treatment (mean HbA<sub>1c</sub> 64 mmol/mol) for 10 years. Rates of microvascular complications were reduced in those who received intensive therapy, but a beneficial effect on macrovascular complications was observed only with metformin in overweight participants in whom there was a reduction in the rate of diabetes-related death. Follow-up of UKPDS participants over further decades reinforced the microvascular benefits of glucose lowering and the specific macrovascular benefits of metformin.

Other trials that examined whether lowering HbA<sub>1c</sub> below 53 mmol/mol could further reduce rates of complications in type 2 diabetes suggested that a lower target of 48 mmol/mol may only be safe for younger people in the initial years following diagnosis due to the risks associated with hypoglycaemia (see Box 21.20).

Therefore, the usual target HbA<sub>1c</sub> is 53 mmol/mol for both type 1 and type 2 diabetes. However, an individualised target is appropriate depending on the needs of the person in question. For example, in recently diagnosed individuals with type 2 diabetes not requiring any agents that cause hypoglycaemia or patients with type 1 diabetes using sensor-augmented CSII (which can substantially reduce the risks of hypoglycaemia), a target of 48 mmol/mol or less may be appropriate. Explicit setting of a higher target (e.g. 58 mmol/mol) is acceptable in some cases, for example older people with shorter duration of diabetes (i.e. at lower lifetime risk of complications), individuals with a high risk of level 3 hypoglycaemia (e.g. those with impaired awareness of hypoglycaemia or cognitive impairment) or those in whom hypoglycaemia could have a particularly adverse consequence (e.g. individuals at high fall risk; Box 21.20). In general, the benefits of lower target HbA<sub>1c</sub> (primarily a lower risk of microvascular disease) need to be weighed against increased risks (primarily hypoglycaemia). The risks of hypoglycaemia are higher in individuals with absent or minimal endogenous insulin (e.g. type 1 diabetes and following total pancreatectomy), in whom there is more marked glycaemic variability (see Fig. 21.10). Achieving strict glycaemic targets in such individuals can be particularly challenging. Type 2 diabetes is associated with much lower glycaemic variability (due to retained endogenous insulin production), but unless major diet and lifestyle changes are achieved, it is usually a progressive condition and so there is usually a need to increase diabetes medication over time to achieve the individualised target HbA<sub>1c</sub>.

### Control of other risk factors

**Type 2 diabetes** Due to underlying insulin resistance, most people with type 2 diabetes have hypertension and dyslipidaemia in addition to hyperglycaemia. Targeting of these cardiovascular risk factors is crucial in reducing risk of macrovascular complications. UKPDS participants were

**Fig. 21.17 Ambulatory blood glucose profile.** The Ambulatory Glucose Profile (AGP) is generated by combining continuous glucose monitor (CGM) data over a prolonged period (usually 14 days). It provides an example of a 'typical day' allowing the person with diabetes and health-care professionals to make more rational adjustments to insulin therapy. An estimated HbA<sub>1c</sub> can also be derived from these data. Black/blue solid line (median line) – the average (middle) point of all glucose levels. Ideally this should be in the target glucose range with minimal variability. Inner blue-shaded band (25th to 75th percentile) – most common glucose levels and how they vary from day to day. Outer light blue-shaded band (10th to 90th percentile) – less common glucose levels and how they vary from day to day. Adapted from DPC Toolkits, *The Ambulatory Glucose Profile (AGP) in 4 steps*. [https://cdn.asp.events/CLIENT\\_CloserSt\\_D86EA381\\_5056\\_B739\\_5482D50A1A831DDD/sites/DPC2020/media/toolkits-2018/The-Ambulatory-Glucose-Profile-AGP-in-4-steps.pdf](https://cdn.asp.events/CLIENT_CloserSt_D86EA381_5056_B739_5482D50A1A831DDD/sites/DPC2020/media/toolkits-2018/The-Ambulatory-Glucose-Profile-AGP-in-4-steps.pdf).

**Fig. 21.18** Target time in range for different groups of people with type 1 diabetes. The different coloured sections represent the proportion of time spent within a glucose range: Green = proportion of time spent within range; yellow = time above range; orange = time significantly above range; red = time below range; brown = time significantly below range. 'In range' glucose levels are much lower for women who are pregnant. A lower 'time in range' is accepted for people at higher risk of hypoglycaemia and in older people. Note: as the percentages are targets they do not add up to 100%. Adapted from Battelino T, et al. *Clinical targets for continuous glucose monitoring data interpretation: recommendations from the international consensus on time in range*. *Diabetes Care* 2019, dci190028.

## 21.20 Diabetes in old age

- **Incidence:** type 2 diabetes becomes more common with increasing age.
- **Aetiology:** almost any form of diabetes can present in older people; do not presume that a new diagnosis of diabetes in an older person is automatically due to type 2 diabetes.
- **Hypoglycaemia:** older people may not recognise hypoglycaemia, increasing their risk of severe hypoglycaemia.
- **Glycaemic targets:** need moderated in frail older people, especially if using agents that cause hypoglycaemia (insulin and sulphonylureas).
- **Dementia:** both Alzheimer's disease and vascular dementia are more common in people with diabetes, which can significantly affect ability to manage diabetes safely. Input from family, carers and community nurses may be essential.

also randomised to tight (<math><150/85\text{ mmHg}</math>) or less tight (<math><180/105\text{ mmHg}</math>) blood pressure control: the former was associated with a reduction in the risk of death as well as fewer complications overall (including retinopathy). The target for blood pressure is now usually below 140/80 mmHg, although some guidelines suggest below 130/80 mmHg (e.g. in those with renal disease). As a rule, anyone with type 2 diabetes over the age of 40 years should be prescribed a statin, irrespective of their blood cholesterol level. Some guidelines do not propose a target level once a statin has been started, but others suggest a total cholesterol of less than 4.0 mmol/L (approximately 150 mg/dL) and an LDL cholesterol of less than 2.0 mmol/L (approximately 75 mg/dL).

**Type 1 diabetes** Elevation of the same cardiovascular risk factors also commonly occurs over time in type 1 diabetes, but is thought at least in the early years to be of secondary importance to hyperglycaemia. Guidelines suggest targeting risk factors in those with a duration of type 1 diabetes of over 15–20 years, or aged over 35–40 years. Similar BP and cholesterol treatment targets are recommended as for people with type 2 diabetes. Caution should be exercised in prescribing for women of childbearing potential, especially drugs with teratogenic potential (including ACE inhibitors and statins).

## Education, diet and lifestyle

Broadly, people with diabetes should follow similar dietary recommendations as appropriate for non-diabetic people, but if overweight or obese should seek to lose weight. However, this can be difficult as 'healthy' diet recommendations are rarely followed by the general population, particularly in countries in which cheap calorie-rich foods are widely available and heavily advertised. Labelling of foods as 'suitable for diabetics' was prohibited in the UK in 2016, but some products labelled 'diabetic' are still available. These should be avoided as they are often expensive, sweet-tasting foods (jam, biscuits, chocolate, ice-cream) that can contain synthetic sugars that raise blood glucose. People with diabetes may be misled into believing these products are essential or especially suitable. Diabetes prevention programmes are in place in many countries, essentially supporting low-fat healthy eating, weight reduction and increased physical activity (often referred to as 'non-pharmacological intervention').

## Principles of healthy eating

**Type 1 diabetes** Soon after diagnosis patients should have access to a dietitian for education on 'carbohydrate counting', as this is essential for rational insulin dose adjustment. Books and smartphone apps are available that show carbohydrate content next to pictures of commonly consumed foodstuffs, in varying portion sizes; these can assist individuals in making an educated estimate of the carbohydrate content of a meal (Fig. 21.19). Highly accurate information on the carbohydrate content of pre-prepared foods and basic ingredients is provided on package labels; some people with type 1 diabetes weigh food portions to get as precise information as possible. Carbohydrate counting requires patience and diligence, but becomes easier with lived experience. In theory, people with type 1 diabetes with a normal weight should be able to eat unrestricted types and amounts of carbohydrate, as they can simply take an appropriate amount of insulin to 'cover' the carbohydrate content of the meal. However, in practice, because the time action profiles of available exogenous insulins do not exactly

**Fig. 21.19** Example of a 'carbohydrate counting' guide for people with diabetes. Books and smart phone apps are available that give illustrative examples of different foods, in different portion sizes. The macronutrient and calorie content is provided for each portion. From Cheyette C, Balolia Y. *Carbs and Cals. Carb & Calorie Counter, 6th edition; 2016. Chello Publishing Limited.*

match physiological variations in endogenous insulin, the consumption of unrefined carbohydrate (such as sweets and sugar-rich drinks) and large portions of carbohydrate (>60g) invariably results in 'spikes' in blood glucose. Therefore, the best glycaemic control is generally seen in individuals who mostly avoid unrefined carbohydrate and limit carbohydrate portion size.

Education on advanced carbohydrate counting and how to manage diet and insulin therapy during daily life (e.g. in the context of exercise, alcohol and intercurrent illness) is provided in formal structured and cost-effective programmes, such as 'Dose Adjustment for Normal

Eating' (DAFNE). This involves one week of small group learning with other individuals with the condition supported by a diabetes specialist nurse and a dietician. The COVID-19 pandemic has led to an increased use of remote 'flipped classroom' models of education supported by videotelephony platforms.

**Type 2 diabetes** There is no 'one size fits all' way of eating for people with type 2 diabetes, beyond making healthy choices more often and in smaller portions, as recommended by the Food Standards Agency (Box 21.21). There is no fixed formula for the balance of carbohydrate,

## 21.21 Dietary management of diabetes

### Food Standards Agency Eatwell recommendations 2020

- Eat at least 5 portions of a variety of fruit and vegetables every day
- Base meals on potatoes, bread, rice, pasta or other starchy carbohydrates; choosing wholegrain versions where possible
- Have some dairy or dairy alternatives (such as soya drinks), choosing lower fat and lower sugar options
- Eat some beans, pulses, fish, eggs, meat and other proteins (including 2 portions of fish every week, one of which should be oily)
- Choose unsaturated oils and spreads and eat in small amounts
- Drink 6-8 cups/glasses of fluid a day
- If consuming foods and drinks high in fat, salt or sugar have these less often and in small amounts
- Eat <6.0 g salt per day

Available from: <https://www.food.gov.uk/sites/default/files/media/document/eatwell-guide-master-digital.pdf>.

fat and protein ('macronutrient composition'); neither is there a universal 'diet sheet' or list of 'banned' foods. Current advice is loosely based on the principles of a 'Mediterranean' diet (for which there is high level evidence of protection against cardiovascular disease) combined with a focus on choosing unrefined carbohydrates (e.g. brown rice, brown pasta, brown noodles, porridge, granary bread, and beans and lentils) rather than refined carbohydrates (fruit juices, pastries, white bread, white pasta, white rice). Nutritional advice should be tailored to individuals and take account of age, lifestyle, culture and personal circumstances. A variety of structured education programmes, which focus on dietary and lifestyle factors, are available for type 2 diabetes, including DESMOND (Diabetes Education and Self Management for Ongoing and Newly Diagnosed).

## Weight management

Over 80% of people with type 2 diabetes are overweight or obese. Central obesity with increased waist circumference is particularly associated with insulin resistance and increased cardiovascular risk. Following a diagnosis of type 2 diabetes, there should be an intense focus on reversing any unhealthy habits and behaviours with the aim, where appropriate, of weight loss. It is extremely challenging for most overweight people (with or without type 2 diabetes) to lose body weight and avoid regain. However, if weight loss can be achieved, it markedly improves glycaemic control and slows diabetes progression. Substantial weight loss in obese people (usually around 15 kg or about 15% initial body weight) can put type 2 diabetes into remission and there are programmes now available to help people achieve this using, for example, an 800 kcal/day liquid 'meal replacement' diet with gradual and supported meal re-introduction at 3 months (see p. 765). Trained supervision is essential and in the UK is increasingly provided by the NHS.

Some health professionals and people with type 2 diabetes are strong advocates of low-carbohydrate, high-fat ('ketogenic' or 'Atkins') diets to promote weight loss, or alternatively intermittent fasting 2 days out of every 5 ('5:2' diet). Perhaps because they help to provide and sustain motivation, these approaches are successful in achieving and sustaining weight loss in some individuals, but to date it has not been possible to predict in advance who will respond or to demonstrate general efficacy of these diets in controlled trials. They must only be used with extreme caution in type 1 diabetes due to the risks of hypoglycaemia or ketoacidosis.

Bariatric surgery (see p. 766) induces marked weight loss in obese individuals with type 2 diabetes and this is often associated with significant improvements in HbA<sub>1c</sub> and withdrawal of or reduction in diabetes medications. Shared decision-making is important as surgery is not without risk of short- and long-term complications.

Over 50% of adults with type 1 diabetes are now also obese, at least in the United States and the UK. Insulin is an anabolic hormone, so if

insulin dosing is imperfectly matched to carbohydrate intake, calorie ingestion may at times be required to prevent hypoglycaemia. Some individuals appear to be more susceptible to insulin-induced weight gain than others. Increasing use of technology (CSII and CGM) may help with this problem, as may adjunct therapy with SGLT2 inhibitors.

## Exercise

People with diabetes should be advised to follow advice on physical activity as for the general population. Supervised and structured exercise programmes may be of particular benefit in type 2 diabetes. The American Diabetes Association recommends that all adults with diabetes reduce sedentary time (avoiding periods >90 minutes) and do either 150 minutes per week of moderate-intensity exercise or 75 minutes per week of vigorous-intensity exercise. Muscle-strengthening (resistance) exercise is recommended on 2 or more days of the week. Of course, older individuals and those with disabilities may not be able to follow these recommendations in full.

People with type 1 diabetes (and people with insulin-treated type 2 diabetes) face additional challenges in relation to exercise compared with the general population due to the risk of exercise-induced hypoglycaemia (see p. 725). However, following support in planning reduction of bolus insulin dosing (and in some cases increased carbohydrate ingestion) prior to exercise, many can participate in high-level competitive sports including golf, rowing and marathon running.

## Alcohol and smoking

In type 2 diabetes, recommendations on alcohol are as for the general population (i.e. no more than 14 units per week for adults) to prevent liver cirrhosis and weight gain. In type 1 diabetes (and for people with insulin-treated type 2 diabetes) alcohol can also reduce hypoglycaemia awareness and suppress gluconeogenesis, increasing risk of level 3 hypoglycaemia. In addition, the signs of hypoglycaemia can be mistaken for alcohol intoxication by observers. People with insulin-treated diabetes are therefore advised during ingestion of alcohol to: (i) let a companion know that they have diabetes and how to treat them if they have hypoglycaemia; (ii) continue to monitor and correct blood glucose by eating while drinking; and (iii) measure and ensure glucose is not low before retiring to bed.

Given the risk of cardiovascular complications associated with diabetes and despite increasing access to smoking cessation support, around 20% of people with type 1 diabetes and 15% of people with type 2 diabetes in most cohorts are current cigarette smokers (rates similar or higher to that in the general population). Research is required into better methods of achieving behaviour modification.

## Driving

European legislation on driving has had a major impact on people with diabetes. Legislation varies from country to country and so individuals should discuss with their diabetes health-care professional if their treatment necessitates reporting to the licensing authority (Box 21.22). To drive a car or ride a motorcycle in the UK, people with diabetes who take insulin therapy must notify the Driver and Vehicle Licensing Agency (DVLA). They must have adequate awareness of hypoglycaemia, have had no more than one episode of level 3 hypoglycaemia in the preceding 12 months, meet the standards for visual acuity and visual fields, and not be regarded as a likely risk to the public while driving. In addition, blood glucose testing is required to be performed no more than 2 hours before the start of a journey and every 2 hours while driving. Blood glucose levels should be over 5.0 mmol/L (90 mg/dL) before driving; if they are below 4.0 mmol/L (72 mg/dL) or there are symptoms of hypoglycaemia, the person should not drive. CGM has been approved for monitoring glucose at times relevant for driving in the UK, provided the glucose level is above 4.0 mmol/L, there are no symptoms of hypoglycaemia and the CGM device reading is consistent with symptoms experienced. Legislative

requirements in the UK for people on insulin therapy who have Group 2 licences to drive larger vehicles such as buses or lorries require, in addition, an annual examination by a diabetes specialist, along with review of 3 months of glucose readings.

## Ramadan

The Quran requires Muslims to fast from sunrise to sunset during the 29 or 30 days of Ramadan, the ninth month of the Muslim calendar. While people with diabetes are a recognised exception to this and are not required to fast, many choose to do so. In this context, people with diabetes should schedule a visit with a diabetes health-care professional 6–12 weeks before Ramadan. Prior to fasting the person should be counselled on their personal risk of fasting and an individualised management plan should be developed. This should include: structured education around fluids and meal planning, when to exercise, the role of

increased frequency and/or timing of glucose monitoring (which does not invalidate the fast) and adjustment to the dose time and/or frequency of glucose-lowering agents. The majority of people with type 2 diabetes can be supported to fast during Ramadan provided they are prepared to stop the fast in the case of frequent hypo- or hyperglycaemia or worsening of other related medical conditions. While people with type 1 diabetes are advised not to fast, this advice should be considered on a case-by-case basis. The highest risk of hypoglycaemia is in people who are managed with sulphonylureas and insulin (especially if they are older age, or have renal failure or advanced macrovascular complications); such individuals need careful blood glucose monitoring and, if necessary, their treatment regimens may need to be adjusted. Glucose-lowering therapies that do not cause hypoglycaemia are safest during Ramadan, if glycaemic control permits. Dipeptidyl peptidase (DPP-4) inhibitors or glucagon-like peptide-1 (GLP-1) receptor agonists provided they are initiated at least 6–8 weeks before, may be especially useful because their effect on insulin secretion is glucose-dependent. Published guidance is available to help guide dose and timing adjustments from the International Diabetes Federation and the Diabetes and Ramadan International Alliance (IDF-DAR).

### i

#### 21.22 Diabetes and driving

The main risk is hypoglycaemia due to insulin treatment. Health professionals should be proactive in supporting people with diabetes on insulin therapy to drive safely within the regulations while following legislation designed to protect road-users.

- Licensing regulations vary considerably between countries.
- In the UK, it is a legal requirement for people with diabetes requiring insulin therapy to notify the Driver and Vehicle Licensing Agency (DVLA)
- Group 1 licences (car, motorcycle, van) are 'period-restricted' for insulin-treated drivers, i.e. usually renewable every 3 years but with specific criteria: particularly no more than one episode of level 3 hypoglycaemia while awake in the preceding 12 months (the most recent episode more than 3 months ago)
- Group 2 licences (bus and lorry) may be granted for insulin-treated drivers: stricter criteria to be met – in particular no episode of level 3 hypoglycaemia (see [Box 21.14](#)) within the last 12 months and full awareness of hypoglycaemia regardless of whether this occurred when asleep. The licence is renewable annually.
- Blood glucose must be monitored appropriately. Those with a Group 1 licence may use continuous glucose monitoring systems, but must confirm the reading using a capillary blood glucose reading in specific circumstances (e.g. glucose  $\leq 4.0$  mmol/L)
- Insulin-treated drivers should:
  - Check blood glucose before driving and 2-hourly during long journeys
  - Keep an accessible supply of fast-acting carbohydrate in the vehicle
  - Take regular snacks or meals during long journeys
  - Stop driving if hypoglycaemia develops
  - Pull over and sit in the passenger seat
  - Wait 45 mins after correction of hypoglycaemia before resuming driving (delayed recovery of cognitive function)
  - Carry identification in case of injury

**Note:** Intermittently scanned monitoring (isCGM) is now approved in the UK for Group 1 licences provided the driver has the facility to check capillary blood glucose if symptoms of hypoglycaemia or hyperglycaemia are experienced. See: *Assessing fitness to drive: a guide for medical professionals (ch. 3)*. [https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment\\_data/file/866655/assessing-fitness-to-drive-a-guide-for-medical-professionals.pdf](https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/866655/assessing-fitness-to-drive-a-guide-for-medical-professionals.pdf).

## Glucose-lowering agents

Type 1 diabetes is managed with insulin from the time of diagnosis. When glucose levels are above target in type 2 diabetes despite appropriate lifestyle advice, drug therapy will usually be initiated and subsequently increased ('intensified') with the aim of establishing or re-establishing adequate glucose control, abolishing osmotic symptoms and preventing microvascular complications. Some individuals require pharmacological therapy from the time of (or very soon after) diagnosis. Over the following years and decades, the majority will require to take combinations of glucose-lowering drugs, oral or injectable, and some will also require insulin.

Seven main classes of glucose-lowering drugs are generally used to manage type 2 diabetes ([Box 21.23](#)). Four are oral agents: metformin (the only available biguanide), sulphonylureas, pioglitazone (the only available thiazolidinedione), DPP-4 inhibitors and sodium glucose transporter-2 (SGLT2) inhibitors. GLP-1 receptor agonists are usually given by subcutaneous injection, but an oral preparation is available. Insulin is given by subcutaneous injection. The effects of these drugs are compared in [Box 21.23](#). Acarbose (an intestinal disaccharidase inhibitor that prevents dietary glucose absorption) and meglitinides (oral agents that stimulate endogenous insulin) are also available, but little used due to relatively low efficacy and, in the case of acarbose, frequent (gastrointestinal) side effects. Other agents are in development.

To date, the totality of evidence confirms that any agent that reduces blood glucose will also reduce the long-term risk of microvascular complications. Factors that determine which of these drugs should be prescribed first – and then which should subsequently be added in – include:

- individual profile (severity of initial symptoms, degree of obesity)
- glucose-lowering efficacy
- protective properties in relation to cardiovascular and renal complications (see below)

### i

#### 21.23 Glucose-lowering agents in type 2 diabetes: additional information (see also [Fig. 21.20](#))

	Insulin	Sulphonylureas	Metformin	Thiazolidinediones ('glitazones')	DPP-4 inhibitors ('gliptins')	GLP-1 receptor agonists	SGLT2 inhibitors
<b>Introduced</b>	1922	1956	1957	1999	2006	2007	2013
<b>Route of administration</b>	SC injection	Oral	Oral	Oral	Oral	SC injection (oral)	Oral
<b>Cost</b>	High	Low	Very low	Low	Moderate	Very high	High

(DPP-4 = dipeptidyl peptidase 4; GLP-1 = glucagon-like peptide 1; SC = subcutaneous; SGLT2 = sodium and glucose transporter 2)

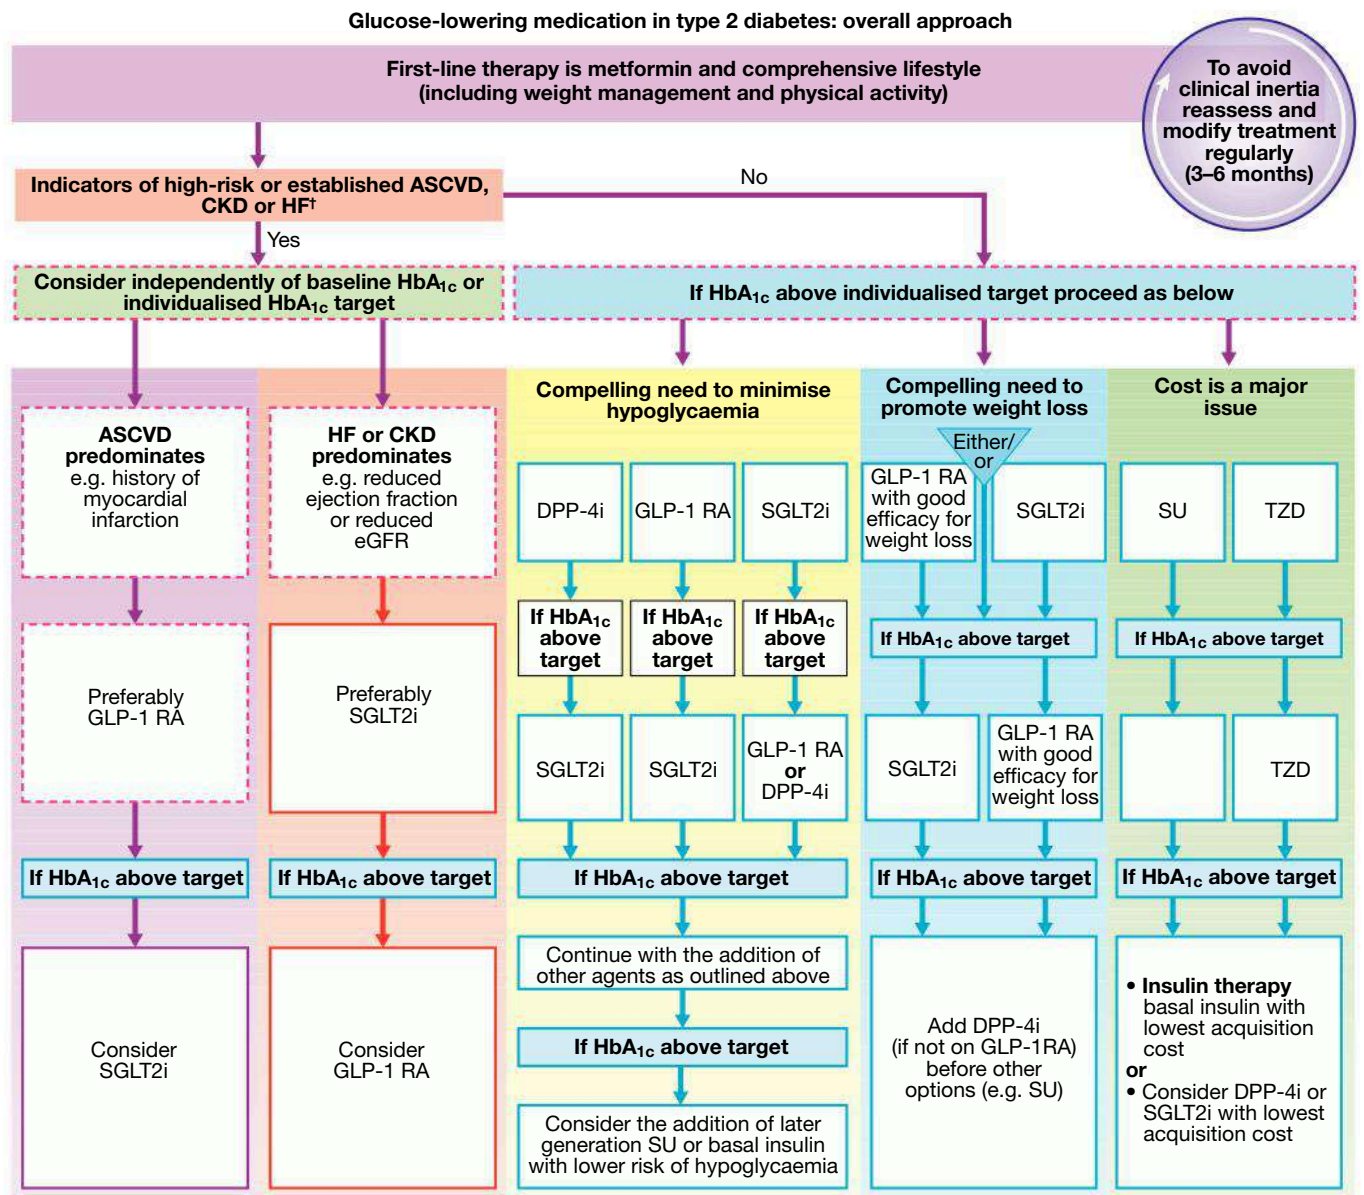

- adverse effect profile (hypoglycaemia, weight gain)
- renal function
- drug factors (mechanism of clearance/metabolism)
- ability or willingness to self-inject
- occupation (e.g. driving, working at heights)
- cost: important whether covered by a national health-care system, reimbursed by an insurance company, or paid for 'out-of-pocket'.

Algorithms to guide prescribing decisions are available, e.g. consensus documents from the American Diabetes Association and the European Association for the Study of Diabetes (ADA/EASD; Fig. 21.20). These are frequently updated.

Metformin is often positioned as first-line, with second-line treatment personalised for each patient according to the above factors. A third or even fourth oral agent may be added in over time, but injectable therapy

(GLP-1 receptor agonists or insulin) should not be delayed while levels of glycaemia above target are sustained for months or years; this will almost inevitably result in severe complications years later.

Unlike microvascular complications, it cannot be assumed that all agents that lower glucose also reduce rates of macrovascular complications, i.e. myocardial infarction and stroke. Some newer agents clearly protect against cardiovascular disease (GLP-1 receptor agonists and SGLT2 inhibitors), but are more expensive. Others (metformin and thiazolidinediones) provide some cardiovascular protection, but are cheaper, while others do not (sulphonylureas, DPP-4 inhibitors and insulin). SGLT2 inhibitors have additional protective properties in heart failure and diabetic kidney disease, while TZDs (thiazolidinediones) increase rates of heart failure. It is therefore likely that the protective (and adverse) effects of these different classes of glucose-lowering agents are via 'off-target' mechanisms, i.e. unrelated to glucose-lowering.

SU

**Fig. 21.20** Guidelines for glucose-lowering treatment in type 2 diabetes: adapted from ADA-EASD 2020. This pathway is illustrative – for treatment decisions please refer to the figure provided in the full guideline (<https://doi.org/10.1007/s00125-019-05039-w>) and region-specific drug licensing information. (DPP-4i = dipeptidyl peptidase 4 inhibitor; GLP-1 RA = glucagon-like peptide 1 receptor agonist; SGLT2i = sodium and glucose co-transporter 2 inhibitor; TZD = thiazolidinedione; SU = sulphonylurea; eGFR, estimated glomerular filtration rate; ASCVD = atherosclerotic cardiovascular disease; CKD = chronic kidney disease; HF = heart failure; LVH = left ventricular hypertrophy) Adapted from: Buse JB, Wexler DJ, Tsapas A, et al. 2019 update to: Management of hyperglycaemia in type 2 diabetes, 2018. A consensus report by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD). *Diabetologia* 2020; 63, 221–228.

