for this are unknown and may result from loss of  $\alpha$ -cell regulation by insulin or other products of the  $\beta$  cell.

Rates of hypoglycaemia are generally lower in insulin-treated type 2 diabetes than in type 1 diabetes, particularly in individuals with shorter duration of diabetes. This is likely due to preservation of significant endogenous insulin release for longer in most individuals, but also to differences in insulin regimens, i.e. more frequent use of intermediate- or longer- (rather than short-) acting insulins.

### 21.15 Most common symptoms of hypoglycaemia

#### Autonomic

- Sweating
- Trembling
- Pounding heart
- Hunger
- Anxiety

#### Neuroglycopenic

- Delirium
- Drowsiness
- Speech difficulty
- Inability to concentrate
- Incoordination
- Irritability, anger

#### Non-specific

- Nausea
- Tiredness
- Headache

**N.B.** Symptoms differ with age; children exhibit behavioural changes (such as naughtiness or irritability), while older people experience more prominent neurological symptoms (such as visual disturbance and ataxia).

Level 3 hypoglycaemia is about 10 times less common in people with type 2 diabetes treated with sulphonylureas than in those treated with insulin therapy. As these agents were previously widely prescribed, the proportion of cases of hypoglycaemia attributable to their use was high. However, with decreasing use of sulphonylureas over the last 20 years (due to the advent of newer agents), this proportion has dramatically fallen. Nevertheless, hypoglycaemia remains a significant risk in older people who are taking these agents, particularly those with renal impairment.

### Clinical assessment

Symptoms of hypoglycaemia ([Box 21.15](#)) comprise two main groups: those related to acute activation of the autonomic nervous system and those secondary to glucose deprivation of the brain (neuroglycopenia). Symptoms of hypoglycaemia are idiosyncratic, differing with age and duration of diabetes, and also depending on the circumstances in which hypoglycaemia occurs. Hypoglycaemia also affects mood, inducing a state of increased tension and low energy. Learning to recognise the early onset of hypoglycaemia is an important aspect of the education of people with diabetes managed with insulin.

### Awareness of hypoglycaemia

For most individuals, the glucose level (threshold) at which they first become aware of hypoglycaemia is not constant, but varies according to the circumstances in which hypoglycaemia arises (e.g. during the night or during exercise). In addition, with longer duration of diabetes, and particularly in response to frequent hypoglycaemia, the threshold for generation of symptom responses to hypoglycaemia shifts to a lower glucose concentration. This cerebral adaptation has a similar effect on the counter-regulatory hormonal response to hypoglycaemia. Taken together, this means that individuals with type 1 diabetes may develop reduced (impaired) awareness of hypoglycaemia. Symptoms can be experienced less intensely, or even be absent, despite blood glucose concentrations below level 2 hypoglycaemia. Such individuals are at an especially high risk of level 3 hypoglycaemia. The prevalence of impaired awareness of hypoglycaemia increases with time; overall, it affects around 20%–25% of people with type 1 diabetes and under 10% with insulin-treated type 2 diabetes.

### Risk factors and causes of hypoglycaemia

Risk factors and causes of hypoglycaemia in patients taking insulin or sulphonylurea drugs are listed in [Box 21.16](#). Hypoglycaemia is the limiting factor in glycaemic management for people with type 1 diabetes: it is unpleasant and fear of the lived experience and its consequences is understandable. In some people with diabetes, fear can have a major impact on their willingness and ability to achieve target glucose levels. Level 3 hypoglycaemia can cause serious morbidity (e.g. convulsions, coma, cerebral oedema, focal neurological lesions) and has a mortality