The adverse risk profile of each agent plays an important role in personalisation of second- and third-line therapy. For example, agents that cause hypoglycaemia should be avoided in those who drive for a living (particularly those holding Group 2 licences in the UK) or who work at heights.

There is little evidence to help the clinician and patient select the optimal second- or third-line treatment in advance, so a trial-and-error approach is often used, i.e. stopping a drug that does not seem to be effective (or that causes side-effects) and trying another. It is hoped that biomarkers will in the future help predict who will respond better and/or experience fewer side-effects with one drug rather than another.

## Biguanides

Metformin is the only biguanide available. Its long-term benefits include not just reduction in rates of microvascular complications, but also reducing the risk of myocardial infarction, as shown in the UKPDS. It is widely used as first-line therapy for type 2 diabetes. Approximately 15% of individuals experience significant gastrointestinal side-effects, including bloating, nausea, diarrhoea and abdominal pain, such that they are unable to tolerate metformin. Metformin monotherapy may not be sufficient to provide rapid relief from symptoms in individuals with marked osmotic symptoms and weight loss at diagnosis (see sulphonylureas below).

### Mechanism of action

The mechanism of action of metformin has not been precisely defined. While classically considered an 'insulin sensitiser' because it tends to lower (rather than raise) insulin levels, its main effects are on fasting glucose. Metformin reduces hepatic glucose production, may also increase insulin-mediated glucose uptake, and has effects on gut glucose uptake and utilisation. At the molecular level, metformin acts as a weak inhibitor of mitochondrial respiration, which increases intracellular adenosine monophosphate (AMP) and reduces adenosine triphosphate (ATP). This has direct effects on the flux through gluconeogenesis and activates the intracellular energy sensor, AMP-activated protein kinase (AMPK), leading to multiple beneficial effects. However, although metformin has been available for more than 60 years, it is not yet clear whether other AMPK-independent mechanisms may be just as important.

### Clinical use

Metformin causes modest sustained weight loss (on average 1–2 kg), does not cause hypoglycaemia and has established benefits in microvascular disease. It is prescribed first-line therapy for the majority of people unless they do not tolerate it, and it is usually maintained when additional agents are required (see Fig. 21.20). Metformin is usually introduced at low dose (500 mg twice daily) to minimise the risk of gastrointestinal side-effects. The usual maintenance dose is 1000 mg twice daily (maximum licensed dose 1000 mg three times daily). Modified-release formulations of metformin are better tolerated by some individuals with gastrointestinal side-effects on the regular preparation.

Due to inhibition of mitochondrial respiration, metformin can cause asymptomatic hyperlactataemia, which during acute illness can present as lactic acidosis. However, this is much less common than previously thought and most instances of lactic acidosis that occur in the context of metformin prescription are due to other factors. As metformin is cleared by the kidneys, it can accumulate in renal impairment, so the dose should be halved when estimated glomerular filtration rate (eGFR) is below 45 mL/min/1.73 m<sup>2</sup>, and it should not be used below an eGFR of 30 mL/min/1.73 m<sup>2</sup>. It should be omitted temporarily during any acute illness potentially involving dehydration as acute kidney injury greatly increases the risk of lactic acidosis. Metformin is contraindicated in the presence of significantly impaired hepatic function and in those who drink alcohol to excess as they are more vulnerable to lactic acidosis.

## Sulphonylureas

Sulphonylureas are 'insulin secretagogues', i.e. they promote pancreatic  $\beta$ -cell insulin secretion. Similar to metformin, the long-term benefit of sulphonylureas in reducing rates of microvascular complications was established in the UKPDS.

### Mechanism of action

Sulphonylureas act by closing the pancreatic  $\beta$  cell ATP-sensitive potassium ( $K_{ATP}$ ) channel, decreasing  $K^+$  efflux, and triggering insulin secretion by a series of molecular events (see Fig. 21.3C).

### Clinical use

Sulphonylureas are an effective therapy for lowering blood glucose. They may be used to relieve osmotic symptoms in individuals with newly diagnosed diabetes who have very high blood glucose, although insulin should also be considered in this context, particularly if a diagnosis of new-onset type 1 diabetes remains possible (as in this context they are dangerous because they are ineffective). They are more often used as an add-on to other glucose-lowering therapy when glycaemia is inadequately controlled (see Fig. 21.20) or in non-obese people with type 2 diabetes (who likely have significant  $\beta$ -cell dysfunction). Sulphonylureas are also particularly effective in some forms of monogenic and neonatal diabetes (see p. 719). The main adverse effects of sulphonylureas are weight gain and hypoglycaemia (as insulin secretion occurs irrespective of the prevailing blood glucose). A number of sulphonylureas are available: gliclazide is most commonly used in the UK and glibenclamide (known as glyburide) in the United States. Glibenclamide, however, is long-acting and prone to inducing hypoglycaemia, so should be avoided in older people. Other sulphonylureas include glimepiride and glipizide. The dose–response of all sulphonylureas is steepest at low doses, i.e. little additional benefit is obtained when the dose is increased above half-maximal doses.

## Thiazolidinediones

### Mechanism of action

These drugs (also called TZDs, 'glitazones' or PPAR $\gamma$  agonists) bind and activate peroxisome proliferator-activated receptor- $\gamma$ , nuclear receptors present mainly in adipose tissue (similar to steroid and thyroid nuclear receptors), which regulate the expression of several genes involved in adipocyte differentiation. By promoting adipogenesis in subcutaneous depots, TZDs decrease circulating concentrations of free fatty acids, enhancing the actions of endogenous insulin. Therefore, they tend to increase body weight. They also alter release of 'adipokines', e.g. increasing levels of adiponectin improves insulin sensitivity in the liver. TZDs appear to be particularly effective at improving glycaemic control in women and people with a raised BMI.

### Clinical use

TZDs were widely prescribed in the late 1990s and 2000s, but their use declined with the advent of other agents with fewer adverse effects and greater efficacy. One popular TZD, rosiglitazone, was withdrawn from the market in 2010 due to a subsequently disproven concern that it might increase rates of myocardial infarction. Pioglitazone, the other drug in this class, remains in use and may reduce hepatic steatosis and NASH (see Fig. 21.20) as well as providing protection from stroke. However, it exacerbates cardiac failure by causing fluid retention and increases the risk of bone fracture (and possibly bladder cancer) with long-term use.

## DPP-4 inhibitors

### Mechanism of action

The incretin hormones (see Fig. 21.4) GLP-1 and GIP are gut hormones that potentiate post-prandial insulin secretion (see Fig. 21.3). GLP-1 and GIP are rapidly broken down by dipeptidyl peptidase 4 (DPP-4). The 'gliptins', or DPP-4 inhibitors, prevent physiological breakdown of endogenous GLP-1 and GIP and so enhance their circulating concentrations. Incretin-based therapies (DPP-4 inhibitors and GLP-1 agonists) are 'glucose-dependent', i.e. promote insulin secretion only when glucose is high

(Fig. 21.21). Thus, insulin secretion is not augmented when blood glucose is normal, i.e. there is minimal risk of hypoglycaemia when these therapies are used as monotherapy or in combination with other drugs that do not cause hypoglycaemia.

### Clinical use

DPP-4 inhibitors include sitagliptin, linagliptin, alogliptin, vildagliptin and saxagliptin. All are well tolerated and have a neutral effect on weight, but are less potent than GLP-1 receptor agonists and provide only moderate glucose-lowering activity (see Box 21.23). They are safe but do not improve cardiovascular outcomes. The DPP4 inhibitors are useful in combination with other drugs to get HbA<sub>1c</sub> to target when it is only modestly elevated and are commonly used in older people as they have few adverse effects. Linagliptin is the only DPP4 inhibitor that does not require dose reduction in renal impairment.

## GLP-1 receptor agonists

### Mechanism of action

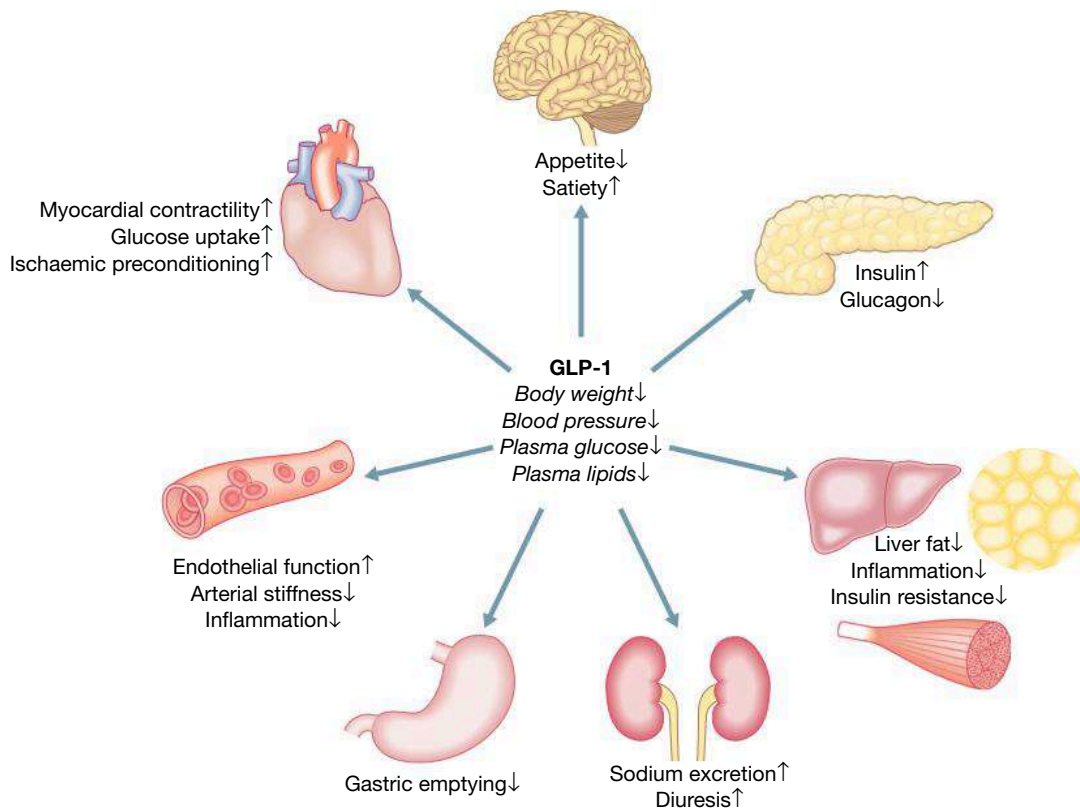

The GLP-1 receptor agonists are peptide hormones that mimic the action of GLP-1; most require to be given by subcutaneous injection. Some have a high degree of structural homology to native GLP-1, but are modified at the sites usually cleaved by DPP-4 to prevent breakdown (liraglutide, semaglutide, dulaglutide). Others are synthetic forms of exendin-4, a 39 amino acid peptide originally isolated from the salivary secretions of the Gila monster, native to the Arizona desert (exenatide, lixisenatide). As incretin-based therapies, they potentiate release of insulin, but with greater potency than DPP-4 inhibitors. However, they also have central actions, acting centrally on receptors in specific areas of the hypothalamus (including the arcuate nucleus); in addition they delay

gastric emptying, giving a feeling of satiety after eating (see Fig. 21.21). GLP-1 receptor agonists therefore decrease appetite and feeding behaviour, resulting in weight loss of on average 3–5 kg. Modifications of either the molecule or the formulation allow some agents within the class to be injected once weekly (semaglutide, dulaglutide, extended-release exenatide), rather than once daily (liraglutide) or twice daily (exenatide). An orally administered GLP-1 receptor agonist has now been approved (encapsulated semaglutide with an advanced gastrointestinal delivery system), although it must be taken once daily on an empty stomach with a sip of water and nothing should be consumed for 30 minutes afterwards.

### Clinical use

The main side-effect of GLP-1 receptor agonists is nausea (and even vomiting) in the first few days of use; this is prevented in many individuals by slowly uptitrating from a low starting dose to a therapeutic dose. Several of the GLP-1 receptor agonist class, particularly those with high structural homology to native GLP-1 (liraglutide, semaglutide and dulaglutide), have been shown in large cardiovascular outcome trials to reduce rates of major cardiovascular adverse events. These are now the most frequently prescribed drugs in the class, although as they are expensive compared with other agents, guidelines in the UK recommend that they should only be used third-line, as add-on therapy with other agents and only in those with a BMI of >30 kg/m<sup>2</sup> (Scottish Intercollegiate Guideline Network, SIGN) or even 35 kg/m<sup>2</sup> (National Institute for Health and Care Excellence NICE). However, some international guidelines (e.g. European Society for Cardiology) now recommend they should be started earlier, even before metformin, in individuals at high risk of a cardiovascular event.

Since their initial launch in 2007, GLP-1 receptor agonists have contributed to a revolution in the treatment of type 2 diabetes. For several

**Fig. 21.21 Actions of incretin-based therapies.** GLP-1 receptor agonists (GLP-RA) mediate all of the actions shown and have potent effects on blood glucose and weight. Many GLP-1 RAs are associated with a reduction in cardiovascular events. Dipeptidyl peptidase 4 inhibitors (DPP-4i) have less potent glucose-lowering ability and have a neutral effect on weight and cardiovascular disease. DPP-4is do not mediate all of the actions shown, e.g. do not reduce gastric emptying or have significant effects on appetite. (GLP-1 = glucagon-like peptide 1)

years, there was a concern that they (and DPP4-inhibitors) might increase the risk of pancreatitis or pancreatic cancer, but meta-analysis of large clinical trials has demonstrated this is not the case. Even more potent 'dual agonist' agents (with GIP agonist activity) are now in development.

## SGLT2 inhibitors

### Mechanism of action

Sodium-glucose co-transporter 2 (SGLT2) inhibitors are derived from apple tree bark and were first licensed for type 2 diabetes in 2013. The best-known drugs in the class are dapagliflozin, empagliflozin and canagliflozin. The mechanism by which they lower blood glucose exploits the handling of glucose in the kidneys. Glucose is filtered freely in the glomerulus and then completely reabsorbed in the proximal tubules

with sodium (mainly via SGLT2) (Fig. 21.22). During hyperglycaemia, this response reaches saturation and glucose is lost in the urine. Glycosuria is a hallmark feature of type 2 diabetes, but in many cases there is a paradoxical increase in reabsorption of glucose such that the threshold blood glucose value at which glucose is lost in the urine is higher than the usual physiological level; this may be due to increased expression of SGLT2.

SGLT2 inhibitors act by lowering the renal threshold for glucose excretion, such that typically 25% of filtered glucose is not reabsorbed. As well as lowering blood glucose, a negative energy balance is created with 200–300kcal being lost each day (as glucose in the urine), resulting in significant weight loss. As sodium is also lost in the urine (also known as natriuresis), blood pressure is also reduced.

SGLT2 inhibitors reduce rates of major adverse cardiovascular outcomes, particularly heart failure, and also have a reno-protective effect,

**Fig. 21.22** **A** Glucose filtration and reabsorption by the nephron. Some 90% of filtered glucose is reabsorbed by sodium and glucose transporter (SGLT) 2 and 10% by SGLT1. SGLT2 inhibitors reduce net reabsorbed glucose by 25%. For a mean plasma glucose of 8 mmol/L (144 mg/dL) this results in a glucose loss of approximately 80 g per day in the urine, which in turn reduces plasma glucose. This equates to 320kcal per day and subsequent weight loss. **B** SGLT2 inhibition leads to glycosuria and is associated with improved glycaemia, blood pressure reduction and weight loss.

i.e. reducing rates of death, dialysis and transplantation. These beneficial effects are at least in part due to blood pressure and weight lowering but other more complex mechanisms are also of clinical relevance. Compensatory glucagon release from pancreatic  $\alpha$  cells (in response to urinary loss of glucose) decreases the circulating ratio of insulin to glucagon, promoting lipolysis and even mild ketosis; however, because of weight loss this is not sufficient to exacerbate insulin resistance. The work of the myocardium is more efficient when it utilises free fatty acids (and ketones) for fuel than it is when metabolising glucose (as it does in heart failure). Renal benefits of SGLT2 inhibitors are due to constriction of the afferent arteriole (as a reflex response to increased renal tubular loss of sodium, termed 'tubuloglomerular feedback'). This decreases intraglomerular pressure in a complementary manner to ACE inhibitors (p. 619), which cause relaxation of the efferent arteriole by opposing the action of angiotensin II.

### Clinical use

SGLT2 inhibitors are effective oral glucose-lowering agents that are usually added in with other agents second-line after metformin. They help with body weight reduction and are associated with improvements in cardiovascular and renal outcomes that have substantially advanced the treatment of type 2 diabetes. They should now be prescribed for all individuals with type 2 diabetes and prior myocardial infarction, coronary artery disease, stroke, unstable angina, occlusive peripheral arterial disease or cardiac failure. Dapagliflozin is also licensed for use in type 1 diabetes, but must be used with caution due to the increased risk of ketoacidosis (see below).

The main adverse effect (in 5%–10% of those who take these agents) is genital mycotic (fungal) infections usually with *Candida albicans*, i.e. vaginal 'thrush' and balanitis. Urine infection is also more common and, very rarely, severe genital infection (Fournier's gangrene, see Ch. 13) can occur. It is essential for prescribers to mention these side-effects, to ensure that prompt measures can be taken to treat the infection; good genital hygiene is also necessary. Once blood glucose is under control, genital infections are much less likely to occur. Euglycaemic diabetic ketoacidosis (i.e. DKA not associated with marked hyperglycaemia) is a rare complication of this class of drugs, presumably driven by reduced insulin:glucagon ratio and consequent increased levels of circulating ketones. It can be minimised by education about 'sick day rules', i.e. interrupting therapy during acute illness (e.g. gastrointestinal or respiratory), avoiding dehydration and seeking medical attention. The provision of a glucose meter with additional functionality for blood ketone monitoring can also be useful as an early warning of DKA for individuals considered to be at higher risk (e.g. type 1 diabetes).

## Insulin therapy

### Manufacture and formulations

Insulin was first isolated in Toronto in 1921, transforming the previously short life expectancy of children and young adults with type 1 diabetes. It was obtained for therapeutic use by extraction and purification from pancreases of cows and pigs (bovine and porcine insulins), until the emergence of recombinant DNA technology enabled large-scale production of human sequence insulin from the early 1980s. From the mid-1990s, 'analogue insulins', gradually gained ground; these contain alterations to the amino acid sequence and/or additional molecules covalently added to confer desirable pharmacological profiles. They have now largely replaced human sequence insulin.

The underlying principles of insulin pharmacology are simple, but the naming of the various available insulin preparations is complicated by trade names conferred on similar or equivalent products by different manufacturers. The time-action profile of an insulin describes its pharmacodynamic properties as time to onset and peak action as well as its overall duration of action after subcutaneous injection. These properties are depicted using simplified graphs (see Fig. 21.24) as an educational tool for insulin users and health-care professionals. With only a

few exceptions, insulin concentration is standardised internationally at 100U/mL, using a system based on the one developed by the team in Toronto. Expert advice should be sought before using more concentrated insulins and in the UK these are now provided via dedicated pen devices to avoid confusion and prevent prescribing errors.

Unmodified ('soluble' or 'regular') short-acting insulin is clear in appearance and has an onset of action within 30 minutes of injection, wearing off by 6–8 hours. Extending this duration of action was initially achieved in the 1930s by adding protamine and zinc at neutral pH to create Neutral Protamine Hagedorn insulin (known as 'isophane' or NPH insulin) – this has a cloudy appearance (and requires to be resuspended by shaking before use). It is now referred to as 'intermediate-acting' with onset of action at 60–90 minutes, peaking at 6 hours and wearing off by 12–16 hours.

When insulin is injected into subcutaneous tissues, it aggregates into hexamers; these polymers of six insulin molecules must dissociate before systemic absorption can occur. The speed of dissociation can be altered by making small changes to the amino acid sequence (insulin analogues). For example, in insulin lispro, the penultimate lysine and proline residues on the C-terminal end of the B-chain are reversed (Fig. 21.23). This prevents hexamer formation leading to a more rapid onset and shorter duration of action than soluble insulin (Box 21.24). Short-acting insulin analogues allow greater flexibility as they can be injected closer to mealtimes (ideally 15–30 minutes before). Onset of action may be further hastened by the addition of excipients to the formulation (e.g. nicotinamide and L-arginine to insulin aspart to create 'faster insulin aspart').

Other changes to the insulin molecule have been engineered to produce long-acting analogue insulins. An example is insulin glargine, in which a substitution of glycine for asparagine in the A-chain and the addition of two additional arginine residues to the C-terminal end of the B-chain serves to prolong its duration of action to nearly 24 hours by increasing its isoelectric point from pH 5.4 to 6.7, i.e. making it less soluble at a physiological pH (see Fig. 21.23). Other long-acting insulins include insulin detemir and degludec; their duration of action is extended by adding fatty acid side chains to the C-terminal end of the B-chain (Fig. 21.23). Following subcutaneous injection, insulin detemir and degludec bind to albumin in the blood, from which insulin slowly disassociates. The duration of action of insulin degludec is almost 48 hours as the fatty acid moiety also promotes subcutaneous formation of multi-hexamers of insulin (see Box 21.24). It is termed a second generation long-acting insulin. However, a comparable pharmacological profile can be achieved by using a triple concentrated form of insulin glargine ('U300 glargine'); this can also be useful to decrease injection volume for individuals who require high doses to achieve glycaemic control. Modern long-acting insulins provide more consistent basal insulin levels during the day and night and are associated with lower rates of hypoglycaemia, particularly overnight. A long-acting insulin that requires injection only once weekly is currently in development.

Pre-mixed formulations containing short-acting and isophane insulins in various proportions ('biphasic', see below) are also available and widely prescribed in some countries, particularly for individuals with type 2 diabetes with regular mealtimes who wish to avoid injecting more than twice a day (see below).

### Intermittent subcutaneous insulin injection therapy

Insulin is most commonly administered several times a day as an injection into the subcutaneous adipose tissue of the anterior abdominal wall, upper arms or outer thighs with the needle sited at a right-angle to the skin. Even with careful technique, the rate of absorption of insulin is influenced by the site, depth and volume of injection, skin temperature (warming) and exercise. Accidental intramuscular injection results in more rapid absorption and hypoglycaemia; it is more likely to occur in children and slim adults (with little subcutaneous adipose tissue) and can be minimised by using shorter needles (e.g. 4 mm rather than 8 mm). A clinically important reason for delayed absorption is lipohypertrophy, which can develop at over-used injection sites (see p. 738). This is due to the local trophic (growth factor)

**Fig. 21.23 Schematic structure of insulin and insulin analogues.** Insulin is created when C-peptide is cleaved from the A- and B-chains of proinsulin. The areas in the shaded colours show the modifications made to the normal structure of insulin to create analogues. These are important in altering the pharmacokinetic properties of the analogues. Long-acting insulin analogues detemir and degludec are synthesised by adding specific fatty acid chains (shown) at position 29 (lysine) on the B-chain.

21.24 Duration of action (in hours) of insulin preparations			
Insulin	Onset	Peak	Duration
<b>Rapid-acting</b> insulin analogues: lispro, aspart, glulisine, fiasp	<0.5	0.5–2.5	3–4.5
<b>Short-acting</b> soluble (regular)	0.5–1	1–4	4–8
<b>Intermediate-acting</b> isophane (NPH), lente	1–3	3–8	7–14
<b>Long-acting</b> insulin analogues: glargine, detemir, degludec	1–2	None	18–26

action of insulin and results in greater variability in blood glucose. It can be avoided by not injecting into the same place and instead 'rotating' injections around (and within) the recommended sites.

Following absorption into blood, circulating insulin has a half-life of just a few minutes as it is cleared by the liver and kidneys. The total daily dose required may therefore diminish in individuals who develop liver disease or renal failure.

Traditional insulin syringes have largely been replaced by unobtrusive portable 'pen' devices, sufficient for multiple dosing and either disposable or designed to accept insulin in cartridges. Insulin users are advised to keep their stock in a refrigerator (approximately 4°C), but to keep their current pen at room temperature (as cold insulin is more painful to inject). Insulin will denature and become inactive if accidentally

frozen and thawed. The complications of insulin therapy include hypoglycaemia (p. 719), weight gain, peripheral oedema, insulin antibodies, local allergy (rare) and lipohypertrophy or lipoatrophy at injection sites. Fasting hyperglycaemia (referred to as the 'Somogyi effect') has in the past been attributed to a rebound driven by counter-regulatory hormones (cortisol, growth hormone and catecholamines) following undetected overnight hypoglycaemia. However, systematic investigation in the era of CGM has detected little supporting evidence for this as high blood glucose on rising is more often due to a combination of the circadian cycle (or 'dawn phenomenon') and inadequate overnight basal insulin dosing.

#### Intermittent subcutaneous insulin injection regimens

The choice of insulin injection regimen depends on the agreed target for glycaemic control (set using the principle of 'shared decision-making'), need for flexibility in lifestyle and whether an individual can safely and reliably learn to adjust insulin doses in response to counting the carbohydrate content of planned meals. Time-action profiles for different insulin regimens are shown in [Figure 21.24](#).

In general, people with type 1 diabetes should be prescribed either multiple daily insulin injections (MDI) or continuous subcutaneous insulin infusion therapy (CSII). MDI or 'basal-bolus' therapy consists of four or five daily injections: one or two 'basal' injections (with an intermediate- or long-acting insulin, respectively) and an injection of 'bolus' insulin (usually with a rapid-acting analogue) 15–30 minutes before each of three main meals. The purpose of bolus insulin is to limit the magnitude of the rise in blood glucose following a meal. The purpose of basal ('background') insulin is to ensure there are adequate amounts of insulin to reduce hepatic glucose output, both overnight and during periods of the daytime when there is little bolus insulin activity (i.e. if there is a long time-gap between bolus injections). An MDI regimen allows greater freedom of meal timing as bolus insulin is simply administered before the meal.

**Fig. 21.24** Profiles of plasma insulin associated with different insulin regimens. These are theoretical patterns of plasma insulin and may differ considerably in magnitude and duration of action between individuals.

The dose of bolus insulin administered at any one meal is primarily determined by the carbohydrate content of the meal, the prevailing glucose level and the target glucose for the individual. Each patient is advised by health-care professionals of their 'insulin to carbohydrate ratio', i.e. the amount of insulin to take for each carbohydrate portion. In most people, this ratio is around 1:10 (i.e. 1 unit of insulin is taken for each 10g carbohydrate portion in the meal to be consumed), but may be higher or lower depending on the individual's insulin sensitivity. It may also vary between meals (e.g. breakfast vs evening meal). Patients are also advised of their 'insulin sensitivity factor' (or 'correction factor'), i.e. the amount that 1 unit of insulin lowers blood glucose. In most people, 1 unit of insulin lowers glucose by 3 or 4 mmol/L, although this again varies according to insulin sensitivity. Box 21.25 shows a worked example of how a person with diabetes may use this information to determine the dose of insulin to be administered with a meal. Additional adjustments to the final dose also may need to take into account other variables, including exercise and alcohol consumption. Thus, bolus insulin may need to be reduced to cover a meal taken 2 hours prior to vigorous exercise or if consuming large amounts of alcohol (see p. 732).

Basal insulin doses are determined with reference to fasting glucose levels and overnight profiles. Thus, the dose may be decreased if there is overnight or fasting hypoglycaemia and increased if there is overnight hyperglycaemia. Further refinement of daytime basal insulin can be made with reference to daytime glucose profiles following a series of carbohydrate-free meals (which do not require injection of bolus insulin) as the glucose levels in this context are mainly dependent on basal insulin.

The foregoing shows how the therapeutic use of insulin demands considerable attention to detail, with respect to a whole variety of factors, as well as significant numeracy skills. Many people understandably struggle to maintain the motivation required to monitor glucose regularly, count carbohydrate accurately, remember to take all their

### 21.25 Example of bolus insulin dose calculation

You are about to eat a meal with 60 g carbohydrate

Your pre-meal blood glucose is 13.0 mmol/L

Your personalised diabetes data:

Insulin to carbohydrate ratio = 1:10

Insulin sensitivity factor = 3, i.e. 1 unit of insulin lowers blood glucose by 3 mmol/L

Target blood glucose = 7 mmol/L

**Bolus dose calculation**

1. Bolus dose of insulin to cover meal =  $60 \text{ g} \div 10 \text{ g}$   
= **6 units**
2. Blood glucose correction = Actual glucose – target glucose  
=  $13.0 - 7.0 \text{ mmol/L}$   
= **6.0 mmol/L**
3. Correction dose of insulin = Blood glucose correction  $\div$  insulin sensitivity factor  
=  $6.0 \div 3$   
= **2 units**
4. Total bolus dose of insulin = Meal dose + correction dose  
=  $6 + 2 \text{ units}$   
= **8 units**

1800 2200 0200  
insulin injections and to leave an adequate gap between the bolus injection and the start of a meal.

In type 2 diabetes, insulin is usually initiated as a once-daily long-acting insulin, either alone or in combination with oral glucose-lowering agents. However, in time, more frequent insulin injections may be required. Recently, long-acting insulin analogues have been combined with GLP-1 receptor agonists, enabling co-administration of insulin and GLP-1 receptor agonists in a single daily injection.