i 21.16 Hypoglycaemia in diabetes: common causes and risk factors
<b>Excess insulin</b>
<ul style="list-style-type: none"> <li>• Erroneous injection of insulin (e.g. dose miscalculation or injection of incorrect insulin type)</li> <li>• Deliberate overdose</li> <li>• Lipohypertrophy at injection sites (causing variable insulin absorption)</li> <li>• Bariatric surgery (can cause hyperinsulinaemia)</li> </ul>
<b>Increased sensitivity to insulin</b>
<ul style="list-style-type: none"> <li>• Exercise</li> <li>• Weight loss</li> <li>• Sudden reduction in glucocorticoids</li> <li>• Unrecognised Addison's disease</li> </ul>
<b>Reduced carbohydrate intake/increased metabolic demand</b>
<ul style="list-style-type: none"> <li>• Irregular or missed meal</li> <li>• Gastroparesis due to autonomic neuropathy causing variable carbohydrate absorption</li> <li>• Bariatric surgery</li> <li>• Malabsorption, e.g. coeliac disease</li> <li>• Eating disorder</li> <li>• Early pregnancy</li> <li>• Breast feeding</li> </ul>
<b>Reduced gluconeogenesis and/or glycogen reserves</b>
<ul style="list-style-type: none"> <li>• Alcohol</li> <li>• Chronic kidney disease*</li> <li>• Advanced liver disease*</li> </ul>
<b>Increased glucose variability</b>
<ul style="list-style-type: none"> <li>• Absent/minimal endogenous insulin secretion (reduced C-peptide)</li> <li>• Long-duration type 1 diabetes/insulin-treated type 2 diabetes</li> <li>• Young age of onset of type 1 diabetes</li> </ul>
<b>Reduced ability to detect hypoglycaemia</b>
<ul style="list-style-type: none"> <li>• Impaired awareness of hypoglycaemia</li> <li>• Rapid improvement in and/or strict glycaemic control</li> <li>• Previous severe hypoglycaemia</li> <li>• Long-duration type 1 diabetes/duration of insulin-treated type 2 diabetes</li> <li>• Older age</li> <li>• Dementia</li> <li>• Sleep</li> <li>• No or inadequate glucose monitoring</li> </ul>
*Also cause reduced insulin clearance.

of up to 4% in people treated with insulin. Rarely, sudden death during sleep occurs in otherwise healthy young patients with type 1 diabetes ('dead-in-bed syndrome'); this may be a consequence of hypoglycaemia-induced cardiac arrhythmia. Hypoglycaemia is very disruptive to normal daily activities including employment, driving (see Box 21.22), travel, sport and personal relationships.

Nocturnal hypoglycaemia in people with type 1 diabetes is common, but often undetected as it may not cause waking from sleep. People with diabetes may describe poor quality of sleep, morning headaches and vivid dreams or nightmares, or a partner may observe profuse sweating, restlessness, twitching or even seizures. The only reliable way to identify this problem is to use a CGM device with a low glucose alarm.

In healthy individuals, muscle contraction during exercise causes insulin-independent glucose uptake into muscle. Suppression of endogenous insulin secretion is key to the normal physiological response to exercise as glucose derived from hepatic glucose production can be transported into muscle via other pathways; this physiological mechanism minimises any risk of 'spontaneous' exercise-induced hypoglycaemia. However, in insulin-treated diabetes, circulating insulin levels may actually increase with exercise because of improved blood flow at the site of injection, causing a significant risk of hypoglycaemia. This occurs most commonly with prolonged and/or aerobic exercise. In addition, the 'double hit' of hypoglycaemia and exercise is responsible for the additional increased risk of nocturnal hypoglycaemia that

## 21.17 Emergency treatment of hypoglycaemia

### Biochemical or symptomatic hypoglycaemia (Levels 1 and 2)

In the UK, it is recommended that all glucose levels  $<4.0$  mmol/L<sup>1</sup> are treated ('4 is the floor'). People with diabetes who recognise developing hypoglycaemia are encouraged to treat immediately. Options available include:

- Oral fast-acting carbohydrate (10–15 g) is taken as glucose drink or tablets or confectionery, e.g. 5–7 Dextrosol tablets (or 4–5 Glucotabs)
- Repeat capillary glucose measurement 10–15 mins later. If still  $<4.0$  mmol/L, repeat above treatment
- If blood glucose remains  $<4.0$  mmol/L after three cycles (30–45 mins), contact a doctor. Consider glucagon 1 mg IM or IV 10% glucose (600–800 mL/hour – caution in renal and cardiac disease)
- Once blood glucose is  $>4.0$  mmol/L, take additional long-acting carbohydrate of choice
- Do not omit insulin injection if due but review regimen

### Severe (Level 3)

This means individuals are either unconscious or unable to treat hypoglycaemia themselves. Treatment is usually by a relative or by paramedical or medical staff. Immediate treatment as below is needed.