Twice-daily administration of a short-acting and intermediate-acting insulin (usually soluble and isophane insulins), given in combination before breakfast and the evening meal, is still commonly used in many countries. Initially, two-thirds of the total daily requirement of insulin is given in the morning in a fixed ratio of short-acting to intermediate-acting preparation and the remaining third is given in the evening. Pre-mixed formulations are available that contain different proportions of soluble and isophane insulins (e.g. 30:70 and 50:50). These offer convenience in that only two injections per day are required (before breakfast and before the evening meal), but are inflexible as the individual components cannot be adjusted independently, i.e. a late meal or unexpected physical exercise can result in hypoglycaemia. Such regimens usually only provide optimal glycaemic control in individuals who prefer set meal-times with little dietary flexibility and who take part in little moderate or vigorous physical exercise.

### Continuous subcutaneous insulin infusion therapy (insulin pump)

Continuous subcutaneous insulin infusion (CSII), commonly known as insulin pump therapy, is a system of insulin delivery that uses a battery-operated medical device to deliver insulin continuously to people with type 1 diabetes. A variety of insulin pumps are available and the choice is often framed by cost, compatibility with CGM systems and the personal preference or circumstances of the person with diabetes. When using a traditional pump, rapid-acting insulin is infused from a disposable insulin cartridge/reservoir within the pump (which has controls, a processing module and batteries). The disposable insulin cartridge/reservoir is attached to a tubing system that connects to a cannula, which is inserted subcutaneously (disposable infusion set) and secured by an adhesive dressing. The insulin infusion set and site should be changed every 3 days to avoid superficial infection of the site and compromise to the subcutaneous infusion of insulin. Patch pumps eliminate tubing from insulin infusion set as the cannula, cartridge/reservoir and batteries are located in a wearable disposable 'pod'. The controls and processing module are located in a handheld 'personal diabetes manager' that

communicates wirelessly to the pod, which is changed every 3 days, as with the traditional pump. Examples of a traditional pump and patch pump are shown in [Figure 21.25](#).

Basal insulin is delivered in the form of continuous infusion of rapid-acting insulin, usually 40%–50% of total daily dose (TDD). The proportion of basal insulin to TDD can vary, particularly in people who consume low or high carbohydrate diets. The number of units per hour can be calculated simply by dividing the TDD by 24. The basal rate is adjusted by fasting for periods of at least 4 hours while periodically evaluating the blood glucose levels and adjusting the pump infusion rate to maintain glucose in the normal range. Adjustments are made by approximately 10% at a time, 2 hours before a change in blood glucose is required, because of the kinetics of insulin absorption and time to reach steady state. One of the key advantages of CSII is that basal rates can be varied *within* a 24-hour period (this is in contrast to basal insulin in an MDI regimen, for which the dose can be altered, but the basal levels then remain relatively constant for the duration of action of that injection). This flexibility to pre-program adjustments is especially useful overnight, e.g. when basal rates can be reduced to prevent low glucose and then increased pre-dawn to prevent high morning (fasting) glucose. In addition, temporary basal rates can be used to lessen the risk of hypoglycaemia with daily activity (e.g. commuting, grocery shopping) or aerobic exercise (e.g. running, cycling).

Pre-meal boluses are administered 15–30 minutes before food via the insulin pump to limit post-prandial glucose excursions. As with MDI, bolus dosing is determined by the carbohydrate content of the meal, a personalised insulin to carbohydrate ratio and pre-meal glucose levels. Insulin pumps allow more flexibility with bolus insulin infusions in both timing and shape (e.g. using an extended or dual-wave bolus when covering high-fat/protein meals such as pizza or steak, or when diabetes is complicated by gastroparesis). Additionally, insulin pumps have calculators or 'bolus wizards' that calculate the 'active insulin on board', for precise calculation of pre-meal boluses and to allow safer 'correction' doses during periods of hyperglycaemia. This helps reduce the risk of hypoglycaemia from boluses given close together in time, an effect known as 'insulin stacking'.

**Fig. 21.25 Insulin pumps.** An insulin pump is an alternative means of delivering insulin in type 1 diabetes. **A** Different types are available and include the pump device itself (with controls, processing module and batteries), a disposable reservoir for insulin (inside the pump) and a disposable infusion set (with tubing and a cannula for subcutaneous insertion). **B** Alternative configurations include disposable or semi-disposable pumps without infusion tubing. Insulin pumps deliver rapid-acting insulin continuously and can be adjusted by the user, based on regular glucose monitoring and carbohydrate counting.

Overall, CSII reduces blood glucose variability in type 1 diabetes and in some people can help improve HbA<sub>1c</sub>. However, the benefits of insulin pump therapy can only be fully realised with meticulous and attentive carbohydrate counting and glucose monitoring, and pro-active adjustment of bolus and basal insulin in response to glucose levels. There are also risks to pump therapy that limit its suitability for some people. Pump failure leading to an interruption of the subcutaneous insulin infusion can occur for a variety of reasons. Causes include detachment or kinking of the insulin infusion set cannula or malfunction due to expiry of the battery. As the pump delivers rapid-acting insulin and there is no depot of intermediate or long-acting insulin, pump failure can very quickly (within a matter of hours) lead to insulin deficiency and DKA. Therefore, insulin pump users must regularly monitor glucose and promptly check for ketones and change the infusion set and cannula site if they have concerns about pump failure. 'Back-up' unexpired insulin pens should always be available. Individuals who are not prepared or able to monitor glucose regularly are not suitable for CSII because of the risks of DKA. Cannula site infection is another recognised complication of pump therapy; this risk can be reduced by good hygiene and by ensuring the cannula is changed every three days.

### Sensor-augmented CSII therapy

A further iteration in insulin pump therapy in recent years is communication with certain CGM devices via computerised algorithms ([Fig. 21.26](#)). Sensor-augmented insulin pumps can use data from CGM and, with knowledge of the amount of 'active insulin on board', can adjust basal rates towards a target glucose. Rather than preset basal rate infusions, such 'hybrid closed-loop' systems (also known as an 'artificial pancreas') automatically decide whether to infuse a small amount of basal insulin every 5 minutes, with decisions about pre-meal boluses still determined by the person with diabetes ([Fig. 21.27](#)). Features also include 'low-glucose suspend' or 'suspend before low' functions, such that detection of hypoglycaemia or a glucose level falling below a pre-set threshold (e.g. 5.0 mmol/L (90 mg/dL)) respectively, signal the pump to stop infusing insulin temporarily, leading to a substantial reduction in hypoglycaemia without rebound hyperglycaemia. Finally, bi-hormonal fully automated closed-loop systems (containing separate syringe drivers with insulin and glucagon), also known as the 'bionic pancreas', are now in clinical trials but not yet commercially available. The current systems are not perfect (e.g. recurrent low glucose sensor alarms can be irritating), but sensor-augmented CSII technologies are rapidly improving and offer the real prospect of a 'technological cure' for type 1 diabetes, i.e. delivering near normal blood glucose, with little or no hypoglycaemia and with minimal input

**Fig. 21.26 Sensor-augmented insulin pump system.** The artificial pancreas (AP) can vary in its set up but, core to an AP system are: (1) a continuous glucose monitor (CGM) measuring interstitial glucose levels every 5–15 minutes; (2) a smartphone (or personal diabetes manager) with an app that uses the glucose information from the CGM, along with modifications inserted by the user, to calculate how much insulin should be delivered. This is communicated wirelessly to (3) the insulin pump that delivers insulin subcutaneously as directed.

**Fig. 21.27** Download from a sensor-augmented insulin pump system. The user is required to enter the carbohydrate content of meals and snacks. Bolus doses of insulin are determined in part on this information (purple). Basal insulin administration is determined by an algorithm using glucose data and 'active insulin'. Note how the basal insulin infused (pink) varies substantially with time, such that basal insulin ceases when glucose levels are falling (especially if there is still active insulin present from a previous bolus dose). The user is also alerted when there are impending low or high glucose events. These functions facilitate excellent glycaemic control (especially overnight when there is no impact on glucose from food ingestion and exercise) and prevent or minimise low glucose events.

required from the user. However, these technologies are expensive and widespread use may be limited by cost for some time to come. The use of do-it-yourself artificial pancreas systems (DIY-APS), also known as 'looping', is increasing, particularly in high-income countries. DIY-APS are by definition not approved by regulatory bodies, but use existing insulin pumps and CGM devices with free open resource software to link the systems and provide much of the functionality described above.

### Intravenous insulin therapy

Circulating insulin has a half-life of approximately 2.5 minutes (the longer duration of action of subcutaneous insulin is because of the time taken for insulin to be absorbed from subcutaneous sites to the blood). Therefore, direct infusion of insulin via the intravenous route gives maximum flexibility in regulating blood glucose concentrations: an increase in the infusion rate will rapidly correct hyperglycaemia, while cessation of intravenous insulin will arrest a rapidly declining blood glucose. This inherent flexibility makes intravenous insulin a powerful tool in the management of hyperglycaemic emergencies and in stabilising blood glucose in a perioperative situation or in individuals who are unwell, e.g. with poor oral intake or delayed gastric emptying. Subcutaneous insulin does not lower blood glucose quickly enough for hyperglycaemic emergencies, particularly if skin perfusion is reduced during sepsis, while its duration of action may also be too long (i.e. result in hypoglycaemia) if given to an unwell patient who subsequently cannot eat or vomits. Intravenous insulin is, however, a dangerous therapy if not properly supervised and monitored. There are substantial risks of hypoglycaemia, hypokalaemia and hyperglycaemia (including DKA) and so it must only be used in a setting where medical and nursing staff have the necessary experience and time to safely prescribe, prepare and administer the therapy. Standardised ward-level documentation and protocols are essential to support the clinical team.

Intravenous insulin is most commonly given via an electronic syringe driver (insulin injected directly into a bag of intravenous glucose and potassium is now rarely used). Usually, 50 units of soluble insulin (Actrapid® or Humulin S®) is diluted in 50 mL 0.9% sodium chloride, to provide an infusion of 1 unit insulin/mL. In hyperglycaemic emergencies (especially DKA), it is usually given as a fixed rate insulin infusion (FRII). This avoids the possibility of the infusion rate reducing to zero, as can occur with a variable rate insulin infusion (VRII), which might cause a worsening of acidosis and ketosis.

In perioperative and medically unwell patients insulin is usually given as a VRIL (formerly called an 'insulin sliding scale'). Indications and principles of using VRIL in the hospital setting are outlined in [Box 21.26](#). An example of a VRIL prescription chart is shown in [Figure 21.28](#). Bedside capillary blood glucose monitoring should be performed on an hourly basis. Due to the short half-life of intravenous insulin, the insulin infusion must be monitored regularly to ensure it is continuously running;

## 21.26 Variable rate insulin infusion (VRIL)

### Principles

- Desired glucose targets are achieved and maintained
- Avoidance of hypoglycaemia
- Avoidance of ketonaemia by providing adequate carbohydrate and insulin
- Maintenance of fluid and electrolyte balance

### Indications

- People with diabetes undergoing operations, e.g. fasting >24 hours, emergency surgery
- People with diabetes who have uncontrolled hyperglycaemia or who are unable to eat and drink due to prolonged fasting, nausea, vomiting or reduced consciousness

### Do not use

- Diabetic ketoacidosis (DKA)
- Hyperglycaemic hyperosmolar state (HHS)

### Additional requirements

- Capillary blood glucose should be checked at least hourly
- The standard regimen for intravenous fluid prescription is 0.45% sodium chloride + 5% glucose + 0.15% potassium chloride (pre-prepared infusion bags) run at 100 mL/hr through a volumetric pump only
- Potassium monitoring is required to maintain serum level between 4 and 5 mmol/L
- Specialty input is required to guide fluid replacement in special situations, such as cardiac failure, renal failure, following head injury and after neurosurgery

### Considerations when stopping

- Continue long-acting insulin at usual time while on VRIL to allow stopping at any time
- Pre-mixed insulin should not be administered on VRIL – if stopping VRIL give usual dose at breakfast/dinner and stop VRIL after 2 hours (due to short half-life of intravenous insulin and risk of rebound hyperglycaemia)

if there is interruption to the infusion even for a relatively short period of time (e.g. a 'tissued' intravenous cannula, a kink in the infusion tube, a mechanical failure in the pump or the syringe simply running-out), significant hyperglycaemia can quickly ensue. With a VRIL, intravenous glucose (e.g. 0.45% sodium chloride + 5% glucose + 0.15% potassium chloride infused at 100 mL/hr) should be prescribed to provide some energy substrate and to reduce the risk of hypoglycaemia and hypokalaemia. Where possible, the glucose and insulin infusions should be given through a volumetric infusion device via the same intravenous catheter with a Y-connector, so that if the cannula blocks or 'tissues', then both infusions simultaneously cease, reducing the risk of hypoglycaemia from unopposed insulin. If additional fluids or potassium replacement

**Fig. 21.28** Example of a prescription document for a variable rate insulin infusion (VRII). The insulin infusion has a standard concentration of 1 unit/mL. The rate of insulin infusion is adjusted according to the prevailing blood glucose level. Adjustments are made to the infusion rates as capillary blood glucose falls and rises.

are required, depending on the volume and potassium status of the individual, they should be given via a separate infusion. Unused insulin should be discarded every 24 hours and a new infusion prepared. VRIIs should be reviewed at least every 24 hours to ensure that the infusion rates prescribed for a given blood sugar level have resulted in stable glucose levels. If blood sugar levels have been very variable, with frequent adjustments to the infusion rate, this is usually a sign that the prescription needs to be modified (or that it is time for the VRII to be discontinued as the patient has begun to eat).

## Transplantation

The goal of transplantation is to facilitate independence from insulin, reduce complications and improve quality of life.

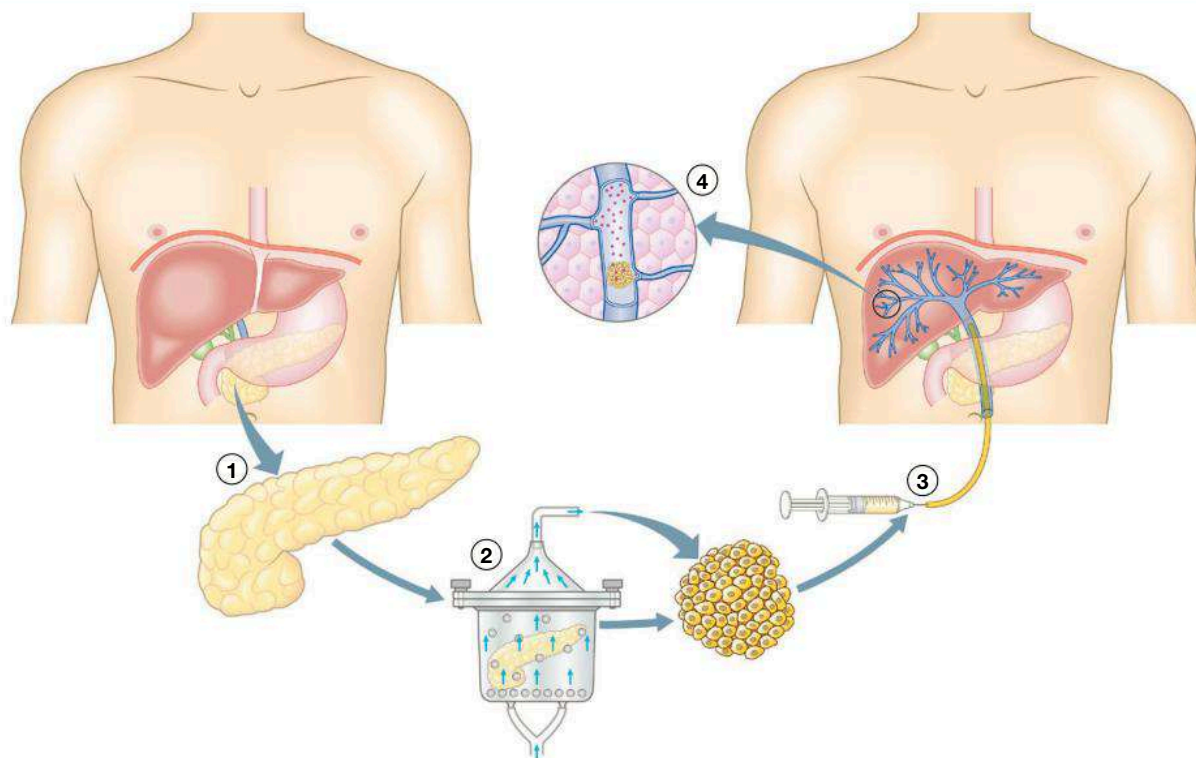

The American Diabetes Association (ADA) criteria for transplantation include three main types of pancreas transplantation:

- Simultaneous pancreas–kidney (SPK) transplant, when pancreas and kidney are transplanted simultaneously from the same deceased donor, or pancreas-after-kidney (PAK) transplant,

when a cadaveric donor pancreas transplant is performed after a previous, and different, living or deceased donor kidney transplant

- Pancreas transplant alone (PTA)
- Islet transplantation

Whole pancreas transplantation is carried out in a relatively small number of people each year. SPK is the most commonly performed procedure. Most SPK and PAK are undertaken in people with diabetes and end-stage kidney disease, in whom successful transplantation will improve glycaemia and may improve kidney survival. PTA is generally considered for people with progressive complications leading to significant loss of quality of life (for example recurrent level 3 hypoglycaemia). The principal complications occurring immediately after surgery include thrombosis, pancreatitis, infection, bleeding and rejection. Prognosis is improving: 1 year after transplantation >95% of all patients are still alive and 80%–85% of all pancreases are still functional. After transplantation, people will need life-long immunosuppression, which carries with it an increased risk of infection and skin cancer.

**Fig. 21.29 Transplanting islet cells.** (1) Pancreas obtained from suitable human donor. (2) Pancreatic islets containing insulin-producing  $\beta$  cells are isolated first in a Ricordi chamber. (3) Islets, once separated and purified, are infused into the hepatic portal vein. (4) Once embedded in the liver, pancreatic islets secrete insulin in response to changes in portal vein glucose.

Islet transplantation involves the transplantation of islets from a donor pancreas into a person with type 1 diabetes. The isolated pancreatic islets are usually infused into the patient's liver via the portal vein. This approach has now been successfully adopted in a number of centres around the world (Fig. 21.29). At present, islet transplantation is usually suitable only for people with unstable glycaemic control characterised by severe intractable hypoglycaemia that cannot be corrected by structured education, modern insulin regimens and technology. Progress is being made towards meeting the needs of supply, purification and storage of islets, but problems remain relating to transplant rejection and destruction by the immune-mediated process against  $\beta$  cells that caused type 1 diabetes in the first place. Nevertheless, the development of methods of inducing tolerance to transplanted islets and the potential use of stem cells mean that this may still prove a promising approach in the long term. Adoption of newer immunosuppressive protocols has resulted in far better outcomes and now nearly 50% of people with diabetes transplanted will be insulin-independent at 3 years post transplantation. This is an evolving therapy area with many new experimental techniques under development. There are no direct comparisons between whole pancreas and islet transplantation, but it appears that whole pancreas transplantation results in higher rates of insulin independence albeit with the greater morbidity of surgery.

## Management of diabetes in special situations

### Diabetes in pregnancy

The management of women with diabetes who are pregnant or who have developed diabetes during pregnancy (gestational diabetes) is discussed in detail in Chapter 32. This is a highly specialised area and requires careful management, as elevated maternal blood glucose in pregnancy is associated with significant maternal and fetal morbidity.

### 21.27 Diabetes in adolescence

- **Type of diabetes:** type 1 diabetes is predominant in children and adolescents, but type 2 diabetes is now presenting in unprecedented numbers of obese, inactive teenagers. Monogenic diabetes (MODY) should also be considered (see Box 21.8).
- **Physiological changes:** hormonal, physical and lifestyle changes in puberty affect dietary intake, exercise patterns and sensitivity to insulin, necessitating alterations in insulin regimen.
- **Emotional changes:** adolescence is a phase of transition into independence (principally from parental care). Periods of rebellion against parental control, experimentation (e.g. with alcohol and recreational drugs) and a more chaotic lifestyle are common, and often impact adversely on control of diabetes.
- **Glycaemic control:** a temporary deterioration in control is common, although not universal. It is sometimes more important to maintain contact and engagement with a young person than to insist on tight glycaemic control.
- **Diabetic ketoacidosis:** a few adolescents and young adults present with frequent episodes of DKA, often because of suboptimal adherence to insulin therapy. This is more common in females. Precipitating factors include desire for weight loss, personality and even manipulation of family or schooling circumstances.
- **Adolescent diabetes clinics:** these challenges are best tackled with support from a specialised multidisciplinary team, including paediatricians, physicians, nurses and psychologists. Support is required for the patient and parents.

### Children, adolescents and young adults with diabetes

Most type 1 diabetes is diagnosed in children below 18 years of age, with peak incidence rates between 5 and 7 years of age and at puberty. The management of diabetes in children and adolescents has important differences to adults, which should be addressed in specialised clinics with multidisciplinary input (Box 21.27). Some of the unique aspects of childhood type 1 diabetes management include changing insulin sensitivity

related to sexual maturity and physical growth, unique vulnerability to hypoglycaemia (especially in children below 6 years of age) and DKA. Family dynamics, child-care and schooling, developmental stages and ability to self-care all have to be considered in the personalised management plan. In older children and adolescents, there may be issues of body image, eating disorders and recreational drug and alcohol use. Innovative models of education such as digital comics and gamification are emerging. It is also notable that there is very limited clinical research in children with diabetes and so most recommendations are based on expert opinion. The prevalence of type 2 diabetes in those below 20 years of age is increasing and is estimated to increase 4-fold in the next 40 years.

## Diabetes in hospital

People with diabetes account for around 20% of all hospital in-patients in the UK. The vast majority (around 9 out of 10) are admitted to hospital for a cause unrelated to diabetes or for a condition where diabetes may be a contributory factor (e.g. an acute cardiovascular event or elective surgery for cataract). Common causes for diabetes-specific admission include foot ulceration, DKA, HHS, newly diagnosed diabetes and hyperglycaemia. Any person with diabetes presenting to hospital acutely unwell should have a blood glucose measurement.

People with diabetes often report unhappiness with how their diabetes was managed during a hospital admission. Clearly admission to hospital disturbs an individual's usual daily routine, including the timings and types of meal being offered, and the amount of physical activity. Acute illness and surgery can cause blood glucose levels to rise and the

individual may not be able to eat or drink for extended periods. Insulin and other glucose-lowering medication may be prescribed by relatively inexperienced trainees or non-specialists and some people with diabetes report a feeling of 'loss of control' in the management of their condition. When the prescribed dose of insulin is different from what is considered appropriate by the person with diabetes this should be discussed and handled sensitively with clear explanations for the rationale behind prescribing decisions. Through lived experience, the person with diabetes may well know more about their condition than the doctor.

Errors in prescriptions of glucose-lowering therapies (especially insulin) are extremely common and may be due to lack of knowledge on the part of medical staff, inadvertent error due to time pressures or other human or system factors (see Chapter 1). It is important that medical staff are proactive in adjusting glucose-lowering therapy to avoid extreme glucose excursions. Hyperglycaemia and hypoglycaemia are unpleasant and potentially harmful; they are also associated with increased length of stay.

## Hyperglycaemia in acute admissions to hospital

Hyperglycaemia is often found in patients who are admitted to hospital as an emergency. In most instances, this occurs in people with known diabetes, but it may also be due to undiagnosed diabetes or stress hyperglycaemia (see p. 719). An example of decision-making support around the management of hyperglycaemia on admission to hospital can be found in Figure 21.30.

Acute intercurrent illness causes catabolic stress and secretion of counter-regulatory hormones (including catecholamines and cortisol) in both normal and diabetic individuals. This results in increased

**Fig. 21.30** Decision-making algorithm for an individual presenting to hospital with hyperglycaemia. The target glucose of individuals with established diabetes is 6–10 mmol/L, but a range of 4–12 mmol/L is acceptable. (DKA = diabetic ketoacidosis; HHS = hyperglycaemic hyperosmolar state; VRII = variable rate insulin infusion) Adapted from Joint British Diabetes Societies for Inpatient Care, *Diabetes at the Front Door*; 2021. <https://abcd.care/joint-british-diabetes-societies-jbds-inpatient-care-group>.

glycogenolysis, gluconeogenesis, lipolysis, proteolysis and insulin resistance. Starvation exacerbates this process by increasing lipolysis. In a person without diabetes, these metabolic effects lead to a secondary increase in the secretion of insulin, which exerts a controlling influence. In people with untreated or poorly controlled diabetes, the uptake of metabolic substrate into tissues is significantly reduced because of insulin deficiency (relative or absolute), catabolism is increased and, ultimately, metabolic decompensation in the form of DKA or HHS may develop.

Hyperglycaemia on admission to hospital is associated with increased length of stay and increased mortality in a wide variety of acute medical emergencies, including acute myocardial infarction and acute stroke. This may be a direct consequence of hyperglycaemia (perhaps through volume depletion from osmotic diuresis, electrolyte imbalance, a secondary pro-coagulant state, and/or negative effects on the immune system) or simply a consequence that more severe illness (with a worse prognosis) causes greater degrees of hyperglycaemia. Intuitively, intensive glycaemic control with intravenous insulin should improve outcomes during acute illness. However, studies to date have shown that strategies aiming for near-normal blood glucose levels in acutely ill patients are associated with either increased mortality or no overall benefit. The reasons for the adverse outcomes are not established, but intensive glycaemic control is inevitably associated with an increased risk of hypoglycaemia, because of the inherent limitations of modern insulins, the limited frequency of glucose monitoring in a ward environment and the relative imprecision of near-patient blood glucose meters. Activation of the sympathetic nervous system and release of counter-regulatory hormones during acute hypoglycaemia likely has deleterious consequences for the acutely ill patient. Therefore, a target blood glucose of between 6 and 10 mmol/L (105 and 180 mg/dL) with an acceptable range of 4–12 mmol/L (72–220 mg/dL) is recommended for in-patients with diabetes. VRII is sometimes used for uncontrolled hyperglycaemia in hospital.

### Surgery and diabetes

People with diabetes are reported to have up to 50% higher perioperative mortality than people without diabetes. Surgery has the same metabolic consequences, described above, as acute intercurrent illness. In addition, hyperglycaemia impairs wound healing and innate immunity, leading to increased risk of infection. People with diabetes are also more likely to have underlying pre-operative morbidity, especially cardiovascular disease. Finally, glycaemic management errors may cause dangerous hyperglycaemia or hypoglycaemia. Careful pre-operative assessment

and perioperative management are therefore essential, ideally with support from the diabetes specialist team.

### Pre-operative assessment

Unless a surgical intervention is an emergency, people with diabetes should be assessed well in advance of surgery so that glycaemic control can be achieved and other risk factors can be addressed (Box 21.28). There is good evidence that a higher HbA<sub>1c</sub> is associated with adverse perioperative outcome. In general, the upper limit for an acceptable HbA<sub>1c</sub> in this context is 69 mmol/mol (8.5%). However, since optimisation of care may take weeks or months to achieve, the potential benefits of improved glycaemia need to be weighed against the potential benefits for early surgical intervention.

### Perioperative management

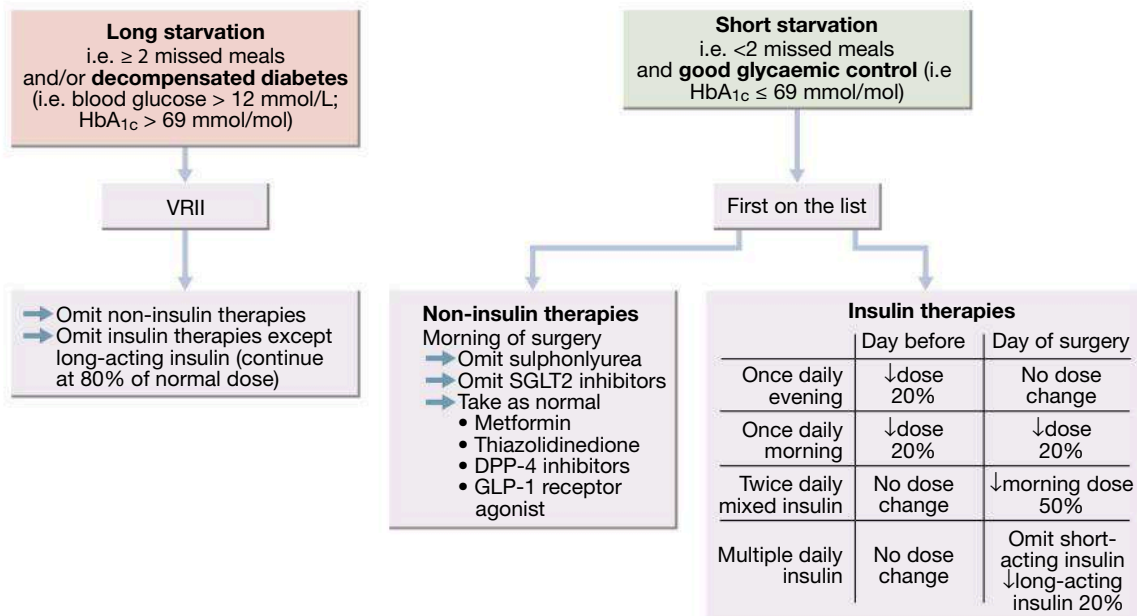

Figure 21.31 outlines a general approach to perioperative management of diabetes, although this may need to be adapted according to the individual, the surgical procedure and local guidelines, i.e. there is no 'one size fits all' approach. People with diabetes who are considered low-risk can attend as day cases or be admitted on the day of surgery. Occasionally, they may be admitted the night before surgery to ensure optimal management.