- If patient is unconscious/fitting or very aggressive or nil by mouth, parenteral treatment is required:
  - IV 75 mL 20% dextrose over 15 mins (= 15 g)<sup>2</sup>
  - Or
  - IV 150 mL 10% dextrose over 15 mins
  - Or
  - IM glucagon (1 mg) – may be ineffective in undernourished people, severe liver disease and in repeated hypoglycaemia. Caution in hypoglycaemia induced by oral glucose-lowering therapy.
- If patient is conscious and able to swallow, but confused, disorientated or aggressive:
  - Give 2 tubes of 40% glucose gel – squeezed into mouth between teeth and gums
  - Repeat blood glucose measurement after 10–15 mins and if ineffective after 3 cycles call doctor and consider IM glucagon (1 mg) or IV 10% glucose

<sup>1</sup>4.0 mmol/L = 72 mg/dL. <sup>2</sup>Use of 50% dextrose is no longer recommended. (IM = intramuscular; IV = intravenous)

Adapted from updated JBDS Diabetes at the Front Door guideline, March 2020. Available at: [abcd.care/resource/diabetes-front-door](http://abcd.care/resource/diabetes-front-door).

can occur after exercise, possibly as a result of glycogen depletion. In contrast, high-intensity exercise may initially cause blood glucose to rise significantly because of stimulation of adrenaline (epinephrine) production. Close monitoring of blood glucose, education and lived experience (usually with an element of trial and error) are key in preventing exercise-induced hypoglycaemia.

Unfortunately, hypoglycaemia sometimes occurs within the hospital setting. This may result from errors in insulin dose or type of insulin prescribed or infusion of IV insulin without glucose. In addition, hypoglycaemia may occur due to changes in meal timings (e.g. fasting for procedures) or content, failure to provide usual snacks, reduced carbohydrate intake because of vomiting or reduced appetite, or factors related to the hospital admission, e.g. concurrent illness or discontinuation of long-term glucocorticoid therapy. The diabetes team has a role in continuing education of health-care staff in all areas to prevent these situations occurring; regular review of any adverse events is also critical to prevention.

## Management

### Reversing hypoglycaemia

Treatment of hypoglycaemia depends on its severity and on whether the patient is conscious and able to swallow (Box 21.17). Levels 1 and 2 hypoglycaemia should be reversed with fast-acting carbohydrate, repeated measurements of glucose and, if necessary, adjustment of glucose lowering therapy. There is an understandable tendency to 'over-treat' episodes of hypoglycaemia, resulting in significant hyperglycaemia

in the aftermath. Level 3 hypoglycaemia may also be treated with oral carbohydrate if the patient does not have impaired consciousness. If parenteral therapy is required, then as soon as the individual is able to swallow, oral glucose should be given. Full recovery may not occur immediately and reversal of cognitive impairment may not be complete until 60 minutes after normoglycaemia is restored. When hypoglycaemia has occurred in a patient treated with a long- or intermediate-acting insulin or a long-acting sulphonylurea, such as glibenclamide, the possibility of recurrence should be anticipated; to prevent this, infusion of 10% dextrose titrated to the patient's blood glucose, or provision of additional oral carbohydrate may be necessary.

If a person with diabetes fails to regain consciousness after blood glucose is restored to normal, then cerebral oedema and other causes of impaired consciousness – such as alcohol intoxication, a post-ictal state or cerebral haemorrhage – should be considered. Cerebral oedema is associated with a high mortality and morbidity.

Following recovery, it is important to try to identify a cause and make appropriate adjustments to therapy. Unless the reason for a hypoglycaemic episode is clear, people with diabetes should be advised to reduce the next dose of insulin by 10%–20% and seek medical advice about further adjustments in dose.

The management of self-poisoning with oral glucose-lowering agents is described on page 228.

### Reducing future risk of hypoglycaemia

Every diabetes consultation should include gathering information about any low glucose levels measurements, the nature of symptoms with the measured levels of hypoglycaemia and whether there have been any episodes of level 3 hypoglycaemia. It is important to review blood glucose monitoring and CGM data with the patient to determine the details around each episode: recognition of patterns can be aided by increasing the number of measurements and triangulation with diary recordings of insulin dosing, carbohydrate intake and physical activity. The lived experience of previous hypoglycaemia and any resultant fear should be explored. Education is fundamental to the prevention of hypoglycaemia and should focus on risk factors for, and treatment of, hypoglycaemia. The importance of regular glucose monitoring, flexible insulin regimens and the need to have glucose (and glucagon) readily available should be reinforced. Relatives and friends also need to be familiar with the symptoms and signs of hypoglycaemia and should be instructed in how to help (including how to inject glucagon).