### Postoperative management

People with diabetes who need to continue fasting after surgery should be maintained on a VRII until they are able to eat and drink. During this time, care must be taken with fluid balance and electrolyte levels; the ideal glucose range is 6–10 mmol/L (105–180 mg/dL), with an acceptable range

**21.28 Pre-operative assessment**

- Consider delaying surgery and refer to the diabetes team if HbA<sub>1c</sub> >69 mmol/mol; this should be weighed against the need for surgery
- Establish an individualized diabetes management plan for the pre-admission period (including optimization if required) and perioperative period (this will be determined by pre-operative glucose-lowering regimens – non-insulin and insulin therapies, glycaemic control and period of starvation (i.e. will the patient miss more than one meal?))
- Patients with high-risk feet (p. 751) should have suitable pressure relief provided during post-operative nursing
- Plan for the patient to be first on the list. This minimises the starvation period and thereby the need for VRII and length of inpatient stay

**Fig. 21.31** A suggested approach to the perioperative management of diabetes. Adapted from Joint British Diabetes Societies for Inpatient Care, *Management of adults with diabetes undergoing surgery and elective procedures: Improving standards*. March 2016.

of 4–12 mmol/L (72–220 mg/dL). Once usual glucose-lowering treatment has been reinstated, good blood glucose control should be maintained to optimise wound healing and recovery.

### Diabetes footcare in hospital

Diabetes foot disease is discussed in detail on p. 751. Between 2% and 3% of people with diabetes admitted to hospital develop a foot ulcer during the admission. Pressure ulceration (due to prolonged contact between part of the foot, such as the heel, and a firm surface, such as a mattress) can occur due to prolonged immobility in a hospital bed and is associated with peripheral vascular disease, poor glycaemic control, malnourishment and dehydration. Delirium, dementia and peripheral neuropathy all increase the risk of developing pressure ulceration, because the individual does not recognise the sensation of abnormal heel pressure. The feet of all people with diabetes should be examined on admission to hospital. Those with feet 'vulnerable' for ulceration must be given protection for their feet. Individuals who are bedbound should wear special 'foot protectors' – moulded plastic boots with padding that specifically redistribute pressure and off-load the heel areas as these are particularly susceptible to pressure ulceration. Pressure relief pads are also available that can be fitted to the end of a bed and are indicated for people with 'at risk' feet who are ambulant. If ulceration is identified on the initial foot assessment or occurs during admission (something that should be a 'never event'), then the patient should be immediately referred to the multidisciplinary diabetes foot team.

## Complications of diabetes

Chronic hyperglycaemia causes irreversible damage over time to a number of tissues: particularly the small blood vessels of the retina (retinopathy), the glomerulus (nephropathy) and peripheral nerves (peripheral neuropathy) (Box 21.29). These so-called microvascular complications are amongst the commonest causes of visual loss, end-stage renal failure (dialysis) and foot ulceration (amputation) in most global populations and have a major adverse impact on quality of life. They are strongly linked to hyperglycaemia and increased duration of diabetes. Hyperglycaemia causes tissue damage via four main biochemical pathways: the polyol pathway, the hexosamine pathway, accumulation of advanced glycation end products and activation of protein kinase C. Each of these leads to overproduction of reactive oxygen species by the mitochondrial electron transport chain, giving rise to oxidative stress. The histopathological hallmark of diabetic microangiopathy is thickening of the capillary basement membrane, with associated increased vascular permeability. This occurs throughout the body resulting in the characteristic microvascular complications and accelerated atherosclerosis.

In the 1990s over 20% of people with type 2 diabetes in the UK had evidence of microvascular complications at the time of diagnosis, but this rate has fallen dramatically in many countries (e.g. to as low as 1% in parts of Germany) with better awareness and screening in the community and consequently earlier diagnosis. Microvascular complications are strongly linked to long-term elevated blood glucose (usually manifest as an elevated HbA<sub>1c</sub>) and individuals with strict glycaemic control have a much lower risk of developing these complications.

Macrovascular complications are less closely linked to blood glucose, particularly in type 2 diabetes. In type 2 diabetes, insulin resistance is also directly and pathophysiologically linked with hypertension and dyslipidaemia (as part of the metabolic syndrome, each of which is also a risk factor for atherosclerosis. Thus, even individuals with impaired glucose tolerance (i.e. who do not have high enough blood glucose to be diagnosed with diabetes) already have an elevated risk of cardiovascular disease. Management of blood pressure and dyslipidaemia in diabetes are discussed briefly on p. 729), while the investigation and management of cardiovascular disease are discussed in detail in Chapters 16 and 29.

In addition to vascular complications, diabetes is associated with an increased susceptibility to infection and increased severity of infection.

## 21.29 Complications of diabetes

### Microvascular/neuropathic

#### Retinopathy, cataract

- Common cause of visual loss

#### Nephropathy

- Renal failure, requirement for dialysis

#### Peripheral neuropathy (foot disease)

- Sensory loss
- Pain
- Ulceration
- Charcot neuroarthropathy

#### Autonomic neuropathy

- Postural hypotension
- Gastroparesis
- Sexual dysfunction

### Macrovascular

#### Coronary circulation

- Angina
- Acute coronary syndrome/ myocardial infarction

#### Cerebral circulation

- Transient ischaemic attack
- Stroke

#### Peripheral circulation (foot disease)

- Claudication
- Ischaemia
- Ulceration

### Infection

- Increased risk of certain infections, e.g. *Candida* spp., urine infection, fungal nail disease
- Increased risk of severe forms of infection, e.g. COVID-19, influenza, tuberculosis
- Increased risk of opportunistic infections, e.g. emphysematous pyelonephritis

### Rheumatological complications

- Cheiroarthropathy, limited joint movement
- Dupuytren's contracture
- Adhesive capsulitis
- Trigger finger

### Skin complications

- Diabetic dermopathy
- Necrobiosis lipoidica
- Xerosis

Glycation of soft tissues and periarticular structures can cause a variety of rheumatological disorders, including diabetic cheiroarthropathy and adhesive capsulitis. Glycation and subsequent osmotic changes in the lens of the eye can cause reversibly reduced visual acuity at presentation of diabetes and can predispose to cataracts. Type 2 diabetes is associated with a 2-fold increased risk of dementia with increased risk of both Alzheimer's disease and vascular dementia. The mechanisms underpinning this association are complex and may involve factors such as micro- and macrovascular disease, abnormalities in insulin action in the brain and glycosylation of neuronal tissue.

## Life expectancy/mortality

The life expectancy of people with type 2 diabetes in the UK is similar to that of the general population for those of higher socioeconomic status. However, those who are subject to social deprivation lose on average 4–5 years of life, even in countries where there is universal access to health care and free prescriptions. This gradient of life expectancy according to factors that are not classically 'biomedical' is more difficult

to measure in countries that do not have universal health-care coverage, but is likely even steeper in those countries with an 'uninsured' section of the population.

Excess mortality in type 2 diabetes is caused mainly by cardiovascular disease, particularly myocardial infarction and stroke. There is also substantial morbidity from myocardial infarction, stroke, angina, cardiac failure and intermittent claudication. The pathological changes of atherosclerosis in type 2 diabetes are similar to those in non-diabetic individuals, but occur earlier in life and are more extensive and severe with the effects of associated major cardiovascular risk factors (smoking, hypertension and dyslipidaemia) amplified. Rates of mortality adjusted for age and socio-economic status are 38% higher in men and 49% higher in women with type 2 diabetes, mainly driven by cardiovascular disease. In the United States, hospitalisation rates for stroke are 1.5 times higher in adults with type 2 diabetes while 60% of non-traumatic amputations are in people with diabetes.

In type 1 diabetes, life expectancy is reduced on average by 11 years in men and 13 years in women. Under the age of 30 years, most deaths occur due to severe acute metabolic complications (DKA and hypoglycaemia). Cardiovascular disease accounts for almost as many deaths aged 30–39 years and predominates after the age of 40 years. Death may also be a consequence of renal failure caused by diabetic nephropathy. In addition, microvascular complications are responsible for substantial morbidity and disability: for example, blindness from diabetic retinopathy, lifestyle restrictions associated with renal dialysis, difficulty in walking and chronic ulceration of the feet from peripheral neuropathy, and bowel and bladder dysfunction from autonomic neuropathy.

## Infections and diabetes

People with diabetes are at increased risk of infection and when such infections occur they may be more severe. Hyperglycaemia affects the function of key aspects of the cellular innate immune system, notably the function of neutrophils and monocytes/macrophages, with reduced chemotaxis, phagocytosis and killing of pathogens. Abnormalities in humoral immunity are also seen, such as reduced levels of complement proteins and cytokines, but the significance of this is less clear. Therefore, diabetes is in effect an immunocompromised state and, as a consequence, infections are more common and more likely to be caused by opportunistic pathogens, such as anaerobic organisms and fungi. In addition, microbes grow better in a high glucose environment and this may contribute to increased virulence. Finally, peripheral vascular disease and neuropathy, especially in the feet, predispose to skin ulceration. Breaks in the skin act as a portal for bacteria to enter the body and, if there is associated vascular disease, the reduced blood supply to the injured tissue impairs wound healing so there is reduced access for neutrophils and other components of the immune system to the damaged tissues. Individuals with glycaemic control above target (raised HbA<sub>1c</sub>) are at higher risk of infection and its consequences, including COVID-19 (see below), although risk remains increased in all people with diabetes.

## Urogenital, skin and soft tissue infections

As already noted, one of the commonest sites of infection in people with diabetes is the urogenital system. Genital infections, especially from yeasts such as *Candida* species, causing balanitis in men and vulvovaginitis in women are common at diagnosis of diabetes, in those taking SGLT2 inhibitors and in individuals with poor glycaemic control. Urine infections, including pyelonephritis, are also more common in people with diabetes and may progress to sepsis and acute kidney injury; rarely, even more serious forms of pyelonephritis can occur in which gas is formed in the renal parenchyma (emphysematous pyelonephritis).

Fungal nail infections and infections of skin and soft tissues are also more prevalent in people with diabetes. Skin and soft tissue infections, e.g. cellulitis, abscesses and boils, are usually caused by *Staphylococcus aureus* or  $\beta$ -haemolytic streptococci, as in non-diabetic patients. However, people with diabetes are more likely to experience

polymicrobial and anaerobic infections, such as necrotising fasciitis, gas gangrene and synergistic gangrene (including Fournier gangrene of genital and perineal skin), presumably because of the combination of relative immunosuppression and poor tissue perfusion (p. 271).

## Bone and joint infection

Approximately 30% of all cases of osteomyelitis are associated with diabetes (see Ch. 26). The most commonly affected sites are the bones of the feet, because of the strong association with peripheral neuropathy, peripheral vascular disease and foot ulceration. Osteomyelitis may occur as a primary consequence of a puncture injury (which has introduced microbes into the wound) or secondary to a long-term skin ulcer or other breach in the skin. Approximately 90% of cases of diabetic foot osteomyelitis occur in the forefoot, with approximately 5% of cases in the mid- and hindfoot, respectively. Osteomyelitis results in destruction of the bone and potentially adjacent joints. It can present as an acute infection, but more commonly is a chronic, insidious infection that progressively worsens.

The clinical features of osteomyelitis in people with diabetes often appear non-severe and may be more suggestive of a soft tissue infection than bone infection. The diagnosis may, therefore, be delayed unless clinicians have a low threshold for suspecting osteomyelitis and carrying out appropriate investigations. Larger ulcers (>2 cm) and deeper ulcers (>3 mm) are associated with an increased risk of osteomyelitis, as is the presence of visible bone in the wound or bone that can be probed. However, none of these signs are diagnostic for osteomyelitis. Plain X-rays are insensitive, especially in milder infections, only showing features of osteomyelitis if more than 30%–50% of bone is lost. MRI and bone scintigraphy have higher sensitivity. Although *Staphylococcus aureus* is most commonly involved, Gram-negative and anaerobic organisms can also be detected. Wound swabs are usually unhelpful, because of contamination from organisms on the skin that are not involved in the bone infection; the most useful microbiological data comes if a bone fragment can be obtained for culture. Osteomyelitis is particularly difficult to treat because many antibiotics do not reach adequate concentrations in bone. Primary antibiotic therapy can be used in milder infections, though often a prolonged course of antibiotics (of many weeks and months) is required. Surgical débridement of infected soft tissue and bone is often required and can reduce the need for amputation. However, osteomyelitis, particularly in the hindfoot, is associated with a poor prognosis and a very high risk of below-knee amputation (~50%).

Septic arthritis and discitis are also more common in people with diabetes, either as a consequence of a direct puncture injury, haematogenous spread from an infection elsewhere or direct spread from an adjacent area of osteomyelitis. *Staphylococcus aureus* is the most commonly implicated organism in both instances: investigation and management are discussed on pages 1025 and 1026.

## COVID-19

Severe infection with SARS-CoV-2, i.e. that resulting in death and/or admission to a critical care unit, is much more common in people with diabetes. Precise estimates of the increased risk vary, but people with type 1 diabetes are at approximately 2.5–3.5 times increased risk, while people with type 2 diabetes are at 1.5–2.0 times increased risk. There is a strong association with glycaemic control, such that those individuals with chronically elevated blood glucose are at the highest risk.

SARS-CoV-2 infection, in turn, appears to have an adverse impact on diabetes itself. There are many reports of people with COVID-19, with or without a previous diagnosis of diabetes, presenting with severe hyperglycaemia and DKA. The mechanisms underlying this remain unclear. It may in part be a consequence of worsening insulin resistance precipitated by severe intercurrent illness (see p. 745). However, SARS-CoV-2 gains entry to cells via the angiotensin-converting enzyme 2 (ACE2) receptor; this is highly expressed in  $\beta$  cells in the pancreas. Thus, tropism of SARS-CoV-2 for  $\beta$  cells could trigger damage that impairs

insulin secretion, resulting in hyperglycaemia and DKA. It has been suggested that SARS-Co-V-2 may act as a trigger for type 1 diabetes, as some paediatric diabetes centres reported increased incidence during the pandemic; however, this association has not consistently been demonstrated.

## Diabetic eye disease

Diabetic retinopathy and diabetic maculopathy are together the most common causes of visual impairment and loss in many countries. The pathogenesis, clinical features and management of diabetic retinopathy and other eye conditions (including cataract) relevant to diabetes are described in [Chapter 30](#).

## Diabetic kidney disease

Diabetes is the most common cause of end-stage renal disease globally, and approximately 40% of people requiring renal replacement therapy (i.e. dialysis or transplantation) have diabetes. In people with type 1 diabetes, kidney disease is most often caused by *diabetic nephropathy* (see below), but in people with type 2 diabetes it may also be caused by other conditions to which people with hyperglycaemia are predisposed (e.g. recurrent sepsis and acute kidney injury as a result of urinary tract infection, hypertension and renal vascular disease). Forty per cent of people with type 2 diabetes have chronic kidney disease (CKD) and usually it is multifactorial in aetiology.

About 30% of individuals with type 1 diabetes develop diabetic nephropathy from 10–20 years after diagnosis, but the incidence after this time falls to less than 1% per year. The risk of nephropathy in populations of European descent with type 2 diabetes is similar to that with type 1 diabetes, but the rate of progression may be exacerbated by concomitant obesity and other risk factors. It is much higher in some ethnic groups (e.g. African Caribbeans, South Asians and Japanese), with epigenetic and genetic factors thought to influence this increased risk. It should be noted that some individuals with long-standing hyperglycaemia do not develop nephropathy, suggesting the presence of as-yet-undiscovered protective (potentially genetic) factors. With improved standards of care focusing on glycaemic control and more widespread use of blood pressure-lowering medication targeting the renin-angiotensin system, the proportion of people with diabetes and CKD is reducing. However, due to the global rise in the incidence of type 2 diabetes, the absolute number of people with diabetes and end-stage renal failure continues to rise.

The pathophysiology underlying diabetic nephropathy is not fully understood. A key molecule is transforming growth factor  $\beta$ , which upregulates flux of glucose into renal cells and activates the renin-angiotensin system leading to renal inflammation and fibrosis. The classical pattern of progression of renal abnormalities in diabetes is shown schematically in [Figure 21.32](#). Initially there is hyperfiltration in the glomeruli, then onset of microalbuminuria due to damage (and thickening) of the glomerular basement membrane causing leaking of protein, which can then progress to frank (dipstick-positive) proteinuria. Matrix material also accumulates in the mesangium and, as disease advances, nodular deposits form in the glomeruli ('focal' glomerulosclerosis; [Fig. 21.33](#)). As glomeruli are progressively lost, renal function deteriorates, which manifests as a declining glomerular filtration rate.

### Diagnosis and screening

Urine should be tested for microalbuminuria and a blood test sent for estimated glomerular filtration rate (eGFR) on an annual basis in all adults with diabetes. CKD in diabetes is defined using criteria listed in [Box 18.3](#). Microalbuminuria is the presence in the urine of small amounts of albumin at a concentration below that detectable using a standard urine dipstick. As the measurement is physiologically variable, a single measurement is not considered informative: it should be confirmed as present in at least two of three 'first-morning' specimens taken on separate days ([Box 21.30](#)). Microalbuminuria is usually reported as a proportion of the concentration or weight of creatinine present in the sample (mg/mmol

**Fig. 21.32** Natural history of diabetic nephropathy. In the first few years of type 1 diabetes mellitus, there is hyperfiltration; thereafter glomerular filtration rate declines fairly steadily to return to a normal value at approximately 10 years (blue line). In susceptible patients (about 30%), there is sustained proteinuria after about 10 years and by approximately 14 years this has reached the nephrotic range (red line).

**Fig. 21.33** Nodular diabetic glomerulosclerosis. There is thickening of basement membranes, mesangial expansion and a Kimmelstiel–Wilson nodule (arrow), which is pathognomonic of diabetic kidney disease.

### 21.30 Screening for microalbuminuria

- Early morning urine is measured for the albumin:creatinine ratio (ACR)
- Microalbuminuria is present if:
  - Male: ACR 2.5–30 mg/mmol creatinine or 25–300 mg/g
  - Female: ACR 3.5–30 mg/mmol creatinine or 35–300 mg/g
- An elevated ACR should be followed by a repeat test:
  - There is established microalbuminuria if 2 out of 3 tests are positive
- Proteinuria (overt or dipstick-positive nephropathy) is likely to be present if ACR > 30 mg/mmol
- This is confirmed by a protein:creatinine ratio (PCR) of >45 mg/mmol
- Nephrotic range proteinuria is present when PCR >300 mg/mmol

or mg/g) to reduce variability, with the threshold for diagnosis higher in women (see [Box 18.9](#)). Overt nephropathy is the presence of macroalbuminuria equivalent to the level of protein detectable on a standard urine dipstick. Microalbuminuria is a good predictor of progression to nephropathy in type 1 diabetes and an indication for ACE inhibitor or angiotensin II receptor blocker therapy to protect the kidneys. It is also a risk marker for macrovascular disease, especially in type 2 diabetes.

### Management

Establishing the presence of microalbuminuria should prompt vigorous efforts to reduce the risk of progression to nephropathy (and to protect against cardiovascular disease) by:

- control of blood pressure
- reduction of cardiovascular risk factors
- optimisation of glycaemic control.

Blockade of the renin–angiotensin system using either ACE inhibitors or angiotensin 2 receptor blockers (ARBs) has been shown to have an additional benefit over similar levels of blood pressure control achieved with other antihypertensive agents and is recommended as first-line therapy. This relieves angiotensin II-mediated vasoconstriction of efferent arterioles downstream from the glomerular capillary tuft (see Fig. 18.1D), decreasing glomerular filtration pressure and, therefore, hyperfiltration and protein leak. Electrolytes and renal function should be checked after initiation or dose increase of these agents as they can cause a marked deterioration in renal function if there is occult stenosis of the main renal artery, i.e. when adequate intraglomerular pressure is critically dependent on efferent arteriolar tone. There is no additional benefit of combining agents from these two classes. However, addition of other antihypertensive agents is required to achieve target BP control in many cases, e.g. calcium channel blockers, diuretics and  $\alpha$ -adrenoceptor antagonists ( $\alpha$ -blockers).

Halving the amount of albuminuria with an ACE inhibitor or ARB results in a nearly 50% reduction in long-term risk of progression to end-stage renal disease and requirement for renal replacement therapy, often in the form of haemodialysis (p. 593). SGLT2 inhibitor therapy in people with type 2 diabetes, overt proteinuria (>300 mg/day) and eGFR >30 mL/min/1.73m<sup>2</sup> reduces the risk of progression to end-stage kidney disease by approximately 30%. SGLT2 inhibitor therapy also reduces cardiovascular events in people with CKD and is rapidly becoming a standard of care as an add-on to ACE inhibitor or ARB therapy.

Individuals with CKD stages 3–5, but no proteinuria, may have CKD due to other factors, e.g. hypertension rather than diabetic nephropathy, and it is not yet clear if SGLT2 inhibitors slow progression of CKD in this group.

Renal transplantation is indicated for people with end-stage kidney disease, who are fit enough to undergo the procedure; it dramatically improves lives of organ recipients (see Ch. 18). Simultaneous pancreas transplantation should be performed, where possible, in people with type 1 diabetes. Anti-rejection immunosuppression carries risks and requires careful monitoring. Recurrence of diabetic nephropathy in the transplanted organ (allograft) is usually too slow to be a serious problem, although other complications may continue to progress.

## Diabetic neuropathy

Diabetic neuropathy causes substantial morbidity, particularly due to foot ulceration. It is diagnosed on the basis of symptoms and signs after the exclusion of other causes of neuropathy (see Ch. 28). It is more common with increased duration of either type 1 or 2 diabetes. The most common type is a 'polyneuropathy' (i.e. evidence that more than one type of nerve fibre is affected). About 25%–30% of adults have evidence of neuropathy 10–15 years on from diagnosis and about half of these have painful diabetic neuropathy (PDN). Like retinopathy, neuropathy occurs secondary to hyperglycaemia and is related to duration of diabetes. Motor, sensory and autonomic nerves may be involved in varying combinations.

Pathological features can occur in any peripheral nerves. They include axonal degeneration of both myelinated and unmyelinated fibres, with thickening of the Schwann cell basal lamina, patchy segmental demyelination and abnormal intraneural capillaries (with basement membrane thickening and microthrombi).

### Clinical features

#### Symmetrical sensory polyneuropathy

This is the commonest type of diabetic neuropathy and is a diffuse, small-fibre neuropathy that is, at least initially, frequently asymptomatic. There is impairment, in a 'glove and stocking' distribution, of all

modalities of sensation including diminished vibration sensation (Fig. 21.34). Symptoms may include paraesthesiae in the feet, sharp pain in the lower limbs (worse at night and felt mainly on the anterior aspect of the legs), burning sensations in the soles of the feet and cutaneous hyperaesthesia. As the condition advances, weakness and atrophy of the interosseous muscles may develop leading to structural changes in the foot with loss of lateral and transverse arches, clawing of the toes and exposure of the metatarsal heads. This results in increased pressure on the plantar aspects of the metatarsal heads, with hard 'callus' skin at these and other pressure points, leading to ulceration and even Charcot neuroarthropathy (see below).

In practice, loss of sensation to a 10 g monofilament provides evidence of increased risk and requirement for increased foot care (e.g. regular foot inspection, care from podiatry, attention to appropriate footwear). When diagnosis is uncertain, formal electrophysiological tests (p. 1132) may be performed demonstrating slowing of both motor and sensory conduction as well as abnormal vibration sensitivity and thermal thresholds.

#### Asymmetrical motor diabetic neuropathy (diabetic amyotrophy)

This is much less common; it presents as severe, progressive weakness and wasting of the proximal muscles of the lower limbs. It is accompanied by severe pain, felt mainly on the anterior aspect of the leg, hyperaesthesia and paraesthesiae. This condition is thought to involve acute infarction of the lower motor neurons of the lumbosacral plexus. Partial recovery usually occurs within 12 months; management is supportive.

#### Mononeuropathy

Mononeuropathies of a single sensory or motor, peripheral or cranial nerve are rare, but more often affect people with diabetes. The nerves most likely to be affected are the 6th and 3rd cranial nerves (resulting in diplopia), the 7th cranial nerve (resulting in Bell's palsy) and the femoral and sciatic nerves. The mononeuropathy is usually severe and of rapid onset, but eventually recovers. Nerve compression palsies are more common in diabetes, e.g. the median nerve, resulting in carpal tunnel syndrome, and less commonly, the ulnar nerve. Compression palsies may be a consequence of glycation and thickening of connective tissue and/or diabetic microangiopathy.

#### Autonomic neuropathy

This may occur independently of other types of neuropathy. It is less clearly associated with glycaemic control and improving control does not usually relieve the symptoms. Parasympathetic or sympathetic nerves may be predominantly affected. Common symptoms include dizziness, nausea and vomiting, post-gustatory sweating, difficulty with micturition, and diarrhoea/faecal incontinence. A postural drop may be detected on lying and standing BP measurement with a resting tachycardia. Pupils may be pinpoint.

Formal testing is rarely performed but involves the 'Ewing tests', which screen for evidence of lack of heart rate variability in response to manoeuvres designed to alter the activity of the autonomic nerve system (Valsalva manoeuvre, deep breathing, sustained handgrip).

Support stockings and fludrocortisone therapy may be helpful for symptoms of postural hypotension. Due to the risk of sudden cardio-respiratory arrest, there is only 50%–70% survival within 10 years of developing overt autonomic neuropathy. Fortunately, severe cases are infrequent.

**Gastroparesis** This is one of the most disabling complications of diabetes. It usually affects people with type 1 diabetes. Following exclusion of mechanical forms of obstruction (by upper gastrointestinal endoscopy), delayed gastric emptying is demonstrated using scintigraphy following a <sup>99m</sup>Tc-labelled standard meal. Gastroparesis is a prominent feature of severe autonomic neuropathy, but can also occur secondary to a co-existent primary eating disorder. The main symptoms (the severity of which tend to wax and wane) are nausea and vomiting (especially of undigested food), abdominal pain and a feeling of fullness/early satiety. It can contribute to increased variability in blood glucose, as there can be

**Fig. 21.34 Diabetic foot disease.** Patients with diabetes can have neuropathy, peripheral vascular disease or both. Clawing of the toes is thought to be caused by intrinsic muscle atrophy and subsequent imbalance of muscle function, and causes greater pressure on the metatarsal heads and pressure on flexed toes, leading to increased callus and risk of ulceration. A Charcot foot occurs only in the presence of neuropathy, and results in bony destruction and ultimately deformity (this X-ray shows a resulting 'rocker bottom foot'). The angiogram reveals disease of the superficial femoral arteries (occlusion of the left and stenosis of the right). *Insets (Proximal arterial occlusion)* From <http://emedicine.medscape.com/article/460178-overview#a0104>; *(Toe clawing)* Bowker JH, Pfeifer MA. a mismatch between the delayed rise in post-prandial glucose and the time-action profile of injected insulin.

Improving quality of life and achieving glycaemic control is difficult. Low-fibre and low-residue diets may be tried, as well as eating smaller amounts more frequently. Prokinetic dopamine antagonist anti-emetics (metoclopramide, domperidone) are often prescribed in an effort to accelerate gastric emptying, but are not recommended for long-term use due to adverse effects. For individuals on MDI, rapid-acting insulin may be better taken after rather than before a meal and CSII is beneficial for some. There may be frequent hospital admissions during 'flare-ups.' A 'gastric pacemaker' device is of benefit in some cases; others may benefit from endoscopic injection of botulinum toxin into the gastric pylorus (to increase gastric emptying). Enteral nutrition is rarely required unless gastroparesis is very severe.

**Sexual dysfunction** Men with type 2 diabetes are 30% more likely than non-diabetic men to have erectile dysfunction, rising to 70% with more than 20 years' duration of diabetes. In type 1 diabetes, the risk of erectile dysfunction is elevated threefold. This is mainly due to autonomic neuropathy and vascular disease (cavernosal microangiopathy). The approach to treatment options is as for non-diabetic men (for further information, see page 612). Women with diabetes also have higher rates of sexual dysfunction, including vaginal dryness, dyspareunia and increased susceptibility to urinary tract infections.

### Management

Tricyclic antidepressants (low dose amitriptyline, duloxetine) and anticonvulsants (pregabalin, gabapentin) – combined if necessary with opiate

analgesia (tramadol, oxycodone) – can improve quality of life in PDN. Management of other forms of neuropathy is shown in [Box 21.31](#)

### Diabetic foot disease

The feet are especially vulnerable in diabetes as there may be loss of protective sensation (due to neuropathy), inadequate blood supply (due to small and large blood vessel disease) or both. For this reason foot care is particularly important. Foot ulceration and associated complications are the most common reasons for prolonged hospital admission for people with diabetes.

### Aetiology

In a vulnerable foot, ulceration is initiated by (often minor) trauma (p. 340 and [Fig. 21.34](#)). Disruption of the protective epidermis then permits infection, particularly in the presence of hyperglycaemia. Most ulcers develop at the site of a plaque of callus skin, which has developed on a 'pressure point' typically on the plantar aspect of the foot, on the metatarsal heads or the tips of clawed toes. The majority of foot ulcers are neuropathic or neuroischaemic. Neuroischaemic ulcers classically occur on the margins of the foot as they are often precipitated by compression of the foot by ill-fitting shoes. Hence, they are seen over the medial aspect of the first metatarsophalangeal joint, the styloid process of the 5th metatarsal and the tips of the toes.

### Management

Systematic annual screening to estimate and record risk of foot ulceration in order to ensure appropriate access to podiatry has been shown to reduce rates of ulceration and amputation. Two simple tests are

required to grade risk according to a 'traffic light' system (Fig. 21.35): a 10g monofilament should be used to assess sensation at five points on each foot and foot pulses should be palpated (dorsalis pedis and/or posterior tibial).

- Green: People with normal protective sensation and palpable pulses are at 'low risk' and can be educated and reassured regarding foot care until next screening (Box 21.32).
- Amber: Those who have reduction or loss of sensation to monofilament, or in whom no pulse can be palpated in at least one foot, are at 'moderate' risk. An assessment and development of a care plan by a trained podiatrist is recommended when first identified and annual screening thereafter. Regular support with foot care may be offered. Well-fitting footwear is essential.
- Red: As for amber, but there is both reduced sensation and absent pulses in at least one foot or callus/structural foot deformity in the presence of either reduced sensation or absent pulses. Assessment and treatment by a specialist podiatrist is required. Orthotic footwear may be recommended.

People with diabetes and their relatives or carers can easily learn to use the Ipswich Touch Test to screen for neuropathy: this involves lightly and briefly (for 1–2 seconds) touching the tips of the first, third and fifth toes of both feet with the index finger: an abnormal result is when touch cannot be felt on two or more toes.

i 21.32 Care of the feet in diabetes
<b>Advice aimed at prevention of ulceration</b>
<b>Low risk (as per general population)</b>
<ul style="list-style-type: none"> <li>• Wash feet every day</li> <li>• Cut or file toenails regularly</li> <li>• Change socks or stockings every day</li> <li>• Moisturise skin if dry</li> <li>• Cover minor cuts with sterile dressings</li> <li>• Treat fungal skin and nail infections promptly</li> <li>• Do not burst blisters</li> </ul>
<b>Moderate and high risk</b>
<ul style="list-style-type: none"> <li>• Inspect feet every day</li> <li>• Avoid walking barefoot</li> <li>• Wear well-fitting shoes (e.g. trainers)</li> <li>• Avoid over-the-counter corn/callus remedies</li> <li>• Do not attempt corn removal</li> <li>• Check footwear for foreign bodies</li> <li>• Avoid high and low temperatures</li> </ul>
<b>Podiatry</b>
<ul style="list-style-type: none"> <li>• Access should be available appropriate to level of risk (see Fig. 21.35)</li> <li>• Access to a multidisciplinary foot team including a specialised podiatrist should be available for urgent referrals and care of active foot ulcers</li> </ul>
<b>Orthotic footwear</b>
<ul style="list-style-type: none"> <li>• Specially manufactured and fitted orthotic footwear is required to prevent recurrence of ulceration and to protect the feet of patients with Charcot neuroarthropathy</li> </ul>

### Foot ulceration

People with a foot ulcer require urgent assessment by a multidisciplinary foot team, involving a diabetes specialist, a podiatrist, a vascular surgeon and an orthotist.

Management involves:

- Débridement of necrotic tissue
- Antibiotic therapy (may be prolonged as infection can accelerate tissue necrosis and lead to gangrene)
- Pressure relief (depending on site, severity and stage of healing): customised insoles, specialised orthotic footwear, total contact plaster cast, irremovable aircast boot.

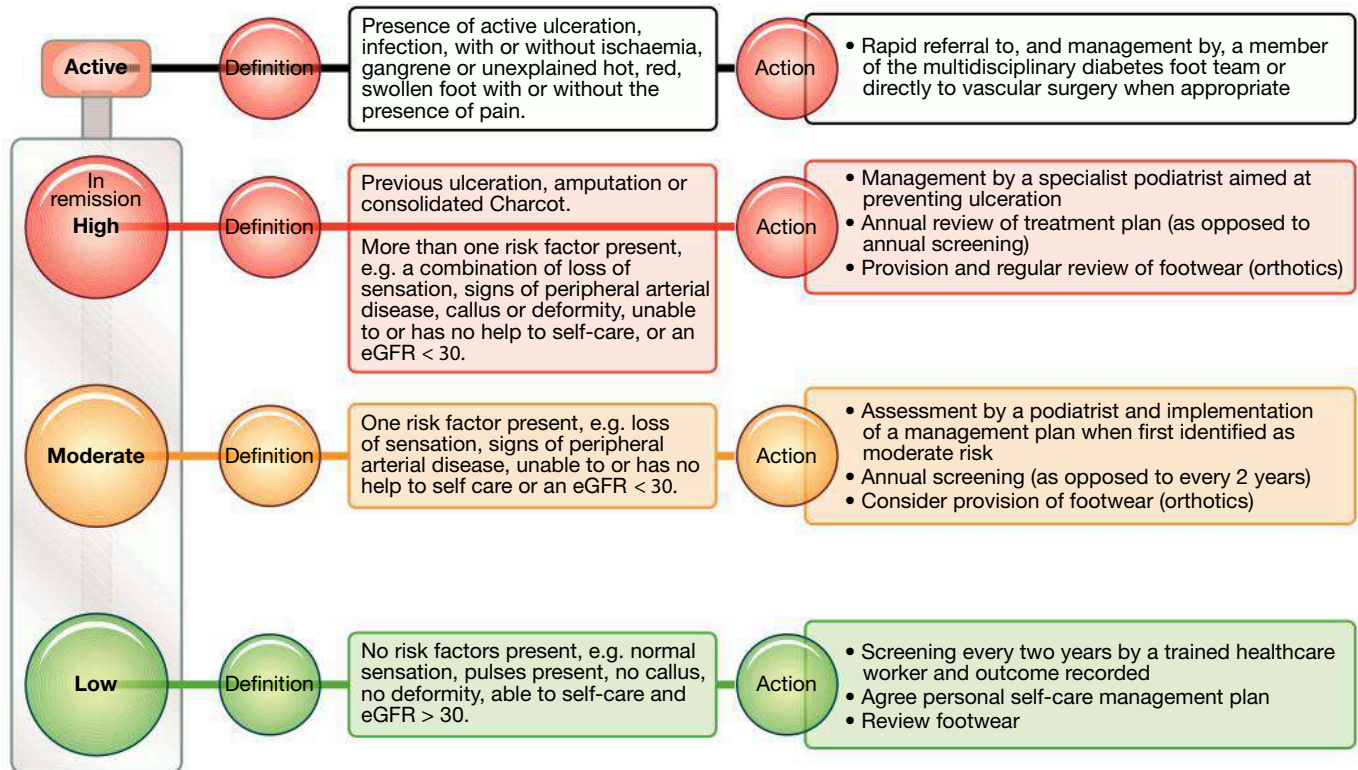

Ulcers that do not heal promptly may progress to osteomyelitis (infection of the underlying bone). If an ulcer is neuroischaemic, a vascular assessment is often carried out by ultrasound or angiography, as revascularisation by angioplasty or surgery may be required to allow the ulcer to heal. In cases of severe secondary infection or gangrene, amputation of the affected toe or of the limb (below or above knee) may be required depending on the severity.

### Charcot neuroarthropathy

This is a rare but severe complication of neuropathy affecting the bones and joints of the foot characterised by early inflammation and then joint dislocation, subluxation and pathological fractures of the foot. It was originally described as a complication of neurosyphilis, but now that this is near eradicated it is almost exclusively seen in diabetes. The pathophysiological mechanisms remain poorly understood.

Charcot neuroarthropathy presents in a structurally abnormal foot with localised swelling, erythema and increased temperature ( $>2^{\circ}\text{C}$  compared with the contralateral foot). Early diagnosis can prevent progressive and debilitating deformity (see Fig. 21.34) and sepsis. The initial X-ray may show bony destruction but is often normal. As about 40% of patients with a Charcot joint also have a foot ulcer, it can be difficult to differentiate from osteomyelitis. Magnetic resonance imaging (MRI) of the foot is a sensitive diagnostic test. Management

## Diabetic foot risk stratification and triage

**All people with diabetes should have written information on how to access podiatry (urgent or otherwise), cardiovascular risk reduction and access to a smoking cessation programme**

Fig. 21.35 Risk assessment and management of foot problems in diabetes. Reproduced with permission of the Scottish Diabetes Foot Action Group.

involves pressure relief and immobilisation (with a plaster cast or inflatable 'aircast' boot) and treating infection. This may take 3–6 months and sometimes longer.

## Skin and rheumatological complications of diabetes

Glycation of collagen in skin, subcutaneous and periarticular tissues, perhaps supplemented by an effect of tissue ischaemia from micro-angiopathy, can cause thickening of the skin, leading to a painless limited mobility of the joints of the hands and feet (cheiroarthropathy or 'diabetic stiff hand syndrome') and a waxy, tight feel to the skin. In the most severe cases it can resemble scleroderma. The inability to extend to 180° the metacarpophalangeal or interphalangeal joints of at least one finger bilaterally can be demonstrated in the 'prayer sign'. Adhesive capsulitis (e.g. causing frozen shoulder), Dupuytren's contracture and trigger finger are all more common in people with diabetes.

Diabetic dermopathy manifests as rounded red papules in the pre-tibial area that become pigmented with time. It is commoner in men and is associated with other complications of diabetes. Necrobiosis lipoidica is a rare granulomatous disorder that occurs predominantly in women with type 1 diabetes and is characterised by reddened plaques, with a yellowish central area that has atrophic skin and telangiectasia (see pages 704 and 1113). Xerosis (or abnormal dryness of the skin) may be a cutaneous manifestation of autonomic neuropathy and can lead to cracks in the skin that act as a portal for infection.

## Multiple Choice Questions

21.1. A 53-year-old woman with type 1 diabetes is currently an inpatient recovering from an elective hernia repair and is now eating and drinking and back on her usual subcutaneous insulin (Novorapid 1 unit for 10g CHO and Levemir 4 units am, 16 units pm). Morning insulin is due to be prescribed and the pre-breakfast meal capillary glucose is 2.9mmol/L (3.5–5.5). This has been a consistent pattern. The patient is conscious, orientated and is able to swallow. What is it most appropriate to give the patient?

- A. 100 mL IV 20% glucose
- B. Give breakfast
- C. 2 tubes of buccal Glucogel
- D. 4–6 Glucotabs
- E. 1 mg glucagon IM

Answer: D.

The patient has mild hypoglycaemia. The most appropriate treatment is 15–20g of fast-acting CHO orally. Other examples are 5–7 Dextrosol tabs. It is important to treat hypoglycaemia first with fast-acting CHO and then repeat glucose in 15 minutes rather than just eating breakfast. If the next meal is not due then advise 20g of slower-acting CHO (1 slice of bread, 2 biscuits) to prevent recurrence of hypoglycaemia. If an insulin bolus is due then it should be administered after correction of hypoglycaemia, in a dose appropriate for the CHO content of the meal, but it is important not to take further insulin for the CHO used to correct hypoglycaemia.

21.2. A 35-year-old man with diabetic ketoacidosis (DKA) has now stepped down to your ward from Medical HDU on the DKA Care Pathway following admission early this morning. He normally takes Novorapid (1 unit for 10g) and had Lantus 20 units at bedtime last night. ECG is normal. On examination he is well and had lunch and is about to have his evening meal. Investigations:

- Haemoglobin A<sub>1c</sub> 134 mmol/mol (target 53 mmol/mol)
- Sodium 138 mmol/L (137–144)
- Potassium 4.8 mmol/L (3.5–4.9)
- Urea 5.2 mmol/L (2.5–7.0)
- Creatinine 64 µmol/L (60–110)
- Glucose 8.4 mmol/L (3.5–5.5)
- Bicarbonate 23 mmol/L (20–28)
- Amylase 172 U/L (60–180)
- C-reactive protein 5 mg/L (<10)
- Capillary ketones 0.3 mmol/L (<0.6)

What is the most likely precipitant of his DKA episode?

- A. Myocardial infarction
- B. Issue with insulin administration
- C. Acute pancreatitis
- D. Sepsis
- E. A carbohydrate counting error

Answer: B.

HbA<sub>1c</sub> is very elevated, suggesting patient has a chronic deficiency of insulin. One carbohydrate counting error should not result in DKA. There is no evidence of sepsis, myocardial infarction or acute pancreatitis and the patient has made a swift recovery. The patient should be referred to the diabetes team the following morning before discharge to check insulin administration (omissions, equipment, injection technique and sites), with further education required.

21.3. A 56-year-old woman with bowel carcinoma and type 2 diabetes (HbA<sub>1c</sub> is 90mmol/mol) treated with Humalog Mix 25 twice daily (20 units am, 16 units pm) attends the surgical outpatient clinic. You are arranging for the patient to attend for urgent abdominal surgery. The patient is likely to miss more than one meal in theatre and post-operative recovery. What is the next management step?

- A. Advise her to take 75% of the usual insulin on the morning
- B. Admit the day before surgery for a variable rate insulin infusion
- C. Advise her to take 50% of the usual dose of insulin on the morning
- D. Advise her to take 25% of the usual dose of insulin on the morning
- E. Withhold her morning insulin until after the procedure

Answer: B.

This is urgent major surgery in a patient with sub-optimal control who will miss more than one meal. Admission pre-operatively for VRII is therefore required.

21.4. After surgery a 68-year-old man undergoing a colectomy is recovering post-operatively. He has a history of type 2 diabetes treated with Humalog Mix 25 twice daily (42 units am, 42 units pm). Subcutaneous insulin was commenced 15 minutes before a normal breakfast. The nurses ask you to review the glucose chart at lunchtime as the patient required treatment for a moderate hypoglycaemic episode at 11am:

Date	Before breakfast			Before dinner		
	Blood sugar	Insulin	Dose (Units)	Blood sugar	Insulin	Dose (Units)
1/4	8.9	Humalog	25			

What was the most likely cause of the hypoglycaemic episode?

- A. Wrong insulin and wrong dose
- B. Wrong dose of insulin
- C. Wrong insulin
- D. Wrong time of insulin
- E. Wrong time of insulin and wrong dose

Answer: A.

Humalog Mix 25 (Lispro 25%, Lispro Protamine 75%): onset 10–20 minutes, duration 16–20 hours, peak 1–6.5 hours. Humalog (Lispro): onset 10–20 minutes, peak 1–3 hours, duration 2–4 hours. Humalog has been given instead of Humalog Mix 25. '25' refers to the proportion of short-acting insulin in the Humalog Mix 25 preparation; it has been wrongly prescribed as a dose of short-acting Humalog insulin. 'Insulin' should have been written as 'Humalog Mix 25' and 'Dose' should have been written as '42 units'. Blood glucose chart should have dose in units and not written 'as charted'. Ideal time to administer Humalog Mix 25 is 15 minutes before breakfast.

21.5. A 65-year-old man with type 1 diabetes is admitted and requires emergency surgery. You are asked to prescribe a variable rate insulin infusion. His insulin regimen is normally Novomix 30 twice daily. He had breakfast 2 hours ago and his current capillary blood glucose is 10.5 mmol/L. Post-operative recovery is swift. What is the next management step?

- A. Give usual s/c insulin dose with lunch, stop intravenous insulin 30 minutes later
- B. Give usual s/c insulin dose with lunch and stop intravenous insulin immediately

- C. Give usual s/c insulin dose with evening meal, stop intravenous insulin 30 minutes later
- D. Give usual s/c insulin dose now and stop intravenous insulin immediately
- E. Give usual s/c insulin dose now and stop intravenous insulin 30 minutes later

Answer: E.

Novomix 30: biphasic insulin Aspart 30%/Aspart Protamine 70%; onset 10–20 minutes, duration up to 16–20 hours, peak action 2.4 hours. Patients can be converted back onto their usual subcutaneous insulin

once eating normally and serum U&Es are at baseline and bicarbonate is normal ( $>18$  mmol/L). This should be done at the next convenient meal. This patient is on twice-daily mixed insulin and so this will be the patient's evening meal. Once the IV insulin is stopped the patient will have no endogenous insulin (IV insulin half life = 2.5 mins) on board and so it should always be continued for 30 minutes after the subcutaneous insulin has been administered.

## Clinical assessment and investigation of nutritional status

Nutritional status is a conceptual term, with no simple measurement test. It incorporates three interrelated components (see Box below), all needed to perform all the functions required in health and to respond to stresses. (1) *'What we eat'* – diet composition, reflecting both availability and supply of nutrients; (2) *'What we are'* – body composition, overall size and amounts of components (e.g. body fat, muscle mass, micronutrients, haemoglobin, etc); (3) *'What we can do'* – our functional capacity, for physical, mental, metabolic and social functions.

Grasping the circular complexity of nutritional status is important for understanding any disease and to optimise management. It is not

sufficient to consider just one or two of the three components in isolation. While certain elements within each of the three components can be measured, and they may point towards a nutritional problem, it is not possible to 'measure' nutritional status with any simple test. Its assessment requires clinical skills and experience.

While body compositional measures are valuable, biochemistry has limited value in assessing nutritional status. Many micronutrient assays are heavily affected by acute-phase responses during illness, so do not reflect whole body status. Moreover, functional micronutrient deficiencies can occur despite body stores being adequate; for example, vitamin A deficiency can occur during illness if its

transport to tissues is frustrated by a decline in retinol-binding protein.

Under-nutrition can go unnoticed in patients with multiple comorbidities. Simple, validated tools (e.g. MUST) are available to screen patients for nutritional problems. It is vital to be aware of under-nutrition as a possible contributor to any acute medical presentation. Early nutritional assessment is crucial: past medical and surgical history (e.g. intestinal surgery), drug history and specific diet history about eating habits and food preferences (ideally by a trained dietitian). Evidence of recent weight loss and muscle wasting should be sought. Body composition can be assessed by clinical anthropomorphic measurements, or more sophisticated methods if required.

### The inter-related components that define nutritional status

#### What we eat – diet composition

- Self-reported intake (retrospective)
- Objectively observed food consumption
- Estimated or measured nutrient consumption

#### What we are – body composition

- Water content, chemical composition
- 2-compartment (fat/lean tissue), imaging
- Bone mass/specific tissue composition

#### What we (can) do – functions

- Metabolic, cellular
- Organ/whole-body function
- Physical, mental and social activities

### Important elements of the diet history

#### Ask about weight

- Current weight
- Weight 2 weeks, 1 month and 6 months ago
- Assessment of degree of change: clothes, loose skin, muscle, stretch marks

#### Ask about current food intake

- Quantity of food and if any change
- Quality of food taken
- Whether normal food is being eaten
- Avoidance of specific food types (e.g. solids)
- Any nutritional supplements
- Reliance on supplements/tube feeding
- Any change in appetite or interest in food
- Any taste disturbance

#### Ask about symptoms that interfere with eating

- Oral ulcers or oral pain
- Difficulties swallowing
- Nausea/vomiting
- Early satiety
- Alteration in bowel habit
- Abdominal (or other) pain

#### Ask about activity levels/performance status

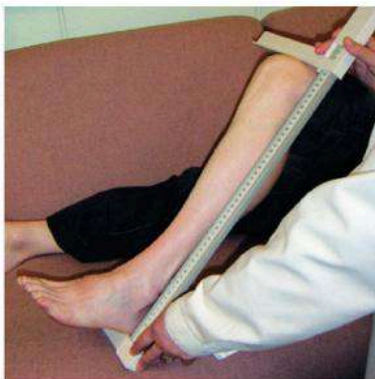

- Normal activity
- Slightly reduced activity
- Inactive < 50% of the time
- Inactive most of the time

## 2 Body mass index (BMI)

$$\text{BMI} = \frac{\text{wt}(\text{kg})}{\text{ht}(\text{m})^2}$$

**Example:** an adult of 70 kg with a height of 1.75 m has a BMI of  $70/1.75^2 = 22.9 \text{ kg/m}^2$

- BMI is a useful way of identifying under- or over-nutrition but cannot discriminate between high lean body or muscle mass and fat mass (e.g. boxers have low fat mass but high BMI)
- Fat mass is also subject to ethnic variation; for the same BMI, South Asians tend to have more body fat than Europeans
- If height cannot be determined (e.g. in older people or those unable to stand), measurement of the femoral length or 'knee height' is a good surrogate

Measurement of knee height.

## 2 Measures of body composition and nutritional status

### Body composition

- Anthropometry (see below)
- Bioelectrical impedance
- Dual X-ray absorptiometry (DXA)
- Magnetic resonance imaging (MRI)

### Muscle function and global nutritional status

- Hand grip strength (dynamometer test) – poor grip associated with increased mortality

### Obesity and fat distribution (android vs gynoid)

- Waist circumference (useful up to BMI  $35 \text{ kg/m}^2$ ) measured midway between superior iliac crest and lower border of rib cage

### Body fat content and muscle mass

- Triceps skinfold thickness (when combined with mid-/upper arm circumference estimates muscle mass)

Triceps skinfold thickness. Lean patients 6–12 mm; obese patients 40–50 mm.

## Nutritional factors and disease

Obtaining adequate nutrition is a fundamental requirement for optimal growth, function and health of every cell, and every organ, determining the health, and ultimately survival, of every individual and even species.

Nutritional adequacy can be threatened by natural supply, by competition, and by ignorance or trickery. The politics of human food provision constitute a prominent factor in wars, natural disasters and the profit-driven global economy. In recent decades, stable plentiful nutrition unknown to previous generations has led to a pandemic of obesity and its health consequences in post-industrial countries. However, shockingly, famine and under-nutrition still dominate ill-health in lower-income countries until they transition suddenly into Westernised overnutrition. Quality, or nutritional balance, of food consumption, and thus the food supply, also influences health (Fig. 22.1). Nutrients are classified into 'macronutrients', which contribute energy (measured as calories or kilojoules), and are eaten in relatively large amounts, and 'micronutrients' (vitamins and minerals), which do not contribute to energy balance but are required in small amounts because they are not synthesised in the body. The fact that we cannot synthesise them tells us that they were plentiful in traditional human diets. When they are lacking, or poorly absorbed, classical deficiency diseases develop, such as anaemia from folate or iron deficiency, or blindness from vitamin A deficiency, which still occur in current medical practice, even with obesity. Foods may contain bioactive compounds, such as caffeine, and toxins, but modern diets cause much more ill-health by contributing to chronic diseases – type 2 diabetes, coronary heart disease and some major cancers.

All doctors must be alert to the three roles of nutrition. In every case, consider if nutrition (1) might contribute to the cause of disease, thus a means of prevention; (2) might be impaired as a result of disease; and (3) might contribute to recovery. A clear understanding of nutrition is thus essential to deal with the needs of individual patients and inform public policy.

## Physiology of nutrition

There are some 27 essential nutrients required by every cell, which must be provided through the bloodstream continuously but at variable rates determined by the changing activities of different cell types (Fig. 22.2). These nutrients come from foods, of different types which are

**Fig. 22.1** Proportion of key food groups recommended for a healthy, well-balanced diet. Crown copyright. Department of Health in association with the Welsh Government, the Scottish Government and the Food Standards Agency in Northern Ireland.

consumed intermittently and sometimes only occasionally. The physiology and language of nutrition is therefore similar to economics, involving intermittent supply, losses at different rates, storage, obligatory costs, impacts on function, and mitigation of impacts by alterations in the internal economy.

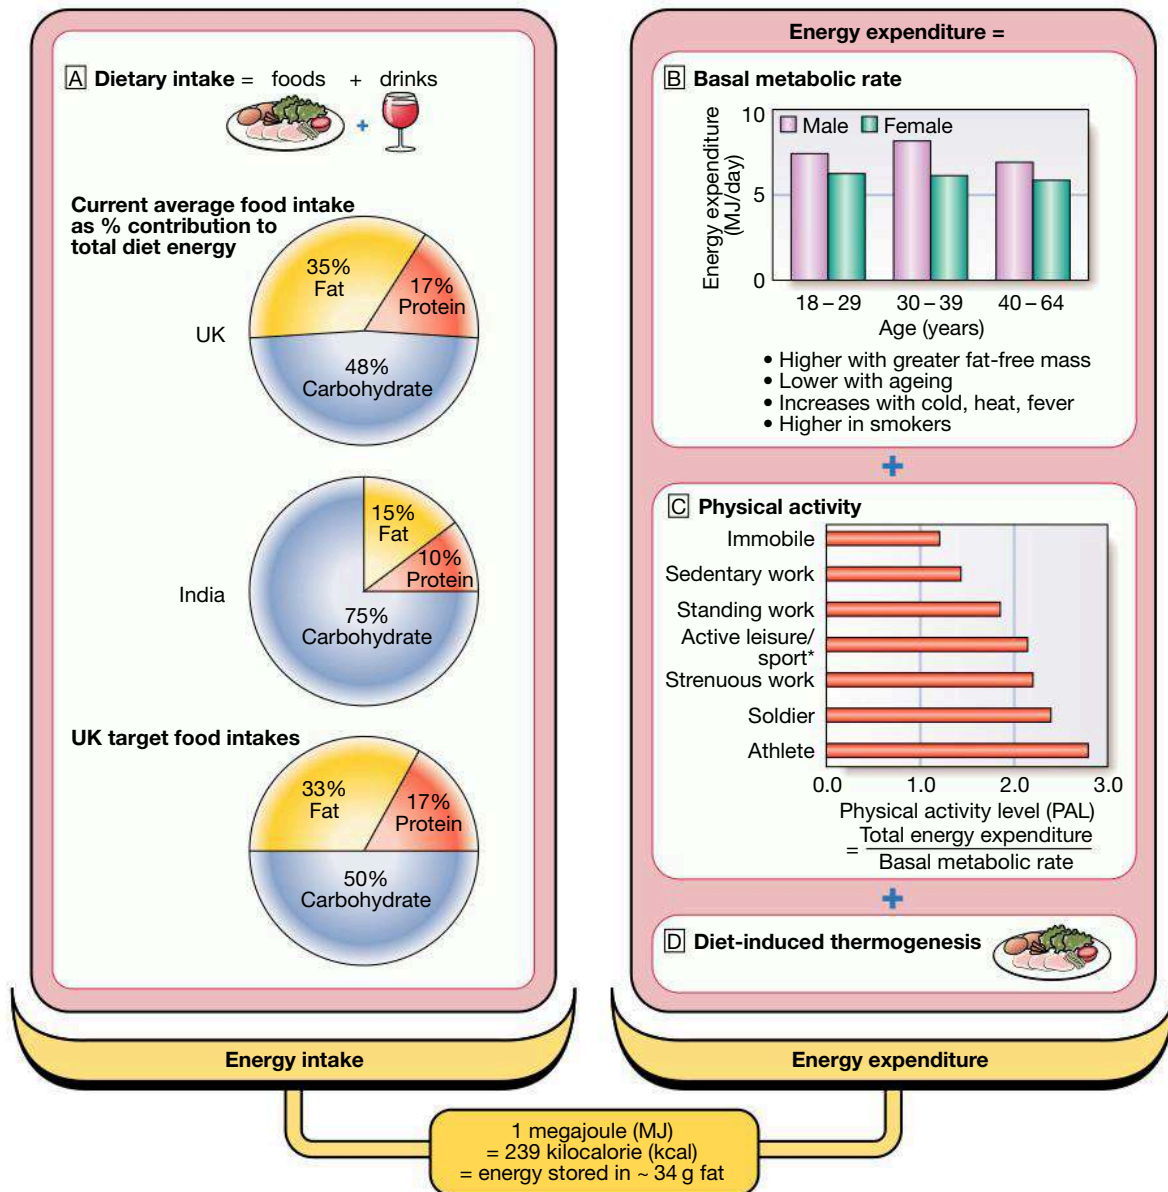

## Energy balance

The laws of thermodynamics dictate that *energy intake = energy expenditure ± changes in energy storage* (Fig. 22.3). The largest component of 24 hour energy expenditure is basal metabolic rate (BMR) – obligatory energy expenditure required to maintain metabolic functions of tissues at rest. It is closely predicted by body weight, and lower in females and older or inactive people (Fig. 22.3B). Extra energy is needed for growth, pregnancy and lactation and for physical activity, which varies considerably with occupation and lifestyle. Physical activity levels are usually defined as multiples of BMR (Fig. 22.3C). The energy required to digest food (generating heat as 'diet-induced thermogenesis' Fig. 22.3D) accounts for approximately 10% of total energy expenditure, protein requiring more energy than other macronutrients.

### The elements of nutrition – 'building blocks'

**Fig. 22.2** The 18 essential chemical elements in our bodies, required to be absorbed after digestion of our foods, are used in a variety of ways by human metabolism to build the compounds needed to grow, function in health and respond to stresses. The essential vitamins, aminoacids and fatty acids must be consumed 'ready-made' in foods.