The goal is always to minimise the risk of hypoglycaemia while still reaching target glucose levels and HbA<sub>1c</sub>. Adjustments in insulin regimen based on patterns of glucose should be agreed with the person with diabetes over time to achieve their goals. HbA<sub>1c</sub> targets should be individualised to balance the risk of hypoglycaemia with the risk of complications. Upgrading insulin regimens to rapid-acting and long-acting insulin analogues is associated with a lower frequency of nocturnal hypoglycaemia. The use of CGM devices (particularly those with low glucose alarms), is invaluable. CGM values and trend arrows provide important information upon which to base decisions on doses of short-acting (bolus) insulin to be administered in relation to planned carbohydrate ingestion; thus, glucose can be kept to target while hypoglycaemia is prevented. The use of sensor-augmented CSII systems, particularly those that incorporate a 'low glucose suspend' feature, can virtually abolish hypoglycaemia. Transplantation should be considered in cases of severe intractable hypoglycaemia (see p. 742).

## Management of diabetes

Contemporary specialist diabetes care is delivered by a multidisciplinary team including medical staff, specialist nurses, nursing assistants, dietitians, podiatrists, pharmacists, retinal screeners, psychologists, health care assistants and administrative staff. Ideally these staff are co-located in an ambulatory care or diabetes centre, which need not necessarily be on a hospital site, and there should be close and dynamic links

with primary care and community-based diabetes specialist nurses, all involved in continuing professional development.

The aims for both types 1 and 2 diabetes are initially to relieve osmotic symptoms (see p. 725) and then to minimise the risks of long-term microvascular and macrovascular complications. Microvascular complications are prevented by targeting hyperglycaemia, but control of macrovascular complications also requires management of associated risk factors, particularly hypertension, dyslipidaemia and cigarette smoking. Initial investigation and management is outlined in [Figure 21.20](#).

Due to the risk of complications, people with all forms of diabetes should be kept under review with regular monitoring, adjustment of treatment, and screening to detect treatable complications as early as possible. Diabetes care is delivered in primary care for the majority of people with type 2 diabetes and in specialist centres for those with type 1 diabetes or complex treatment regimens and/or complications. A checklist for follow-up visits is given in [Box 21.18](#). Frequency of appointments usually ranges from 3-monthly to annually depending on whether targets are being achieved.

**Type 2 diabetes** Where there are no 'red flags' of ketosis or rapid weight loss, initial management of type 2 diabetes involves dietary and lifestyle advice, which should aim at inducing remission of the condition (see p. 732). However, adding in oral glucose-lowering drugs is more likely to be required at an early stage for those who have symptomatic hyperglycaemia or a high HbA<sub>1c</sub>. Education is key to achieving and maintaining a healthy lifestyle in type 2 diabetes. Management should be individualised, taking into account personal and cultural beliefs, individual circumstances, comorbidities and other factors.

**Type 1 diabetes** People with a new diagnosis of type 1 diabetes require substantial initial education and support around diet, glucose monitoring, the technicalities of insulin administration and dose adjustment, and the recognition and treatment of hypoglycaemia ([Box 21.19](#)). A diagnosis of type 1 diabetes can be profoundly life-altering not least because individuals have often previously been healthy and have now been diagnosed with a long-term condition that requires restrictions to diet and lifestyle, regular finger-pricks and multiple daily injections. Hypoglycaemia is unpleasant, can be socially embarrassing and can have significant morbidity and indeed mortality. Type 1 diabetes also has significant potential impact on employment, education, driving, overseas travel, family planning and can result in increased travel and life insurance premiums. Therefore, people living with type 1 diabetes often have higher levels of psychological and psychiatric morbidity and require substantial ongoing support and encouragement from diabetes healthcare professionals, including psychological support.