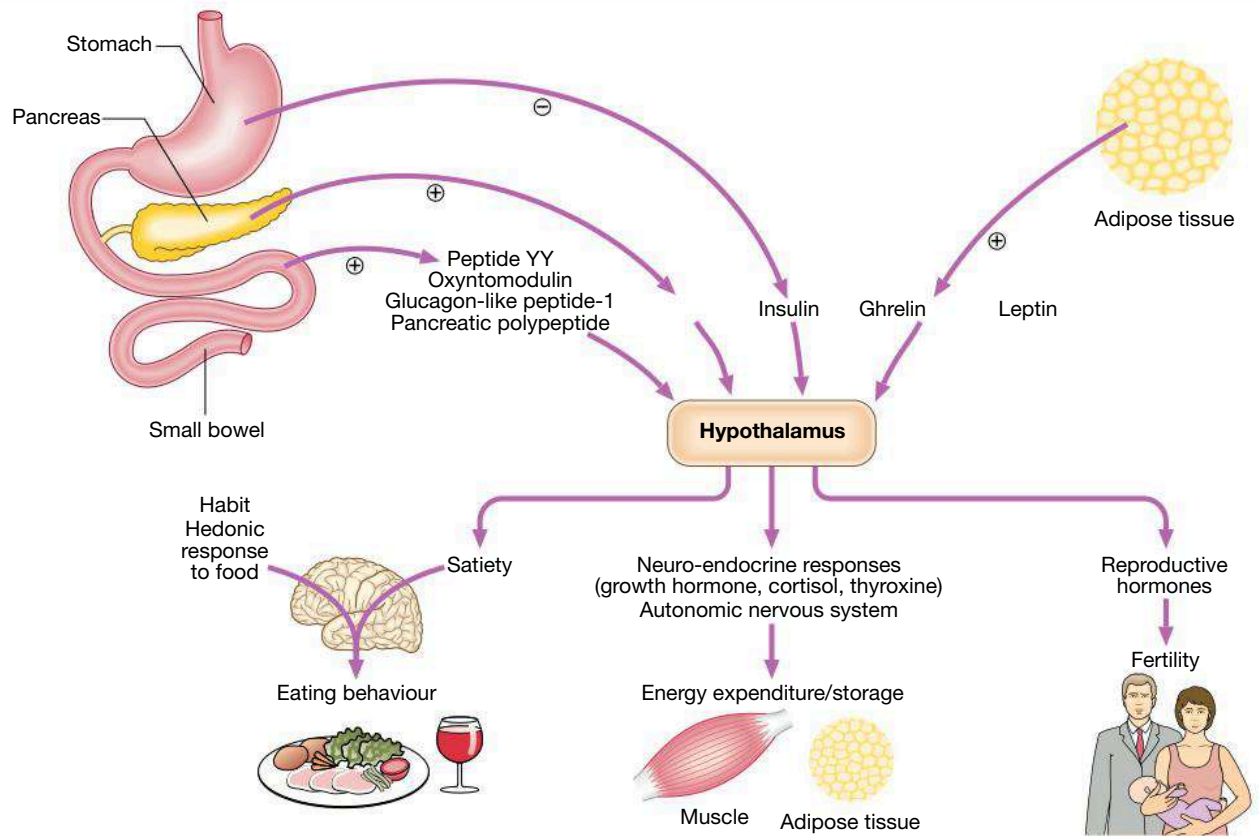

**Fig. 22.3 Determinants of energy balance.** **A** Energy intake is shown as national averages, highlighting the differences in sources of energy in different countries (but obscuring substantial regional variations). The targets are recommendations as a percentage of food energy only. (For WHO targets, see Box 22.4.) In the UK, it is assumed that 5% of energy intake will be derived from alcohol. **B** Data for normal basal metabolic rate (BMR) were obtained from healthy men and women in various countries. BMR declines from middle age and is lower in women, even after adjustment for body size because of differences in fat-free mass. **C** Energy is required for movement and activity. Physical activity level (PAL) is the multiple of BMR by which total energy expenditure is increased by activity. **D** Energy is consumed in order to digest food. \*Leisure or sport activity increases PAL by ~0.3 for each 30–60 minutes of moderate exercise performed 4–5 times per week. The UK population median for PAL is 1.6, with estimates of 1.5 for the 'less active' and 1.8 for the 'more active'. (A) Source: Department of Health.

Energy intake is determined by the 'macronutrients'. Carbohydrate, fat, protein and alcohol provide fuel for mitochondrial oxidation to generate energy (as adenosine triphosphate (ATP)). The energy provided, and the amounts that can be stored in the body, differs:

- fat — 37 kJ/g (9 kcal/g) Stored as body fat, usually sufficient for >40 days
- alcohol — 29 kJ/g (7 kcal/g) Not stored: toxic, must be metabolised immediately
- protein — 17 kJ/g (4 kcal/g) Not stored, but can be oxidised in extreme starvation
- carbohydrate — 16 kJ/g (3.75 kcal/g) Stored as glycogen in liver and muscle, sufficient for 12–24 hours

### Regulation of energy balance

Energy intake and expenditure are highly regulated (Fig. 22.4). In general, appetite matches requirement very closely: even when body weight is doubled by obesity, the mismatch between intake and expenditure is usually under 1%. Food shortage, with loss of weight, is the main threat to survival faced by any organism, and negative energy balance immediately signals a range of physiological messages. Energy is conserved by dropping core temperature, and by reducing BMR and physical activity acutely. Chronic food shortage, or micronutrient deficiency, prevents growth and blocks reproductive function, delaying maturation and halting ovulation. Thus pregnancy is most likely to occur during times of nutritional plenty, when both mother and baby have a better chance of survival. Anorexia nervosa and excessive exercise, as well as

**Fig. 22.4** Regulation of energy balance and its link with reproduction. ⊕ indicates factors that are stimulated by eating and induce satiety. ⊖ indicates factors that are suppressed by eating and inhibit satiety.

weight loss through illness, can cause amenorrhoea. Improved nutrition is thought to be the reason for the increasingly early onset of puberty in many societies. At the other extreme, obesity is also a common cause of amenorrhoea.

Energy balance is coordinated in the hypothalamus, which receives afferent signals that indicate nutritional status in the short term (e.g. the stomach hormone ghrelin, which falls immediately after eating and rises gradually thereafter, to suppress satiety and signal that it is time for the next meal) and the long term (e.g. the adipose hormone leptin, which increases with growing fat mass and also links fat mass to reproductive function). The hypothalamus responds with changes in many local neurotransmitters that alter activity in pathways that influence energy balance (see Fig. 22.3), including hormones acting on the pituitary gland (see Fig. 20.2), and neural control circuits that connect with the cerebral cortex and autonomic nervous system.

### Responses to under- and over-nutrition

These complex regulatory pathways allow adaptation to variations in nutrition. In response to starvation, reproductive function is suppressed, BMR is reduced, and there are profound psychological effects, including energy conservation through lethargy. These adjustments can 'defend' body weight within certain limits. In the low-insulin state of starvation (see Fig. 21.6), however, fuels are liberated from stores, initially from glycogen (in liver and muscle), then from triglyceride (lipolysis in adipose tissue, with excess free fatty acid supply to the liver leading to ketosis) and finally in protein (proteolysis in muscle). In neonates and in women who are pregnant or breastfeeding, with high glucose requirements, starvation can result in ketoacidosis with normal or low blood glucose.

In response to over-nutrition, BMR rises, and extra energy is required to carry increased body weight, so the original body weight is again 'defended' within certain limits. In the high-insulin state of over-nutrition, excess energy is stored principally as fat in adipose tissue but in

individuals predisposed to 'metabolic syndrome' and type 2 diabetes it may also accumulate and damage organ function in liver (non-alcoholic fatty liver disease), pancreas and skeletal muscle. If hypothalamic function is abnormal (e.g. in those with craniopharyngioma) or in rare patients with mutations (e.g. in leptin or melanocortin-4 receptors), loss of response to satiety signals, together with loss of adaptive changes in energy expenditure, result in relentless weight gain.

## Macronutrients (energy-yielding nutrients)

### Carbohydrates

Types of carbohydrate and their dietary sources are listed in Box 22.1. The 'available' carbohydrates (starches and sugars) are broken down to monosaccharides for absorption from the gut and supply about half the energy in a well-balanced healthful diet (see Fig. 22.3A). Carbohydrates can be synthesised *de novo* in small amounts from glycerol or protein. If the available carbohydrate intake is less than 100 g per day, increased lipolysis and fat oxidation leads to dietary ketosis (see Fig. 21.9).

There is much public and media confusion arising from equating carbohydrates with sugars, and a belief that sugars (the product of photosynthesis, on which all life depends) are hazardous. Dietary guidelines do correctly restrict the intake of 'non-milk extrinsic', added, sugars (sucrose, maltose, fructose), which promote dental caries when there is fluoride insufficiency, and may lead to greater energy consumption by children. However, sugars in fruits and milk, or generated by starch hydrolysis in the gut, present no hazard in their natural whole-food matrix. Starches in cereal foods, root foods and legumes provide the largest proportion of energy in most diets around the world, and a high carbohydrate intake in traditional diets is associated with freedom from non-communicable diseases. Starches are polymers of glucose, linked by the same 1–4 glycosidic linkages. Some starches are digested promptly by

22.1 Dietary carbohydrates			
Class	Components	Examples	Source
Free sugars	Monosaccharides	Glucose, fructose	Intrinsic: fruits, milks, vegetables
	Disaccharides	Sucrose, lactose, maltose, galactose	Extrinsic (extracted, refined): beet or cane sucrose, high-fructose corn syrup
Short-chain carbohydrates	Oligosaccharides	Maltodextrins, fructo-oligosaccharides	
Starch polysaccharides	Rapidly digestible		Cereals (wheat, rice), root vegetables (potato), legumes (lentils, beans, peas)
	Slowly digestible		
Resistant starch	Not digested	Starch altered by cooking	Cooked and cooled potato, pasta Some lactose from milk in infancy
Non-starch polysaccharides (NSPs; dietary fibre)	Fibrous	Cellulose	Many plant foods
	Viscous	Hemicellulose Pectins Gums	Pulses
Sugar alcohols		Sorbitol, xylitol	Sorbitol: stone fruits (apples, peaches, prunes) Xylitol: maize, berry fruits Both used as low-calorie sugar alternatives

salivary and then pancreatic amylase, however, producing rapid delivery of glucose to the blood. Other starches are digested more slowly, either because they are protected in the structure of the food, or because the molecule is unbranched (amylose). The area under the curve of blood glucose concentration over 2 hours after eating 50 g carbohydrate in a food, expressed as a percentage of the response to 50 g carbohydrate as glucose or white bread, is termed the 'glycaemic index' of that food. High consumption of high-glycaemic-index foods is weakly associated with type 2 diabetes, but it should be noted that table sugar (sucrose) has a relatively low glycaemic index, being only 50% glucose. Sugar alcohols (e.g. sorbitol), sweeteners that are not absorbed from the gut cause diarrhoea if eaten in large amounts. The main sugar in milk is lactose, a vital energy source for infants, hydrolysed by intestinal lactase for absorption. Some older people, especially East and South East Asians, produce much less lactase, so must limit unfermented milk products. Temporary lactose intolerance is common after any gastroenteritis, but lactase production can be restored by cautious lactose reintroduction.

### Dietary fibre

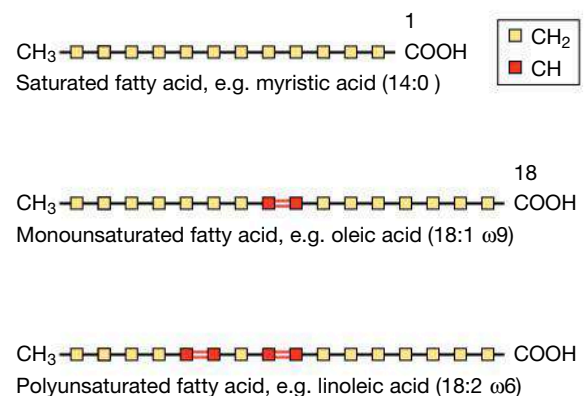

Dietary fibre is carbohydrate that is not digested and absorbed in the small intestine, so passes into the large bowel as the main nutrient for the gut microbiota. Most dietary fibre is 'non-starch polysaccharides' (NSPs) (see Box 22.1), plus some 'resistant' dietary starch, altered by cooking to escape hydrolysis in the small intestine. The many bacterial species which make up the colonic microbiota digest fibre to produce short-chain fatty acids, which are absorbed as fuel for the colonic epithelium and contribute to bowel health and also bioactive, stimulating hormones like glucagon-like peptide (GLP-1) from colon 'H' cells. In infancy, some lactose in milk is not absorbed, and serves the same functions.

Some types of NSP, notably the hemicellulose of wheat, increase the water-holding capacity of the colonic contents and the bulk of faeces. They relieve simple constipation, appear to prevent diverticulosis and may reduce the risk of colon cancer. Viscous dietary fibres, like pectin and guar gum, delay glucose absorption and thus reduce glycaemic index, and reduce bile salt absorption hence plasma cholesterol concentration.

### Fats

Fat is the highest-energy density macronutrient, and incurs minimal energy costs for absorption and storage. Highly prized in ancient times, it is now cheap and carries flavours, so is commercially important by providing 'added-value' for manufactured foods. Quite minor excess consumption is an insidious cause of obesity (see Fig. 22.3A).

Free fatty acids are absorbed, reassembled in chylomicrons (see Fig. 23.5), to enter the circulation directly or via the lymph. Fatty acid

**Fig. 22.5 Schematic representation of fatty acids.** Standard nomenclature specifies the number of carbon atoms and indicates the number and position of the double bond(s) relative to the methyl (–CH<sub>3</sub>, ω) end of the molecule after a colon.

structures are shown in Figure 22.5. The principal polyunsaturated fatty acids (PUFA) in plant seed oils, linoleic acid (18:2 ω6) and α-linolenic acid (18:3 ω3) are the 'essential' fatty acids, which humans cannot synthesise *de novo*. They undergo further desaturation and elongation, to produce, for example, γ-linolenic acid (18:3 ω6) and arachidonic acid (20:4 ω6). These are precursors of prostaglandins and eicosanoids, and form part of the structure of lipid membranes in all cells. Pelagic (shoaling) fish and fish oils are rich in ω3 PUFA (e.g. eicosapentaenoic (20:5 ω3) and docosahexaenoic (22:6 ω3)), which promote the anti-inflammatory cascade of prostaglandin production and occur in the lipids of the human brain and retina. They also reduce blood pressure, improve glucose tolerance and inhibit thrombosis by competitively antagonising thromboxane A<sub>2</sub> formation. Saturated fats have high melting points, mostly coming from warm-blooded animal sources: those with shorter chain lengths, from dairy foods, appear relatively safe, but those with long chain lengths, found particularly in animal fat and manufactured meat products, elevate LDL cholesterol and promote cardiovascular disease. Replacing them with PUFAs may help prevent coronary heart disease, provided the PUFAs are protected by their natural antioxidants. High intakes of *trans* fatty acids (TFAs; isomers of the natural *cis* fatty acids) reflect the use of oils that have been partially hydrogenated in the food industry to raise their melting point for use in manufactured foods. They behave like the long-chain saturated fats to promote cardiovascular disease, so it is recommended that TFAs are limited to <2% of dietary fat intake. Changes in industrial practice in the UK and United States have brought most people's TFA intakes below 1%, with the residual amount coming from ruminant digestion in milk.

22.2 Amino acids	
<b>Essential amino acids</b>	
<ul style="list-style-type: none"> <li>• Tryptophan</li> <li>• Histidine</li> <li>• Methionine</li> <li>• Threonine</li> <li>• Isoleucine</li> </ul>	<ul style="list-style-type: none"> <li>• Valine</li> <li>• Phenylalanine</li> <li>• Lysine</li> <li>• Leucine</li> </ul>
<b>Conditionally essential amino acids and their precursors</b>	
<ul style="list-style-type: none"> <li>• Cysteine: methionine, serine</li> <li>• Tyrosine: phenylalanine</li> <li>• Arginine: glutamine/glutamate, aspartate</li> <li>• Proline: glutamate</li> <li>• Glycine: serine, choline</li> </ul>	

22.3 Daily adult energy requirements in health		
Circumstances	Daily requirements*	
	Females	Males
<b>At rest (basal metabolic rate)</b>	5.4 MJ (1300 kcal)	6.7 MJ (1600 kcal)
<b>Less active</b>	8.0 MJ (1900 kcal)	9.9 MJ (2400 kcal)
<b>Population median</b>	8.8 MJ (2100 kcal)	10.8 MJ (2600 kcal)
<b>More active</b>	9.6 MJ (2300 kcal)	11.8 MJ (2800 kcal)

\*These are based on a healthy target body mass index (BMI) of 22.5 kg/m<sup>2</sup>. For a female, height is 162 cm and weight 59.0 kg; for a male, height is 175 cm and weight 68.8 kg. Previous average recommendations of 8.1 MJ (1950 kcal, usually rounded up to 2000 kcal) for females and 10.7 MJ (2500 kcal) for males should continue to be used, as these fall within experimental error.

Cholesterol is also absorbed from food in chylomicrons and is an important substrate for steroid and sterol synthesis, but not an important source of energy, nor a major contributor to plasma cholesterol concentration as it is also synthesised in the liver.

### Proteins

Proteins, with all their complexity for structural and metabolic/enzymic functions, are made up of some 20 different amino acids. Nine are 'essential' (Box 22.2), i.e. they cannot be synthesised by healthy humans, but are required for synthesis of important proteins, so must always be provided by the diet. While amino acids are well preserved by recycling, there are no stores, so a regular supply is needed to replace losses. Five other amino acids are 'conditionally essential': they can usually be synthesised from other amino acids, but synthesis may be insufficient, demanding a greater dietary supply under certain conditions (e.g. poor diet, pregnancy, growth, illness). The remaining necessary amino acids can be synthesised in the body by transamination, provided there is a sufficient supply of amino groups.

Dietary proteins of animal origin contain a mix of amino acids well matched to human needs, so have greater biological value than proteins of vegetable origin, which are low in one or more of the essential amino acids. However, when different vegetable proteins are eaten together, classically a cereal and a legume, their amino acid contents are complementary and produce an adequate mix, a key feature of most surviving traditional diets, and an important principle for vegan diets.

### Dietary recommendations for macronutrients

Recommendations for energy intake (Box 22.3) and proportions of macronutrients (Box 22.4) in the general population have been developed from detailed analyses, and quality assessment, of the totality of the scientific evidence and have changed little over the last 50 years. Recommended ranges or limits aim to provide sufficient essential nutrients for the great majority of healthy people at different life-stages, and also to minimise the risks of chronic non-communicable diseases

22.4 WHO recommended population macronutrient goals		
Nutrient	Target limits for population average intakes (% of total energy unless indicated)	
	Lower	Upper
<b>Protein</b>	10	
<b>Total fat</b>	15	30
Saturated fatty acids	0	10
Polyunsaturated fatty acids	6	10
<i>Trans</i> fatty acids	0	1
Dietary cholesterol (mg/day)	0	300
<b>Total carbohydrate</b>	55	75
Free (added) sugars	0	10
Complex carbohydrate	50	70
<b>Dietary fibre (g/day)</b>		
As non-starch polysaccharides	>20	
As total dietary fibre	>25	
Total fruit and vegetables	>400	

(obesity, type 2 diabetes, coronary heart disease, diverticulosis, cancers). The requirements during and after illness may be different, and pre-term infants have particular needs.

## Disorders of altered energy balance

### Obesity

Obesity is regarded as a global pandemic, or 'syndemic' as it entails potentially disastrous consequences for human health. In 2020, almost 30% of adults in the UK were obese (i.e. BMI  $\geq 30$  kg/m<sup>2</sup>) compared with 7% in 1980 and 16% in 1995. Moreover, almost 66% of the total UK adult population is overweight (BMI  $\geq 25$  kg/m<sup>2</sup>). The proportion with a normal weight (BMI 18.5–25 kg/m<sup>2</sup>) falls to only about 11% by age 65, presenting a problem for interpreting disease associations because those 11% include very fit people, but also a relatively high proportion who have remained or become thinner through illness.

In low- and middle-income countries, average obesity rates are lower, but these figures may disguise high rates of obesity and non-communicable diseases emerging in urban communities.

### Complications

Obesity affects both mortality and morbidity (Fig. 22.6). Changes in mortality are difficult to analyse due to the confounding effects of lower body weight in cigarette smokers and those with other illnesses (such as cancer). The lowest mortality rates in Europeans are still in the BMI range 18.5–25 kg/m<sup>2</sup> (and at lower BMI in South-east Asians), but there is only a minor rise until BMI is above 30 kg/m<sup>2</sup>. A BMI above 35 kg/m<sup>2</sup> at age 40 years reduces life expectancy by up to 7 years for non-smokers and by 13 years for smokers, and if type 2 diabetes develops, almost always with moderate overweight, life expectancy is reduced by about 7 years at any BMI. Coronary heart disease (Fig. 22.7) is the major cause of death but cancer rates are also increased in the overweight, especially colorectal cancer in males and cancer of the gallbladder, biliary tract, breast, endometrium and cervix in females. Obesity has little effect on life expectancy above 70 years of age, but the severely obese often spend much of their life disabled, physically, mentally and socially. Although an increased body weight results in greater bone density through increased mechanical stress, this does not translate into a lower incidence of osteoporotic fractures. Obesity may have profound psychological consequences, compounded by stigmatisation and victim blaming, rather than offering sympathetic support for effective treatment.

Fig. 22.6 Complications of obesity.

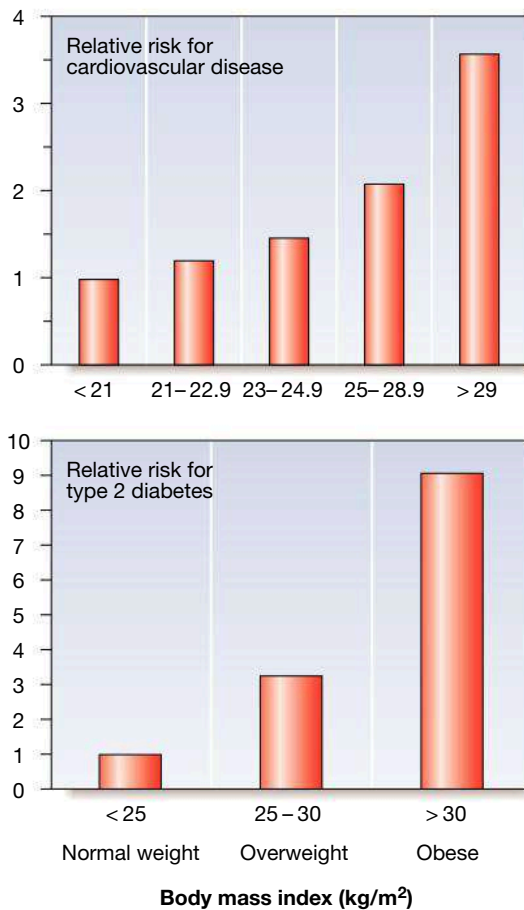

Fig. 22.7 Risks of diabetes and cardiovascular disease in overweight and obese women. Data are from the Nurses' Health Study in the United States and mostly relate to women of predominantly European descent. In some ethnic groups (e.g. South Asians, Indigenous Americans) and in people with higher waist circumference, the metabolic complications are even more severe at a given level of body mass index.

#### Body fat distribution

For some complications of obesity, the distribution rather than the absolute amount of excess adipose tissue appears to be important. Increased intra-abdominal fat causes a 'central' ('abdominal', 'visceral', 'android' or 'apple-shaped') shape, which contrasts with subcutaneous fat accumulation causing 'generalised' ('gynoid' or 'pear-shaped') obesity. The former, more common in men, incurs ectopic fat accumulation with impaired functions in liver, pancreas, skeletal and cardiac muscle, promoting type 2 diabetes, metabolic syndrome and cardiovascular disease (see Fig. 22.6). The intra-abdominal fat drains into the portal vein and thence directly to the liver, thus many factors released from adipose tissue (including free fatty acids; 'adipokines', such as tumour necrosis factor alpha, adiponectin and resistin) are at higher concentration in the liver and muscle, inducing insulin resistance and promoting type 2 diabetes. The key to remission of type 2 diabetes, with restoration of the first-phase insulin response to glucose appears to be loss of ectopic fat in liver and pancreas.

#### Aetiology

Accumulation of fat results from a discrepancy between energy consumption and energy expenditure that is too large to be defended by the hypothalamic regulation of BMR. A continued small daily positive energy balance of only 0.1 MJ (50 kcal; ~2% of intake) would lead to weight gain of ~25 kg over 10 years. With habituation to a subtle energy excess, body fat content shows 'tracking' with age within obesogenic environments, such that children of obese families usually become obese adults. If physical activity decreases with age, which is now common, but food consumption is more driven by habit and marketing than physiology, BMR tends to fall and weight increases throughout adult life (see Fig. 22.3).

The obesity pandemic reflects dramatic changes over the last 40–50 years in both energy intake and expenditure (Box 22.5), although both are difficult to measure reliably. The estimated average global daily supply of food energy per person increased from approximately 9.8 MJ (2350 kcal) in the 1960s to approximately 11.7 MJ (2800 kcal) in the 1990s, but its delivery is unequal. For example, in India it is estimated that 5% of the population receives 40% of the available food energy, leading to obesity in the urban population in parallel with under-nutrition in some rural

communities. In affluent societies, a significant proportion of this food supply is discarded. In the United States, men's average daily energy intake reportedly rose from 10.2MJ (2450kcal) in 1971 to 11.0MJ (2618kcal) in 2000. Portion sizes, particularly of energy-dense foods such as drinks with highly refined sugar content and salty snacks, have increased, and the 'food disappearance' rate (i.e. production and sales) has increased for all food groups, with greater consumption of catered meals and less food waste. Obesity is correlated positively with the number of hours spent watching screens, inversely with sleep time, and inversely with levels of physical activity. Labour-saving devices play a part and minor activities such as fidgeting, termed non-exercise activity thermogenesis (NEAT), may contribute to energy expenditure and protect against obesity.

### Susceptibility to obesity

Susceptibility to obesity varies between individuals. Obese subjects do not have a 'slow metabolism': their BMR is higher than that of lean subjects. Twin and adoption studies confirm a familial influence on obesity, but both environment and genes contribute to 'heritability'. The pattern of inheritance suggests a polygenic disorder, with small contributions from a number of different genes, together accounting for 25%–70% of variation in weight. Genome-wide association studies of polymorphisms have identified a handful of genes, some of which encode proteins known to be involved in the control of appetite or metabolism function. However, these account for less than 5% of variation in body weight. Genes also influence fat distribution and therefore risk of metabolic consequences of obesity.

A few rare single-gene disorders have been identified that lead to severe childhood obesity. These include mutations of the melanocortin-4 receptor (*MC4R*), which account for approximately 5% of severe early-onset obesity; defects in the enzymes processing proopiomelanocortin (*POMC*, the precursor for adrenocorticotrophic hormone (ACTH)) in the hypothalamus; and mutations in the leptin gene (see Fig. 22.4). The latter can be treated by leptin injections. Additional genetic conditions in

which obesity is a feature include Prader–Willi and Lawrence–Moon–Biedl syndromes.

### Clinical features and investigations

- In assessing an individual presenting with obesity, the aims are to:
  - exclude an underlying cause,
  - identify complications,
  - quantify the current and potential problems and
  - agree a management plan with the individual, based on evidence, proportionate to the problem and optimally supported.

Measuring waist circumference is useful with BMI under 35kg/m<sup>2</sup>: above this level, it is unnecessary and becomes unreliable as the waist descends under gravity. Risks of metabolic and cardiovascular complications are worse with a high waist circumference; lower cut-offs of BMI and waist circumference indicate higher risk in South Asians (Box 22.6).

A very general history of dietary patterns and preferences may be helpful in guiding dietary advice but substantial under-reporting of food consumption is almost universal among overweight people. Pathological eating behaviours such as binge eating, nocturnal eating or bulimia demand specific management. Alcohol is rarely a major source of energy intake but should be considered as a possible obstacle to effective treatment. Many commonly prescribed drugs cause weight gain, and impede effective weight loss (Box 22.7). If possible these should be withdrawn or doses minimised.

In a small minority of patients presenting with a short history of marked change in adult weight gain trajectory, specific causal factors such as hypothyroidism or Cushing's syndrome can be identified and treated (see Box 22.7). All obese patients should have thyroid function tests performed, and an overnight dexamethasone suppression test or 24-hour urine free cortisol if Cushing's syndrome is suspected clinically. Monogenic causes of obesity are relevant only in children presenting with severe obesity, but 'syndromic' obesity commonly accompanies conditions with learning and behavioural difficulties such as Down syndrome, where the goodwill of carers may contribute.

Assessment of the multiple complications and impacts on life and work of obesity (see Fig. 22.6) requires a full history, and limited examination and screening investigations. Blood pressure should be measured with a large cuff, if required. Associated type 2 diabetes and dyslipidaemia are detected by measurement of HbA<sub>1c</sub> and a serum lipid profile, respectively, ideally in a fasting morning sample. Elevated serum transaminases occur in patients with non-alcoholic fatty liver disease.

### Management

The health risks of obesity are often reversible if identified and treated early. Effective modest weight loss (5–10kg) ameliorates all the cardio-metabolic risk factors and reduces the incidence of type 2 diabetes.

22.5 Some reasons for the increasing prevalence of obesity – the 'obesogenic' environment	
<b>Increasing energy intake</b>	
<ul style="list-style-type: none"> <li>• ↑ Portion sizes</li> <li>• ↑ Snacking, grazing and loss of regular meals</li> </ul>	<ul style="list-style-type: none"> <li>• ↑ Energy-dense 'added-value' food (fat and sugars)</li> <li>• ↑ Affluence</li> <li>• Effective marketing</li> </ul>
<b>Decreasing energy expenditure</b>	
<ul style="list-style-type: none"> <li>• ↑ Car ownership</li> <li>• ↓ Walking to school/work</li> <li>• ↑ Automation/domestic labour-saving</li> <li>• ↓ Manual labour in occupations</li> </ul>	<ul style="list-style-type: none"> <li>• ↓ Sports in schools</li> <li>• ↑ Time spent on computer games and watching TV</li> <li>• ↑ Central heating, washing machines</li> </ul>

22.6 Quantifying obesity with BMI and waist circumference for risk of type 2 diabetes and cardiovascular disease <sup>1</sup>				
BMI (weight in kg/height in m <sup>2</sup> )	Classification <sup>2</sup>	Waist circumference <sup>3</sup>		
		Men < 94 cm Women < 80 cm	Men 94–102 cm Women 80–88 cm	Men > 102 cm Women > 88 cm
18.5–24.9	Reference range	Low	Increased	Severe
25.0–29.9	Overweight	Low	Moderate	Very severe
>30.0	<b>Obese</b>			
30.0–34.9	Class I	Moderate	Severe	Very severe
35.0–39.9	Class II	(not possible)	Very severe	Very severe
>40.0	Class III	(not possible)	Very severe	Very severe

<sup>1</sup>Lower cut-offs apply for people of South Asian ancestry, see note 2. High waist circumference is the more potent risk indicator, reflecting increase intra-abdominal and ectopic fat accumulation in vital organs. <sup>2</sup>Classification of the World Health Organization (WHO) and International Obesity Task Force. The Western Pacific Region Office of WHO recommends that, among South Asians, BMI > 23.0 is overweight and > 25.0 is obese. Lower cut-offs for waist circumference have also been proposed for South Asians but have not been validated. <sup>3</sup>When BMI is > 35 kg/m<sup>2</sup>, waist circumference is difficult to measure because the waist descends under gravity, so does not add to the increased risk.