As duration of type 1 diabetes increases, maintenance of good glycaemic control can become progressively more challenging, despite the lived experience of managing insulin therapy. Hypoglycaemia tends to become more frequent, as protective counter-regulatory hormone responses and warning symptoms diminish. Maintaining strict glycaemic control, with minimal hypoglycaemia, is extremely challenging with conventional subcutaneous insulin therapy and requires motivation and meticulous attention in terms of dietary factors, glucose monitoring and decision-making around insulin dosing.

Some individuals with type 1 diabetes have long-term sub-optimal glycaemic control. The reasons for this are complex, but in many cases relate to difficulty finding time to devote the effort required to self-manage the condition in the context of other events and demands within their personal, family and work lives. Such factors vary across the lifespan with major differences between individuals. Other individuals have more serious psychological problems in accepting or adjusting to the diagnosis. These factors can lead to behaviours that have a negative impact on glycaemic control such as: omission of insulin injections (either deliberate or accidental), taking insulin injections after meals, taking fixed doses of insulin or doses based on symptoms (e.g. taking extra insulin when person feels thirsty), under-dosing with insulin to reduce risk of hypoglycaemia, consumption of foods high in unrefined carbohydrate,

21.18 How to review a patient in the diabetes clinic	
<b>Approach to the diabetes consultation</b>	
<b>Introduction (agenda-setting)</b>	'How are you?' 'What matters to you?' (Is translator required?)
<b>Demographics</b>	Age, type of diabetes, duration of diabetes
<b>Microvascular complications</b>	Retinopathy/maculopathy Renal function (eGFR) Microalbuminuria/proteinuria Foot examination
<b>Macrovascular complications</b>	Cardiovascular disease Cerebrovascular disease Peripheral vascular disease
<b>Metabolic</b>	BMI/weight trajectory Diet (quality/calories)/CHO counting Current glucose-lowering treatment (adherence/administration) HbA <sub>1c</sub> Step-wise approach to glucose monitoring (frequency, timing, representativeness or reliability of data) Hypoglycaemia (frequency, timing, symptoms, context, episodes of level 3 hypoglycaemia, consequences, driving) Hyperglycaemia (frequency, timing, symptoms, context, episodes of DKA/HHS, consequences) Glycaemic variability if AGP available
<b>Cardiovascular risk</b>	BP Cholesterol Smoking cessation

non-adherence to carbohydrate counting, over-treatment of episodes of hypoglycaemia and avoidance of glucose monitoring. Attempts to improve glycaemic control may involve enhanced input and support from diabetes specialist nurses and dietitians, more regular review in out-patient clinics, referral into structured education programmes and (increasingly) provision or recommendation of technologies like CGM and CSII therapy (where resources permit). However, even with these potentially life-transforming interventions and technologies, type 1 diabetes remains a very challenging condition.

21.19 Learning outcomes on the day of type 1 diabetes diagnosis	
<ul style="list-style-type: none"> <li>• Explain what is type 1 diabetes</li> <li>• Explore any fears and anxieties and ask questions</li> <li>• Be able to check blood glucose/ketones</li> <li>• Be able to administer insulin and understand the correct storage of insulin</li> <li>• Understand the target blood glucose</li> <li>• Understand the role of rapid-acting insulin and its relationship with food</li> <li>• Understand how to safely dispose of used needles and lancets</li> <li>• Appreciate that people with diabetes should follow similar dietary recommendations as appropriate for non-diabetic people and that insulin is adjusted to carbohydrate content of diet</li> <li>• Understand what a 'hypo' is and how to treat it</li> <li>• Be aware they can access their own diabetes health records</li> <li>• Understand what to expect from the diabetes team, how to make contact and the date/time/mode of their next interaction</li> <li>• Understand that notifying DVLA* about the diagnosis of type 1 diabetes is a legal requirement and the precautions to be taken before driving</li> <li>• Understand that sub-optimal glycaemic control increases risks to both mother and baby</li> <li>• Understand that their employer should know they have been diagnosed with type 1 diabetes</li> </ul>

Type 1 diabetes is associated with other immune-mediated disorders (see Ch. 4), including thyroid disease, coeliac disease, Addison's disease, pernicious anaemia and vitiligo. Awareness of these is important so that they can be diagnosed promptly and managed appropriately. Approximately 30% of women and 15% of men with type 1 diabetes have at least one related immune-mediated condition. The association with hypothyroidism is strongest (present in ~20% overall); coeliac disease is the second most common (present in 4%) and is particularly associated with childhood-onset diabetes. Thyroid function should be checked annually in all patients with type 1 diabetes and systematic screening for coeliac disease is recommended in many countries.