## 22.7 Secondary causes of weight gain

### Endocrine factors

- Hypothyroidism
- Cushing's syndrome
- Insulinoma
- Hypothalamic tumours or injury

### Drug treatments (worse in combination)

- Atypical antipsychotics (e.g. olanzapine)
- Antidepressants (e.g. amitriptyline, mirtazepine)
- Gabapentin, pregabalin
- Sulphonylureas, thiazolidinediones, insulin
- Pizotifen
- Glucocorticoids
- Sodium valproate
- $\beta$ -blockers

More substantial weight loss (10–15 kg or more) is needed to gain remission of established type 2 diabetes, or of sleep apnoea. Sustaining substantial weight loss is notoriously hard, so population strategies to prevent and reverse obesity are high on public health priority agendas. Many initiatives have evidence for limited success while the initiative is in place, including promoting 'healthy eating' in schools, enhancing walking and cycling options for commuters, and liaising with the food industry to reduce energy, sugar and fat content and to label foods appropriately. Unfortunately these measures tend most to benefit those better educated who already suffer less from overweight and obesity. Taxes on high-sugar drinks have been introduced in some countries, with some evidence for short-term changes in consumption but not in effect on body weights, probably because artificially sweetened alternatives still stimulate an appetite for more energy-dense foods. Unfortunately, many heavily promoted 'low-fat' foods are often still energy-dense.

Most patients seeking assistance with obesity appear motivated to lose weight and have often done so previously, without long-term success. These patients may hold inaccurate perceptions of their energy intake and expenditure, and an unrealistic view of the target weight that they would regard as a 'success'. An empathetic explanation of energy balance, which recognises that some individuals are more susceptible to obesity than others, and find it more difficult to lose body weight and sustain this loss, is important. Reassurance that there is no underlying endocrine or metabolic problem can be helpful, especially for family members or carers. Appropriate goals for weight loss should be agreed, recognising that a given amount of weight loss achieves greater risk reduction at higher levels of BMI, but accommodating the perceptions of the patient. An initial reasonable goal for most patients with BMI up to 30 kg/m<sup>2</sup> is to lose 5%–10% of body weight using conventional diet and lifestyle modifications. With BMI above 30 kg/m<sup>2</sup>, or if type 2 diabetes or other serious complications are present, greater weight loss of over 10–15 kg is recommended, and more intensive intervention is indicated, with separate strategies for inducing and for maintaining weight loss of this order (Fig. 22.8). Modern adjunctive drug treatment can be very effective (e.g. GLP-1 agonists), but mainly to sustain major weight losses for those who alter their diet substantially.

### Lifestyle advice

Behavioural modification to avoid or mitigate some effects of the 'obesogenic' environment (see Box 22.5) is the cornerstone of long-term control of weight. Adopting more disciplined eating patterns, and pre-planned meals, is advised. Advising modest extra activity to increase physical activity level (PAL) ratios (see Fig. 22.3C), may be successful for younger people, but this must be sustainable and regular as a daily routine (e.g. walking rather than driving to work): older patients, and those with arthritis or type 2 diabetes find increasing physical activity very hard. Regular support, and positive strategic encouragement when problems arise, from a dietitian or weight loss group is very valuable.

**Fig. 22.8 Therapeutic options for obesity.** Relevant comorbidities include type 2 diabetes, hypertension, cardiovascular disease, sleep apnoea, and waist circumference of >102 cm in men or 88 cm in women. This is an approximate consensus of the numerous national guidelines, which vary slightly in their recommendations and are revised every few years. (BMI = body mass index).

### Weight loss diets

The general lifestyle advice above, with medical encouragement, may gradually induce weight loss and a grateful patient. However, regain is a huge problem, as people slip back to their 'normal' diets and lifestyles, especially when life-events step in. Contrary to much previous teaching, the evidence is now consistent that more rapid and greater early weight loss tends to result in better quality of life, and to better long-term maintenance. More rapid weight loss may also be required to prepare for surgery.

Very-low-energy diets (VLEDs, under 800 kcal/day) or low energy diets of 800–1000 kcal/day are similarly effective for rapid weight loss of 1.5–2.5 kg/week, compared to 0.5 kg/week on conventional regimens. Both are safe if provided as a nutritionally complete formula diet, and most successful with encouragement from an experienced and supportive physician or nutritionist. A minimum content of 40–50 g protein daily minimises muscle degradation, over 20 g of fat helps to avoid gallstone formation, with sufficient magnesium to avoid constipation, and fluid intake of at least 2.5 L/day to avoid dehydration which can cause orthostatic hypotension, headache, constipation and nausea. Medical supervision is needed for patients whose glucose-lowering and antihypertensive medications need withdrawal or reduction with rapid weight loss.

### Drugs

The obesity pandemic has stimulated huge investment by the pharmaceutical industry in finding drugs for obesity, unfortunately hitherto directed and licensed only for 'weight loss' although the greater problem for patients is in fact long-term maintenance of a lower weight. There is no role for diuretics, or for thyroxine. Metformin does generate an average weight loss of about 2 kg, but is not licensed or effective for weight management. Drug therapy should only be used as an adjunct to optimal, evidence-based, lifestyle advice and support, which should be continued throughout treatment.

Orlistat inhibits pancreatic and gastric lipases. The standard dose of 120 mg taken with each of the three main meals reduces dietary fat absorption by about 30%. It is not absorbed, and adverse effects relate to fat malabsorption if the diet still contains too much fat: loose oily stools, faecal urgency, flatus and malabsorption of fat-soluble vitamins. Its efficacy is partly explained because patients taking orlistat adhere better to low-fat diets in order to avoid unpleasant gastrointestinal side-effects, but it is favoured by few patients. The combination of low-dose phentermine and topiramate extended release, approved in the United States, results in weight loss of ~6% greater than placebo. Concerns over teratogenicity of topiramate and cardiovascular effects of

both phentermine and topiramate (albeit at higher doses) have blocked its approval in Europe. The combination of the opioid antagonist naltrexone and the noradrenaline (norepinephrine)/dopamine re-uptake inhibitor bupropion is similarly effective, and approved in both the United States and Europe. Its main adverse effects are dry mouth and constipation.

The most effective medications for obesity treatment are the glucagon-like peptide-1 (GLP-1) receptor agonists, usually at higher doses than are used to treat type 2 diabetes. These drugs are remarkably safe, their main drawback being high cost. Their main side-effects are gastrointestinal and avoided if the dose is very low to start, and then slowly increased. Patients are very willing to accept subcutaneous administration for effective treatment. Liraglutide is approved for obesity treatment in Europe and the United States, and for high-risk obese patients, at a daily subcutaneous dose up to 3 mg. The mean weight loss in randomised trials was about 10 kg, including trials of people with type 2 diabetes. Even better results can be achieved in routine practice if it is stopped early when it proves ineffective. It is recommended to stop liraglutide if 3 mg/day for 3 months fails to generate >5% weight loss (usually indicating poor dietary compliance). Another GLP-1 agonist, semaglutide, also already licensed for type 2 diabetes, is under consideration in both the United States and Europe for approval at a dose of 2.4 mg/day subcutaneously. It generates even greater weight losses than liraglutide, with similar safety, and weekly injection and an oral form are in trials.

Drug therapy is usually reserved for patients with high risk of complications from obesity (see Fig. 22.8). All licensed drugs do reduce the cardiovascular and diabetes risks and weight loss of >10% is associated with reduced cardiac events. However, approvals are currently for weight loss, not maintenance, so duration of drug treatment is controversial. Withdrawing an effective drug means it no longer works, so weight regain is usual. Although life-long therapy is advocated on the basis of short-term research trials for many drugs that reduce risks (e.g. drugs for hypertension and osteoporosis), this is not yet widely accepted for obesity treatment. Weight regain despite continued drug treatment generally reflects reduction in professional support and relaxation of dietary control, for which reinforcement and new lifestyle measures are needed. Patients who demonstrate early weight loss (e.g. >5% after 12 weeks on the optimum dose) achieve greater and longer-term weight loss. Treatment can be stopped in non-responders at this point and alternative treatments considered.

### Surgery

'Bariatric' surgery is the most effective treatment for obesity, in terms of amount and duration of weight loss (see Fig. 22.8 and Box 22.8), and associated with improvements in all obesity-related risk factors and reduced mortality. Bariatric surgery should be contemplated in motivated patients who have very high risks of complications of obesity, when optimal dietary and drug therapy has been insufficiently effective. It is usually reserved for those with severe obesity (BMI >40 kg/m<sup>2</sup>), or those with a BMI >35 kg/m<sup>2</sup> and significant complications, such as type 2 diabetes or obstructive sleep apnoea, although some evidence-based guidelines now suggest surgery can be considered at a lower weight with recent-onset diabetes and a BMI >30 kg/m<sup>2</sup>. Only experienced specialist surgeons should undertake these procedures, in collaboration with a multidisciplinary team and plans for lifelong follow-up. Several approaches are used (Fig. 22.9) and all can be performed laparoscopically. The mechanism of weight loss, and its maintenance, after bariatric surgery is controversial. It may not simply relate to limiting the stomach size, or absorptive capacity, but also in disrupting release of ghrelin from the stomach or promoting release of other peptides from the small bowel, thereby enhancing satiety signalling in the hypothalamus. Diabetes usually improves rapidly after surgery, particularly after gastric bypass, but this is mainly attributable to severe energy restriction in the perioperative period. Increased release of incretin hormones such as GLP-1 may contribute to improved glucose control.

Bariatric surgery has taught us a lot about the pathogenesis of obesity and the health improvements possible with substantial weight loss, but it

## 22.8 Effectiveness and adverse effects of laparoscopic bariatric surgical procedures\*

Procedure	Expected 2-year weight loss (kg)	Adverse effects
<b>Gastric banding</b>	19–25	Band slippage, erosion, stricture Port site infection Mortality <0.2% in experienced centres
<b>Sleeve gastrectomy</b>	20–30	Iron deficiency Vitamin B <sub>12</sub> deficiency Mortality <0.2% in experienced centres
<b>Roux-en-Y gastric bypass</b>	20–40	Internal hernia Stomal ulcer Dumping syndrome Hypoglycaemia Iron deficiency Vitamin B <sub>12</sub> deficiency Vitamin D deficiency Mortality 0.5%

\*Weight regain is a frequent problem beyond 5 years after all bariatric surgery, particularly banding and sleeve gastrectomy.

is not a 'one-step solution'. Complications of one kind or another, often multiple and some serious, affect almost all patients after bariatric surgery, depending on the approach. Perioperative mortality is now under 1% in experienced centres, but post-operative respiratory problems, wound infection and dehiscence, staple leaks, stomal stenosis, marginal ulcers and venous thrombosis may occur. Additional problems may arise at a later stage, such as pouch and distal oesophageal dilatation with loss of effectiveness, persistent vomiting, hypoglycaemic or hypotensive 'dumping' syndromes, hypoglycaemia and micronutrient deficiencies, particularly of folate, vitamin B<sub>12</sub> and iron, which are of special concern to women contemplating pregnancy; this should be delayed for at least 2 years following surgery.

Cosmetic surgical procedures may be needed for a full physical and mental recovery after major weight loss. Apronectomy is a major operation to remove an overhang of unsightly, infected or ulcerated abdominal skin, a common problem in obese women after the menopause. This operation is not without risks, and of no value for long-term weight reduction if food intake remains unrestricted.

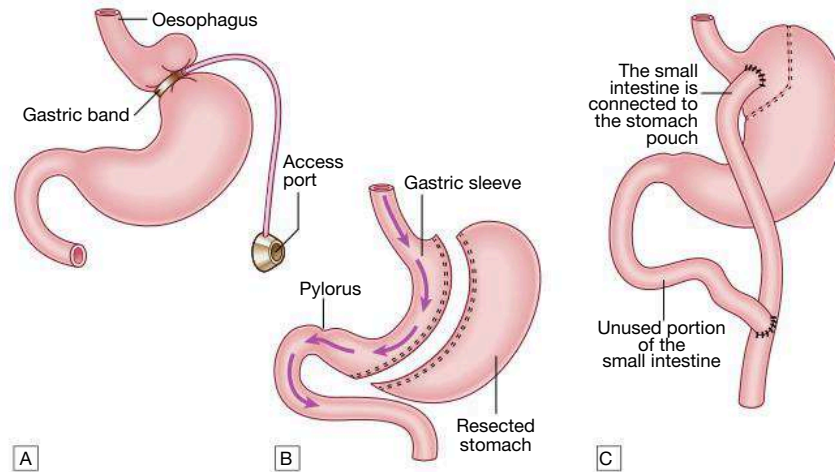

### Treatment of additional risk factors

Obesity must not be treated in isolation. Other risk factors must be addressed, including smoking, excess alcohol consumption, diabetes, hyperlipidaemia, hypertension and obstructive sleep apnoea.

## Under-nutrition

### Starvation and famine

There remain regions of the world, particularly rural Africa, where under-nutrition due to famine is endemic, where up to 20% of adults have BMI <18.5 kg/m<sup>2</sup> (Box 22.9), and stunting due to under-nutrition affects 50% of children. The World Health Organization (WHO) reports that chronic under-nutrition is responsible for more than half of all childhood deaths worldwide. Starvation is manifest as marasmus (malnutrition with marked muscle wasting) or, when added complications such as multiple infections and oxidative stress come into play, kwashiorkor (malnutrition with oedema). Growth retardation is due to deficiencies of key nutrients (protein, zinc, potassium, phosphate and sulphur). Treatment of these childhood conditions is not discussed in this adult medical textbook. In adults, starvation is the result of chronic sustained negative energy (calorie) balance, commonly with coexisting micronutrient deficiencies and many possible causes (Box 22.10).

**Fig. 22.9 Bariatric surgical procedures.** **A** Laparoscopic banding, with the option of a reservoir band and subcutaneous access to restrict the stomach further after compensatory expansion has occurred. **B** Sleeve gastrectomy. **C** Roux-en-Y gastric bypass.

22.9 Classification of under-nutrition in adults by body mass index (weight/height <sup>2</sup> )	
BMI (kg/m <sup>2</sup> )	Classification
>20	Adequate nutrition
18.5–20	Marginal
<18.5	<b>Under-nutrition</b>
17–18.4	Mild
16–17	Moderate
<16	Severe

22.10 Causes of under-nutrition and weight loss in adults	
<b>Decreased energy intake</b>	
<ul style="list-style-type: none"> <li>• Famine</li> <li>• Persistent regurgitation or vomiting</li> <li>• True anorexia from depression</li> <li>• True anorexia from drug side-effects</li> <li>• Eating disorders (e.g. anorexia nervosa <a href="https://we.tl/t-KFTRESkTDA">https://we.tl/t-KFTRESkTDA</a>)</li> <li>• Malabsorption (e.g. small intestinal disease)</li> <li>• Maldigestion (e.g. pancreatic exocrine insufficiency)</li> </ul>	
<b>Increased energy expenditure</b>	
<ul style="list-style-type: none"> <li>• Increased basal metabolic rate (thyrotoxicosis, trauma, fever, cancer cachexia, anxiety)</li> <li>• Excessive physical activity (e.g. marathon runners)</li> <li>• Energy loss (e.g. glycosuria in diabetes)</li> <li>• Impaired energy storage (e.g. Addison disease, pheochromocytoma)</li> </ul>	

### Clinical features

In starvation, the severity of malnutrition can be assessed by anthropometric measurements, such as BMI (see p. 757 and [Box 22.9](#)). Demispan and mid-arm circumference measurements are most useful in monitoring progress during treatment. The clinical features of severe under-nutrition in adults are listed in [Box 22.11](#).

Under-nutrition often includes vitamin deficiencies, especially of thiamin, folate and vitamin C (see below). Diarrhoea can lead to depletion of sodium, potassium and magnesium. The high mortality rate in famine situations is often due to outbreaks of infection, such as gastroenteritis, typhus or cholera ([Box 22.12](#)), but the usual signs of infection (e.g. fever, tachycardia) may not be apparent. In advanced starvation, patients shut down non-essential metabolism, with hypothermia and bradycardia, and become physically inactive in a flexed, fetal position,

22.11 Clinical features of severe under-nutrition in adults	
<ul style="list-style-type: none"> <li>• Weight loss</li> <li>• Thirst, craving for food, weakness and feeling cold</li> <li>• Nocturia, amenorrhoea or impotence</li> <li>• Lax, pale, dry skin with loss of turgor and, occasionally, pigmented patches</li> <li>• Cold and cyanosed extremities, pressure sores</li> <li>• Hair thinning or loss (except in adolescents)</li> <li>• Muscle-wasting, best demonstrated by the loss of the temporalis and periscapular muscles and reduced mid-arm circumference</li> <li>• Loss of subcutaneous fat, reflected in reduced skinfold thickness and mid-arm circumference</li> <li>• Hypothermia, bradycardia, hypotension and small heart</li> <li>• Oedema, which may be present without hypoalbuminaemia ('famine oedema')</li> <li>• Distended abdomen with diarrhoea</li> <li>• Diminished tendon jerks</li> <li>• Apathy, loss of initiative, depression, introversion, aggression if food is nearby</li> <li>• Susceptibility to infections (see <a href="#">Box 22.12</a>)</li> </ul>	

22.12 Infections associated with starvation	
<ul style="list-style-type: none"> <li>• Gastroenteritis and Gram-negative sepsis</li> <li>• Respiratory infections, especially bronchopneumonia</li> <li>• Certain viral diseases, especially measles and herpes simplex</li> <li>• Tuberculosis</li> <li>• Streptococcal and staphylococcal skin infections</li> <li>• Helminthic infestations</li> </ul>	

minimising heat loss. In the last stage of starvation, death comes quietly and often quite suddenly, commonly through asymptomatic pneumonia or primary arrhythmia. The very old are most vulnerable: younger people may be able to adapt to prolonged undernutrition. At necropsy all organs are atrophied, except the brain, which tends to maintain its weight.

### Investigations

In a famine, laboratory investigations may be impractical but will show that plasma free fatty acids are increased and there is ketosis and a mild metabolic acidosis. Plasma glucose is low but albumin concentration is often maintained because the liver still functions reasonably normally. Insulin secretion is diminished, glucagon and cortisol tend to increase, and reverse T<sub>3</sub> replaces normal triiodothyronine. The resting metabolic rate falls, partly because of falling lean body mass, and partly because of hypothalamic compensation (see [Fig. 22.3](#)). The urine has a fixed specific gravity and creatinine excretion becomes low. There may be

mild pancytopenia. The erythrocyte sedimentation rate (ESR) is normal unless there is infection. Tests of delayed skin hypersensitivity, e.g. to tuberculin, become falsely negative. The electrocardiogram shows sinus bradycardia and low voltage.

### Management

Undernutrition in a famine, or with anorexia nervosa, tends to preserve muscle mass, while with prolonged infections and inflammation, muscle tends to be lost more rapidly, reflected in lower mid upper arm circumference (MUAC). Undernutrition represents the only emergency in clinical nutrition. Starvation kills, but usually slowly: an average man or woman has enough body fat to live on for about 40 days, provided fluids are still consumed but ill-guided attempts at treating undernutrition can rapidly kill an otherwise healthy patient.

The severity of under-nutrition is graded according to BMI (see Box 22.9). People with mild starvation are not in great danger; those with moderate starvation need extra feeding; and those who are severely underweight need hospital care, particularly to avoid death from 'refeeding syndrome' (Box 22.13). Correcting fluids and electrolytes first, and their careful monitoring for at least 7 days of refeeding, is vital as there is often marked depletion of potassium, phosphate and magnesium after starvation. If insulin is stimulated by food without correcting these, their sudden movement into cells can cause a sudden arrhythmic death.

It is also essential to give thiamine to all severely undernourished patients (initially parenterally to be sure of absorption) to correct possible deficiency before food is administered, in order to avoid precipitating beri beri. Thiamine should be given on suspicion, without waiting for confirmatory blood tests, and without waiting for clinical signs of beri beri to emerge: a delay could be catastrophic, with permanent sequelae.

When food becomes available, and can be taken, it should be given by mouth in small, frequent amounts at first, using a suitable formula preparation (Box 22.14). Gastrointestinal involution often causes a degree of malabsorption, and diarrhoea, initially. Secondary lactose intolerance is common so milk-based foods are inappropriate. Individual energy requirements can vary by 30%, but minor over-feeding is more hazardous, causing fatty liver, than modest under-feeding, so rapid refeeding should be avoided. During rehabilitation, more concentrated formula can be given with additional more palatable foods similar to the usual staple meal. Salt should be restricted and micronutrient supplements (e.g. potassium, magnesium, zinc and multivitamins) may be essential. Between 6.3 and 8.4 MJ/day (1500–2000 kcal/day) will arrest progressive under-nutrition but additional energy may be required for regain of weight. During refeeding, a weight gain of 5% body weight per month indicates satisfactory progress. Other care is supportive and includes attention to the skin, adequate hydration, treatment of infections and careful monitoring of body temperature, since thermoregulation may be impaired.

Circumstances and resources are different in every famine but many problems are non-medical and concern organisation, infrastructure, liaison, politics, procurement, security and ensuring that food is distributed on the basis of need. Lastly, plans must be made for the future for prevention and/or earlier intervention if similar circumstances prevail.

### Under-nutrition in hospital

It is a worry that under-nutrition remains a serious issue in many sectors of high-income countries, particularly for older people and those who are less independent. In the UK, 30% of people requiring acute admission to hospital show evidence of under-nutrition and 65% of those admitted will lose an average of 5% of their total body weight during that admission. In the older population, levels of under-nutrition and vitamin deficiencies parallel levels of independent living. In Scotland, 33% of those aged over 65 who are living in their own home are deficient in folic acid and 10% are deficient in vitamin C. The prevalence of vitamin deficiencies rises further in less independent groups in residential homes.

Under-nutrition is poorly recognised and poorly documented in hospital admissions and discharges, with potentially serious medical and medico-legal consequences. Physical effects include impaired immunity,

### 22.13 Recognition and management of refeeding syndrome

- Refeeding after undernutrition is essential, but:
  - Refeeding without correcting K/Mg/PO<sub>4</sub> is a common cause of death
  - Refeeding without correcting subclinical thiamine deficiency causes permanent brain injury (Korsakoff psychosis). Always give IV thiamine before commencing refeeding – do not wait for biochemical confirmation of deficiency
- Classical patients at risk: kwashiorkor/marasmus, chronic malnutrition, alcoholism
- Others risk factors: BMI <16 kg/m<sup>2</sup>; unintentional weight loss >15% in 3–6 months; little/no oral intake for >10 days; low K+, Mg++, PO<sub>4</sub> before feeding
- Can occur with lesser degrees of weight loss and higher BMI levels; also in 'sarcopenic obesity'
- Refeeding leads to: uptake of glucose, K+, Mg++ and PO<sub>4</sub> into cells, and reduced plasma levels; thiamine utilisation and depletion; and retention of Na+ and water
- General treatment measures: careful monitoring, daily weights, cautious rehydration, cardiac monitoring if ECG changes, e.g. prolonged QTc interval
- Give repeated IV infusions of small doses of PO<sub>4</sub> (10–20 mmol)
- IV correction of hypokalaemia and hypomagnesaemia
- Energy: start at 10–20 kcal/kg daily increasing to meet energy needs over 5–7 days

(BMI – body mass index; ECG = electrocardiogram; IV = intravenous)

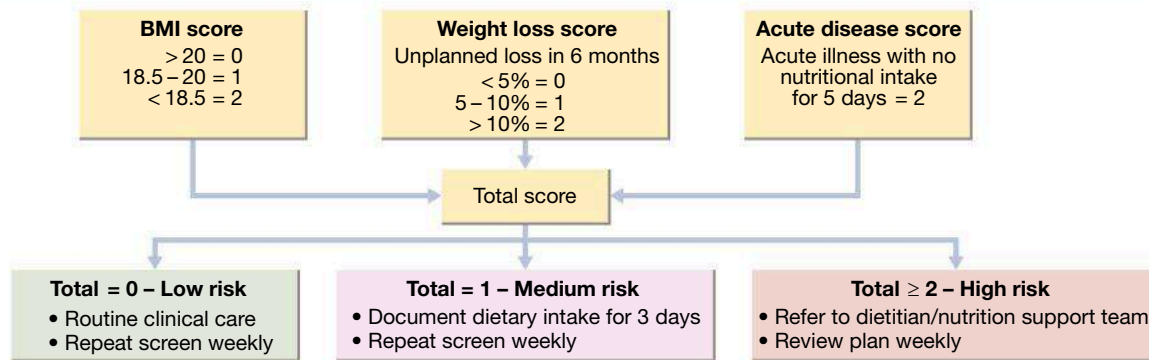

### 22.14 WHO recommended diets for refeeding

Nutrient (per 100 mL)	F-75 diet <sup>1</sup>	F-100 diet <sup>2</sup>
Energy	315 kJ (75 kcal)	420 kJ (100 kcal)
Protein (g)	0.9	2.9
Lactose (g)	1.3	4.2
Potassium (mmol)	3.6	5.9
Sodium (mmol)	0.9	1.9
Magnesium (mmol)	0.43	0.73
Zinc (mg)	2.0	2.3
Copper (mg)	0.25	0.25
<b>Percentage of energy from:</b>		
Protein	5	12
Fat	32	53
<b>Osmolality (mOsmol/kg)</b>	333	419
<b>Dose</b>	170 kJ/kg (40 kcal/kg)	630–920 kJ/kg (150–220 kcal/kg)
<b>Rate of feeding by mouth</b>	2.2 (mL/kg/hr)	Gradual increase in volume, 6 times daily

<sup>1</sup>F-75 is prepared from milk powder (25 g), sugar (70 g), cereal flour (35 g), vegetable oil (27 g) and vitamin and mineral supplements, made up to 1 L with water. <sup>2</sup>F-100 (1 L) contains milk powder (80 g), sugar (50 g), vegetable oil (60 g) and vitamin and mineral supplements (no cereal).

muscle weakness, which in turn affects cardiac and respiratory function, osteomalacia, and delayed wound healing with increased risks of secondary infection. The under-nourished patient is often withdrawn and this may be mistaken for depressive illness. Engagement with treatment and rehabilitation can be adversely affected. Much of this can be avoided through better awareness of under-nutrition, prompt nutritional assessment and monitoring with appropriate intervention. Screening systems, such as the Malnutrition Universal Screening Tool (MUST) (Fig. 22.10), raise awareness across multidisciplinary teams, and encourage staff to assess and monitor food intake and weigh patients regularly.

**Fig. 22.10** Screening hospitalised patients for risk of malnutrition. Acute illnesses include decompensated liver disease, cancer cachexia or being kept 'nil by mouth'. Adapted from the British Association of Parenteral and Enteral Nutrition Malnutrition Universal Screening Tool ([www.bapen.org.uk](http://www.bapen.org.uk)).

Causes are often complex (see [Box 22.10](#)). Social issues impact on food choices and may cause or exacerbate disease. Social isolation, low levels of disposable income and a lack of knowledge or interest in healthy eating may increase reliance on calorie-dense convenience foods of poor nutritional quality. The non-specific effects of chronic inflammation, infection or malignancy, as well as specific gastrointestinal disorders, may adversely affect appetite, reducing food intake.

Loss of appetite is common with gastrointestinal diseases, but occurs as a non-specific response to myriad other conditions or their treatments. The most frequent side-effects of many prescription drugs are nausea and gastrointestinal disturbance. Surgical resection of the gastrointestinal tract can have major nutritional sequelae in the years following, ranging from intolerance of normal volumes of food, or specific nutrient malabsorption, to intestinal failure (where there is partial or complete failure of the intestine to perform its vital functions). This is especially so after partial or total gastrectomy, extensive small bowel surgery or pancreatic (Whipple's) resection. It helps to consider systematically where the problem(s) might lie ([Box 22.15](#)).

### An approach to assisted nutrition in hospital patients

All patients in hospital or a care home should be screened periodically for possible malnutrition using the MUST tool ([Fig. 22.10](#)), and formally assessed if indicated. Poor appetite, immobility, poor dentition or even being kept 'nil by mouth' for hospital procedures all contribute to weight loss. A decision to intervene to tackle and reverse nutritional difficulties may involve simply ensuring that adequate supplies of suitable food are delivered accessibly (it is difficult to eat lying down) or that dentures fit properly, but may require an assessment of a patient's swallow or of the intestine's ability to digest foods. Whenever possible, it is best to use the most physiological means of feeding, i.e. by mouth, reserving more invasive interventions for when swallowing and digestion are impaired or absent. Enteral feeding is always preferred to parenteral, with its multiple hazards, provided the intestine is accessible and functioning.

### Oral nutritional supplements

Where swallow and intestinal function remain intact, the simplest form of assisted nutrition is the use of oral nutritional supplements, starting with attractive foods. Most branded supplement products are nutritionally complete (fortified with the daily requirements of vitamins, minerals and trace elements) and come in various formulations and textures, including 'shakes' and 'puddings' with a thicker consistency. They are expensive, but can be cost-effective and useful for people who may require just a small number of additional calories each day to maintain or gain weight in the short or longer term. However, they should not be used to replace normal meals or snacks. And their use and effect must be monitored. In spite of their nutritional value, small volume and range of flavours, many people find them unpalatable or difficult to tolerate, in which case they will be ineffective, but patients may not volunteer this information.