## Self-assessment of glycaemic control

**Type 2 diabetes** People with type 2 diabetes usually only need to self-test capillary blood glucose regularly if they require insulin or sulphonylurea therapy. For those on insulin, blood glucose testing 1–4 times daily (depending on the intensity of the prescribed regimen) helps guide insulin dosing and to manage diet, exercise and illness. It also helps detect and protect against hypoglycaemia. This is also the case for sulphonylurea therapy. People with type 2 diabetes who are on neither of these therapies do not have an absolute need to test blood glucose, but it can be useful, e.g. for self-education on the effects of food and exercise on glycaemia. Fasting or pre-meal blood glucose target is usually 5.0–7.0 mmol/L (90–126 mg/dL). Those who require to test should be taught how to monitor their own blood glucose using an electronic meter and prescribed adequate supplies of blood glucose testing strips.

**Type 1 diabetes** People with type 1 diabetes are advised to test capillary blood glucose four or more times per day as they usually require intensive insulin regimens. Blood glucose meters with dual functionality for ketone testing are particularly useful to provide early warning of ketosis and help prevent ketoacidosis when blood glucose is high and/or during intercurrent illness.

CGM systems are increasingly becoming a standard of care in type 1 diabetes. Specific devices are funded by the NHS in the UK, as their use is associated with improved glycaemic control and is cost-effective. CGM widens the lens through which day-to-day glycaemia can be monitored

by people with diabetes and provides a more holistic view of the lived experience of diabetes. CGM data are summarised in an Ambulatory Glucose Profile (AGP). This display provides a graphical representation of interstitial glucose over time, allowing trends to be readily identified (Fig. 21.17). Summary metrics include: mean glucose, time in range, time above range and time below range (see below). Glucose variability over time is reported as standard deviation and percentage coefficient of variation. A 'Glucose Management Indicator' is now available on some CGM devices corresponding to 'estimated HbA<sub>1c</sub>' (eA<sub>1c</sub>): the accuracy of this statistic increases with the volume of CGM data available (minimum 10 days and preferably >14 days).

The proportion of time spent within an optimal glycaemic range is increasingly recognised as a clinically meaningful tool. Time in range (TIR) denotes the percentage of time each day spent within agreed glucose targets (Fig. 21.18). The international consensus for 'in range' glucose values is between 3.9 and 10 mmol/L (70–180 mg/dL) inclusive, with lower and higher levels termed time below range (TBR) and time above range (TAR). TIR of >70% is considered the optimum target for most people living with diabetes on the basis of extrapolation from the Diabetes Control and Complications Trial. In people at higher risk of hypoglycaemia, 50% TIR is accepted, with an understanding that this means more TAR. In pregnancy stricter glucose targets are specified (3.5–7.8 mmol/L (63–140 mg/dL)), with 70% TIR (see Ch. 32).

## Therapeutic goals

### HbA<sub>1c</sub> targets

**Type 1 diabetes** The first evidence that improved glycaemic control decreases the risk of microvascular complications in diabetes came in 1993 from the Diabetes Control and Complications Trial (DCCT). The DCCT randomised adolescents and young adults with type 1 diabetes in the United States and Canada to intensive treatment (mean HbA<sub>1c</sub> 53 mmol/mol) or conventional treatment (mean HbA<sub>1c</sub> 75 mmol/mol) for 6.5 years. There was a 60% overall reduction in the risk of developing microvascular complications with an intensive therapy strategy, although severe hypoglycaemia was increased up to threefold in those in whom HbA<sub>1c</sub> was most reduced. Thirty-year follow-up of both groups of DCCT participants demonstrated that macrovascular complications were also reduced even many years after a period of intensive control – this was termed 'metabolic memory'.

**Type 2 diabetes** In the UK Prospective Diabetes Study (UKPDS), published in 1998, adults with type 2 diabetes were randomised to intensive blood glucose control mainly with sulphonylureas and insulin (mean HbA<sub>1c</sub> 53 mmol/mol) versus conventional glucose control mainly with dietary