## 22.15 Factors affecting adequacy of nutritional intake in hospitalised patients

### Factors affecting appetite

- Unfamiliar or ill-prepared food
- Altered taste or smell
- Anxiety (social, cultural, financial, general and mental health issues may all be relevant, individually or in combination)
- Nausea and/or vomiting
- Non-specific effects of illness and/or drugs

### Issues of quantity

- Insufficient food on the plate?
- Reliance on 3 meals a day without the normal 4th meal or snacks

### Getting the food from the plate to the mouth

- Generalised reduced mobility
- Reduced manual dexterity
- Horizontal posture, bedrest
- Loss of upper limb or hand function

### Difficulties chewing food and initiating swallow

- Tooth loss
- Poorly fitting dentures
- Pain in the mouth, tongue or jaws
- Respiratory failure

### Specific problems with the oesophagus and gastrointestinal tract

- Obstruction (intrinsic or extrinsic)
- Ischaemia
- Inflammation
- Malabsorption

### Cultural issues

- Is the food provided appropriate to the patient's beliefs?

### More general evidence of self-neglect

- Evidence of chronic coexisting illness
- Evidence of mental health problems – low mood may be 'cause' or 'effect' in under-nutrition

### Enteral feeding

Where swallowing or food ingestion is impaired but intestinal function remains intact enteral tube feeding is the next choice (naso-enteral, gastrostomy or jejunostomy feeding). There are a number of theoretical advantages to enteral feeding, as opposed to parenteral, with uncertain evidence. These include:

- preservation of intestinal mucosal architecture, gut-associated lymphoid tissue and hepatic and pulmonary immune function
- reduced levels of systemic inflammation and hyperglycaemia
- interference with pathogenicity of gut micro-organisms.

However, the areas in which advantage has been consistently proven are:

- fewer episodes of infection
- lower cost
- earlier return to intestinal function
- shorter length of hospital stay.

The risks of enteral feeding are those related to tube insertion (Box 22.16) and diarrhoea (Box 22.17).

### Nasogastric tube feeding

This is simple, readily available, comparatively low-cost and most suitable for short-term feeding (up to 4 weeks). Insertion of a nasogastric tube requires care and training (see Box 23.40 and Box 22.16). Patients with reduced conscious level may pull at tubes and displace them: a nasal 'bridle' device can help by fixing the tube around the nasal septum, unless forcible tugging is likely.

### Gastrostomy feeding

Gastrostomy is a more invasive insertion technique, but easier to manage when longer-term feeding (>4 weeks) is required. Gastrostomies are less liable to displacement than nasogastric tubes and allow for fewer feed interruptions, so more of the prescribed feeds can be administered. An endoscopic, minimally invasive, technique is usual. Both endoscopic and radiological gastrostomy insertion involve inflating the stomach, thus opposing it to the anterior abdominal wall. The stomach is then punctured percutaneously and a suitable tube placed (Fig. 22.11) with an internal retainer device (plastic 'bumper' or balloon) that sits snugly against the gastric mucosa, and an external retainer to limit movement. These retainers hold the gastric wall against the abdominal wall, effectively creating a controlled gastrocutaneous ('Eck') fistula that matures over 2–4 weeks. Patient assessment and selection prior to gastrostomy placement should be done by a multidisciplinary nutrition support team, to weigh benefits against risks, recognising the need for stoma care (Box 22.18 and see Box 22.26).

### Post-pyloric feeding

In patients with a high risk of pulmonary aspiration or gastroparesis, it may be preferable to feed into the jejunum (via a nasojejunal tube,

### 22.16 Complications of nasogastric tube feeding

- Tube misplacement, e.g. tracheal or bronchial placement (*rarely*, intracranial placement)
- Reflux of gastric contents and pulmonary aspiration
- Interrupted feeding or inadequate feed volumes
- Refeeding syndrome

### 22.17 Diarrhoea related to enteral feeding

#### Factors contributing to diarrhoea

- Fibre-free feed may reduce short-chain fatty acid production in colon
- Fat malabsorption
- Inappropriate osmotic load
- Pre-existing primary gut problem (e.g. lactose intolerance)
- Infection

#### Management

- Often responds well to a fibre-containing feed or a switch to an alternative feed
- Simple antidiarrhoeal agents (e.g. loperamide) can be very effective

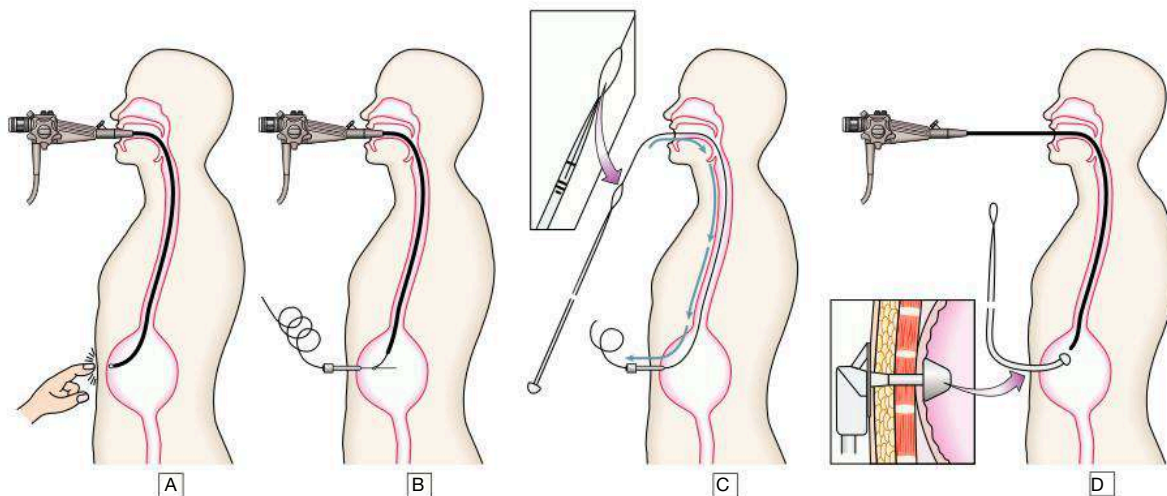

### 22.18 Complications of gastrostomy tube feeding

- Reflux of gastric contents and pulmonary aspiration (same as nasogastric tube)
- Risks of insertion (pain, damage to intra-abdominal structures, intestinal perforation, pulmonary aspiration, infection, death)
- Risk of tumour 'seeding' if an endoscopic 'pull-through' technique is used in head and neck or oesophageal cancer patients
- Refeeding syndrome

gastrostomy with jejunal extension or direct placement into jejunum by radiological, endoscopic or surgical means).

### Parenteral nutrition

This is strictly reserved for clinical situations where the absorptive functioning of the intestine is severely impaired, usually by resection, and will remain so indefinitely. Nutrition is delivered directly into a large-diameter systemic vein, completely bypassing the intestine and portal

**Fig. 22.11** Percutaneous endoscopic gastrostomy (PEG) placement. **A** Finger pressure on the anterior abdominal wall is noted by the endoscopist. **B** Following insertion of a cannula through the anterior abdominal wall into the stomach, a guidewire is threaded through the cannula and grasped by the endoscopic forceps or snare. **C** The endoscope is withdrawn with the guidewire. The gastrostomy tube is then attached to the guidewire. **D** The guidewire and tube are pulled back through the mouth, oesophagus and stomach to exit on the anterior abdominal wall, and the endoscope is repassed to confirm the site of placement of the retention device. The latter closely abuts the gastric mucosa; its position is maintained by an external fixation device (see inset). It is also possible to place PEG tubes using fluoroscopic guidance when endoscopy is difficult (radiologically inserted gastrostomy).

## 22.19 Complications of parenteral nutrition

### Intravenous catheter complications

- Insertion (pneumothorax, haemothorax, arterial puncture)
- Catheter infection (sepsis, discitis, pulmonary or cerebral abscess)
- Central venous thrombosis

### Metabolic complications

- Refeeding syndrome
- Electrolyte imbalance
- Hyperglycaemia
- Hyperalimantation
- Fluid overload
- Hepatic steatosis/fibrosis/cirrhosis

## 22.20 Parameters for monitoring parenteral nutrition in hospital

Parameter	Monitoring requirement
<b>Electrolytes</b> (sodium, potassium, magnesium)	Daily until stable and then 2–3 times per week
<b>Bone profile</b> (calcium, phosphate)	
<b>Liver function tests</b> (bilirubin, alanine aminotransferase, alkaline phosphatase, $\gamma$ -glutamyl transferase)	
<b>Markers of inflammation</b> (C-reactive protein, leucocyte count)	
<b>Blood glucose</b>	At least twice daily until stable and then daily
<b>Cholesterol and triglycerides</b>	Weekly initially, reducing to every 3 months when stable

venous system. As well as being more invasive, more expensive and less physiological than the enteral route, parenteral nutrition has many more complications (Box 22.19), mainly infective and metabolic (disturbances of electrolytes, hyperglycaemia). Strict adherence to aseptic practice in handling catheters and careful monitoring of clinical (pulse, blood pressure and temperature) and biochemical (urea, electrolytes, glucose and liver function tests) parameters are necessary to minimise risk (Box 22.20). Overfeeding is a particular hazard, causing fatty liver and potentially liver failure and death: accurate estimation of energy requirement is needed, preferably measurement using a metabolic cart.

The parenteral route is most often required in acutely ill patients with multi-organ failure, in severely under-nourished patients undergoing surgery which cannot be delayed, and with short bowel syndrome following resection. One by one, previous indications for parenteral feeding, e.g. thoracic duct rupture, have been found responsive to enteral feeding. There are major ethical issues around starting, and stopping, parenteral feeding, particularly if the patient lacks capacity.

## Intestinal failure ('short bowel syndrome')

Intestinal failure (IF) is defined as a reduction in gut function to below the minimum necessary for both adequate absorption of macronutrients and/or water and electrolytes. Intravenous supplementation is then required to support health and/or growth.

IF can be classified according to its onset, metabolic consequences and expected outcome.

- *Type 1 IF*: a common acute-onset, usually self-limiting condition with few long-term sequelae. It is most often seen following abdominal surgery or in the context of critical illness. Intravenous fluid and electrolyte support may be required for a few days to weeks.
- *Type 2 IF*: far less common, following an acute intra-abdominal event (ischaemia, volvulus, trauma or perioperative complication) often with septic and metabolic problems, creating complex

## 22.21 Causes of short bowel syndrome in adults

- Mesenteric ischaemia
- Post-operative complications
- Crohn's disease
- Trauma
- Neoplasia
- Radiation enteritis

## 22.22 Likely requirements for support according to length of intact residual small bowel

Residual length of jejunum (cm)	Oral fluid restriction	Oral glucose/electrolyte solution	Intravenous fluids	Parenteral nutrition
<200	Yes	Yes	May avoid	May avoid
<100	Yes	Yes	Yes	May avoid
<75	Yes	Yes	Yes	Yes

nutritional issues, requiring support for weeks to months with multidisciplinary input (nursing, dietetic, medical, biochemical, surgical, radiological and microbiological).

- *Type 3 IF*: a chronic condition in which patients are metabolically stable but require full intravenous nutrition support over months to years. It may or may not be reversible.

### Management

IF is a complex clinical problem with profound and wide-ranging physiological and psychological effects, which is best cared for by a dedicated multidisciplinary team. Most IF results from short bowel syndrome (Box 22.21), with chronic intestinal dysmotility and chronic intestinal pseudo-obstruction accounting for most of the remainder. The severity of the physiological upset correlates well with how much functioning intestine remains (rather than how much has been removed). Measuring the remaining small bowel (from the duodeno-jejunal flexure) at the time of surgery is essential to plan future therapy (Box 22.22). The aims of treatment are to:

- provide nutrition, water and electrolytes to maintain health with normal body weight (and allow normal growth in affected children)
- utilise the enteral or oral routes as much as possible
- minimise the burden of complications of the underlying disease, as well as the IF and its treatment
- allow a good quality of life.

If the ileum and especially the ileum and colon remain intact, long-term nutritional support can usually be avoided. Unlike the jejunum, the ileum can adapt to increase absorption of water and electrolytes over time. The presence of the colon (part or wholly intact) further improves fluid absorption, and can contribute energy from absorption of bacterially produced short-chain fatty acids.

### Jejunum–colon patients

Those with an anastomosis between jejunum and residual colon (jejunum–colon patients) may look well in the days or initial weeks following the acute insult but develop protein-energy malnutrition and significant weight loss, becoming seriously under-nourished over weeks to months.

Stool volume is determined by oral intake, with higher intakes causing more diarrhoea and the potential for dehydration, sodium and magnesium depletion and acute renal failure. The absence of the ileum leads to deficiencies of vitamin B<sub>12</sub> and fat-soluble vitamins. The absorption of various drugs, including thyroxine, digoxin and warfarin, can be reduced. Approximately 45% of patients will develop gallstones due to disruption of the enterohepatic circulation of bile acids, and 25% develop calcium oxalate renal stones due to increased colonic absorption of oxalate (see Fig. 23.44).

### 22.23 Management of short bowel patients (and 'high-output' stoma)

#### Accurate charting of fluid intake and losses

- Vital: oral intake determines stool volume and should be *restricted* rather than encouraged

#### Dehydration and hyponatraemia

- Must first be corrected intravenously to restore circulating volume and reduce thirst
- Stool volume should be minimised and any ongoing fluid imbalance between oral intake and stool losses replenished intravenously

#### Measures to reduce stool volume losses

- *Restrict* oral fluid intake to  $\leq 500$  mL/24 hrs
- Give a further 1000 mL oral fluid as oral rehydration solution containing 90–120 mmol Na/L
- Slow intestinal transit (to maximise opportunities for absorption):
  - Loperamide, codeine phosphate
- Reduce volume of intestinal secretions:
  - Gastric acid: omeprazole 20 mg/day orally
  - Other secretions: octreotide 50–100  $\mu$ g 3 times daily by subcutaneous injection

#### Measures to increase absorption

- Teduglutide (a recombinant glucagon-like peptide 2) significantly reduces requirements for intravenous fluid and nutritional support by promoting growth and integrity of small bowel mucosa

### Jejunostomy patients

Patients left with a stoma (usually a jejunostomy) behave very differently, although stool volumes are again determined by oral intake. The jejunum is intrinsically highly permeable, and in the absence of the ileum and its net absorptive role, high losses of fluid, sodium and magnesium dominate the clinical picture from the outset. Dehydration, hyponatraemia, hypomagnesaemia and acute renal failure are the most immediate problems but protein-energy malnutrition will also develop. The jejunum has no real potential for adaptation in terms of absorption, so it is essential to recognise and address dehydration and electrolyte disturbance early as it is likely to be permanent (Box 22.23).

### Small bowel and multivisceral transplantation

Long-term intravenous nutritional support is the mainstay of therapy for chronic IF but has its own morbidity and mortality. The 10-year survival for patients on long-term home parenteral nutrition is approximately 90%. Most deaths are due to the underlying disease process but 5%–11% will die from direct complications of parenteral nutrition itself (especially catheter-related sepsis). A minority of patients with chronic IF, for whom the safe administration of parenteral nutrition has become difficult or impossible, may benefit from small bowel transplantation (Box 22.24). The first successful small bowel transplant was carried out in 1988. The introduction of tacrolimus allowed a satisfactory balance of immunosuppression, avoiding rejection while minimising sepsis. Since then, over 2000 transplants have been performed worldwide. Survival rates continue to improve, for both isolated small bowel and multivisceral transplantation (small bowel along with a combination of liver and/or kidney and/or pancreas), although major complications are still frequent (Box 22.25). Current 5-year survival rates are 50%–80%, with better outcomes for younger patients and those receiving isolated small bowel procedures.

### Further developments in treatment of intestinal failure

Long-acting recombinant human GLP-2 analogues, such as teduglutide and apraglutide, enhance intestinal absorption by:

- increasing intestinal blood flow to the intestine
- increasing portal blood flow away from the intestine
- slowing intestinal transit times
- reducing gastric acid secretion.

### 22.24 Potential indications for small bowel transplantation

#### Complications of central venous catheters

- Central venous thrombosis leading to loss of two or more intravenous access points
- Severe or recurrent line sepsis
- Recurrent severe acute kidney injury related to dehydration

#### Metabolic complications of parenteral nutrition

- Parenteral nutrition-related liver fibrosis, cirrhosis and liver failure

### 22.25 Complications of small bowel/multivisceral transplantation

- Sepsis:
  - Enteric bacterial species
  - Staphylococci
  - Fungal species
- Cytomegalovirus infection
- Post-transplantation lymphoproliferative disease (PTLD)
- Graft-versus-host disease
- Acute and chronic rejection
- Chronic renal impairment

In patients with short bowel syndrome and IF, the increased intestinal absorptive function induced by teduglutide can significantly reduce the volumes of parenteral fluids and nutrition required, and may allow some patients to regain independence from parenteral support. Side-effects include abdominal cramps and distension (seen in 50%), peristomal swelling, pain, nausea, vomiting and local injection site reactions. Since teduglutide stimulates proliferation of the intestinal epithelium, it should be avoided in those with history of gastrointestinal malignancy. In patients with a colon, a pre-treatment screening colonoscopy should be undertaken to detect and remove any polyps. Use of teduglutide is currently limited by high costs.

### Artificial nutrition at the end of life

In some situations, assisted nutrition may not reverse weight loss or improve quality and duration of life. Such scenarios may present when approaching the end of life, or with weight loss due to progressive incurable disease, such as advanced respiratory or cardiac failure, malignancy or dementia. A decision not to intervene may then be appropriate. An intervention that merely prolongs life without preserving or adding to its quality is seldom justified as in the patient's best interest, particularly if the intervention is not without risk itself. A thoughtful and sensitive discussion explaining what artificial nutrition can and cannot achieve is vital, involving the multidisciplinary team looking after the patient, along with carers, next of kin and, in some cases, legal representatives (Box 22.26).

### Nutrition and dementia

Weight loss is seen commonly in older people (Box 22.27) or in those with dementia, and nutritional and eating problems are a significant source of concern for those caring for them. It is appropriate to:

- screen for malnutrition
- assess specific eating difficulties (e.g. Edinburgh Feeding Evaluation in Dementia questionnaire)
- monitor and document body weight
- encourage adequate intake of food
- therapeutic trial of oral nutritional supplements.

Undernutrition can be distressing and there may be specific circumstances where a trial of enteral feeding can be justified (see Box 22.26).

**22.26 Ethical and legal considerations in the management of artificial nutritional support**

- Care of the sick involves the duty of providing adequate fluid and nutrients
- Food and fluid should not be withheld from a patient who expresses a desire to eat and drink, unless there is a medical contraindication (e.g. risk of aspiration)
- A treatment plan should include consideration of nutritional issues and should be agreed by all members of the health-care team
- In the situation of palliative care, tube feeding should be instituted only if it is needed to relieve symptoms
- Tube feeding is usually regarded in law as a medical treatment. Like other treatments, the need for such support should be reviewed on a regular basis and changes made in the light of clinical circumstances
- A competent adult patient must give consent for any invasive procedures, including passage of a nasogastric tube or insertion of a central venous cannula
- If a patient is unable to give consent, the health-care team should act in that person's best interests, taking into account any wishes previously expressed by the patient and the views of family
- Under certain specified circumstances (e.g. anorexia nervosa), it is appropriate to provide artificial nutritional support to the unwilling patient

Adapted from British Association for Parenteral and Enteral Nutrition guidelines, [www.bapen.org.uk](http://www.bapen.org.uk).

**22.27 Energy balance in old age**

- **Body composition:** muscle mass falls with inactivity, and percentage of body fat increases.
- **Energy expenditure:** with lower lean body mass, basal metabolic rate is decreased and energy requirements are reduced.
- **Weight loss:** after weight gain throughout adult life, weight often falls beyond the age of 75–80 years. This may reflect decreased appetite, loss of smell and taste, and decreased interest in and financial resources for food preparation, especially after loss of a partner.
- **BMI:** less reliable in old age as height is lost (due to kyphosis, osteoporotic crush fractures, loss of intervertebral disc spaces). Alternative measurements include arm demispan and knee height, which can be extrapolated to estimate height.

Success is more likely in those with mild to moderate dementia, after a reversible crisis precipitated by some acute event. In dementia, tube feeding rarely improves quality of life (Fig. 22.12), but PEG is better tolerated than the nasal route.

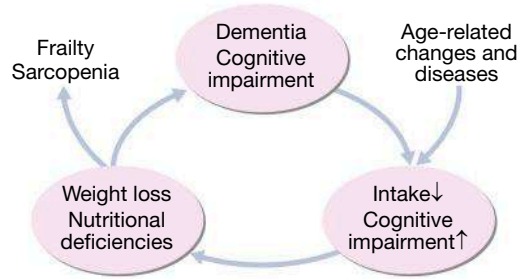

**Micronutrients, minerals and their diseases**

**Vitamins**

Vitamins are organic compounds with vital roles as cofactors in certain metabolic pathways. They are categorised into the fat-soluble (vitamins A, D, E and K) and water-soluble (vitamins of the B complex group and vitamin C).

Recommended daily intakes of micronutrients (Box 22.28) vary between countries. In the UK, the 'reference nutrient intake' (RNI) has been calculated as the mean plus two standard deviations (SD) of daily intake in the population, which therefore describes intake that satisfies 97.5% of the population. The lower reference nutrient intake (LRNI) is the mean minus 2 SD, below which may be insufficient for 2.5% of the population. These dietary reference values (DRV) have superseded the terms RDI (recommended daily intake) and RDA (recommended daily amount) still used in other countries. Additional amounts of some micronutrients may be required in pregnancy and lactation (Box 22.29).

Vitamin deficiency diseases are most prevalent in lower-income countries, but still occur in high-income countries. Older people (Box 22.30) and alcohol misusers are at risk of deficiencies in B vitamins and in vitamins D

**Fig. 22.12 Malnutrition in dementia – a vicious circle.** From Volkert D, Chourdakis M, Faxen-Irving G, et al. *ESPEN guidelines on nutrition in dementia.* Clin Nutr 2015; 34:1052–1073.

and C. Nutritional deficiencies in pregnancy can affect either the mother or the developing fetus, and extra increments of vitamins are recommended in the UK (see Box 22.29). Darker-skinned individuals living at higher latitude, and those who cover up or do not go outside are at increased risk of vitamin D deficiency due to inadequate sunlight exposure. Fat-soluble deficiencies, notably and catastrophically vitamin E, can result from rare abetalipoproteinaemia. Deficiencies of vitamins occur with intestinal malabsorption, both primary gastrointestinal problems and secondary to hepatic or pancreatic diseases or to autoimmune conditions (e.g. coeliac, pernicious anaemia) (Box 22.31). Routine dietary supplements are recommended for these 'at-risk' groups. Doctors must also be alert to micronutrient deficiencies induced by some drugs, and from extreme diets. Severe carbohydrate restriction limits thiamine consumption and beri beri can develop. Some extreme, non-evidence-based, diets can jeopardise vitamin A status.

There is a great deal of unscrupulous marketing and claims about vitamins. Some vitamins may have pharmacological actions when given at supraphysiological doses, such as vitamin A for acne. Taking vitamin supplements is highly promoted for commercial reasons, and fashionable in many population sectors, although there is no evidence of benefit. Serious toxic effects are met with high dosages of vitamins A, B<sub>6</sub> and D. Cocktails of micronutrients referred to as 'antioxidant' (vitamin C, beta-carotene and often selenium or zinc) are still marketed as remedies to prevent heart disease, although large clinical trials have shown more, not less, heart disease in supplemented groups.

Investigation of suspected vitamin deficiency or excess may involve biochemical assessment of body stores (Box 22.32). Measurements in blood should be interpreted carefully, however, in conjunction with the clinical presentation.

**Fat-soluble vitamins**

**Vitamin A (retinol)**

Pre-formed retinol is found only in foods of animal origin. Vitamin A can also be derived from carotenes, which are present in green and coloured vegetables and some fruits. Carotenes provide most of the total vitamin A in the UK and constitute the only supply in vegans. Retinol is converted to several other important molecules:

- *11-cis-retinaldehyde* is part of the photoreceptor complex in rods of the retina.
- *Retinoic acid* induces differentiation of epithelial cells by binding to specific nuclear receptors, which induce responsive genes. In vitamin A deficiency, mucus-secreting cells are replaced by keratin-producing cells.
- *Retinoids* are necessary for normal growth, fetal development, fertility, haematopoiesis and immune function.

The most important consequence of vitamin A deficiency is irreversible blindness in young children, and it also contributes to worse outcomes from many infections, such as measles. Asia is most notably affected and the problem is being addressed through widespread vitamin A

## 22.28 Summary of clinically important vitamins and WHO recommended daily intakes<sup>1</sup>

Vitamin	Sources <sup>2</sup>		Reference nutrient intake (RNI) <sup>3</sup>
	Rich	Important	
<b>Fat-soluble</b>			
A (retinol)	Liver	Milk and milk products, eggs, fish oils	700 µg men 600 µg women
D (cholecalciferol)	Fish oils	Ultraviolet exposure to skin Egg yolks, margarine, fortified cereals	10 µg if >65 years or no sunlight exposure
E (tocopherol)	Sunflower oil	Vegetables, nuts, seed oils	No RNI. Safe intake: 4 mg men 3 mg women
K (phylloquinone, menaquinone)	Soya oil, menaquinones produced by intestinal bacteria	Green vegetables	No RNI. Safe intake: 1 µg/kg
<b>Water-soluble</b>			
B <sub>1</sub> (thiamin)	Pork	Cereals, grains, beans	0.8 mg per 9.68 MJ (2000 kcal) energy intake
B <sub>2</sub> (riboflavin)	Milk	Milk and milk products, breakfast cereals, bread	1.3 mg men 1.1 mg women
B <sub>3</sub> (niacin, nicotinic acid, nicotinamide)	Meat, cereals		17 mg men 13 mg women
B <sub>6</sub> (pyridoxine)	Meat, fish, potatoes, bananas	Vegetables, intestinal microflora synthesis	1.4 mg men 1.2 mg women
Folate	Liver	Green leafy vegetables, fortified breakfast cereals	200 µg
B <sub>12</sub> (cobalamin)	Animal products	Bacterial colonisation	1.5 µg
Biotin	Egg yolk	Intestinal flora	No RNI. Safe intake: 10–200 µg
C (ascorbic acid)	Citrus fruit	Fresh fruit, fresh and frozen vegetables	40 mg

<sup>1</sup>See WHO document: <https://apps.who.int/iris/bitstream/handle/10665/42716/9241546123.pdf?ua=1>. <sup>2</sup>Rich sources contain the nutrient in high concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are eaten. <sup>3</sup>Requirements vary by age, and recommendations differ between countries. These figures are mostly generous: deficiency is unlikely unless intakes are well below them.

## 22.29 Nutrition in pregnancy and lactation

- **Weight gain** to reach BMI = 30 kg/m<sup>2</sup> in the third trimester is desirable. Heavier women need not gain so much.
- **Obesity**: promotes gestational diabetes and fetal abnormalities, but weight loss is undesirable during pregnancy. Overweight women should reach a healthier weight before pregnancy.
- **Energy requirements**: increased in both mother and fetus but can be met through reduced maternal energy expenditure.
- **Micronutrient requirements**: adaptive mechanisms ensure increased uptake of minerals in pregnancy, but extra increments of some are required during lactation (see Box 22.32). Additional increments of some vitamins are recommended during pregnancy and lactation:

**Vitamin A**: for growth and maintenance of the fetus, and to provide some reserve (important in some countries to prevent blindness associated with vitamin A deficiency). Teratogenic in excessive amounts.

**Vitamin D**: to ensure bone and dental development in the infant. Higher incidences of hypocalcaemia, hypoparathyroidism and defective dental enamel have been seen in infants of women not taking vitamin D supplements at >50° latitude.

**Folate**: taken pre-conceptually and during the first trimester, reduces the incidence of neural tube defects by 70%.

**Vitamin B<sub>12</sub>**: in lactation only.

**Thiamin**: to meet increased fetal energy demands.

**Riboflavin**: to meet extra demands.

**Niacin**: in lactation only.

**Vitamin C**: for the last trimester to maintain maternal stores as fetal demands increase.

**Iodine**: in countries with high consumption of staple foods (e.g. brassicas, maize, bamboo shoots) that contain goitrogens (thiocyanates or perchlorates) that interfere with iodine uptake, supplements prevent infants being born with cretinism.

## 22.30 Vitamin deficiency in old age

- **Requirements**: although requirements for energy fall with age, those for micronutrients do not. If dietary energy intake falls, a vitamin-rich diet is required to compensate.
- **Vitamin D**: levels are commonly low due to low total dietary intake, low sun exposure and less efficient skin conversion. This leads to bone loss and fractures. Supplements have modest effectiveness for preventing fractures, so should be given to those at risk of falls in institutional care, but other measures to prevent falls are vital.
- **Vitamin B<sub>12</sub> deficiency**: a causal relationship with dementia has not been identified, but it does produce neuropsychiatric effects and should be checked in all those with declining cognitive function.

## 22.31 Common gastrointestinal disorders that may be associated with malabsorption of fat-soluble vitamins

- Biliary obstruction
- Pancreatic exocrine insufficiency
- Coeliac disease
- Ileal inflammation or resection

supplementation programmes. Adults are not usually at risk because liver stores can supply vitamin A when foods containing vitamin A are unavailable.

Early deficiency causes impaired adaptation to the dark (night blindness), but this is rarely recognised. Keratinisation of the cornea (xerophthalmia) gives rise to characteristic Bitot's spots and progresses to keratomalacia, with corneal ulceration, scarring and irreversible blindness

22.32 Biochemical assessment of vitamin status	
Nutrient	Biochemical assessments of deficiency or excess
<b>Vitamin A</b>	Serum retinol may be low in deficiency Serum retinyl esters: when vitamin A toxicity is suspected
<b>Vitamin D</b>	Plasma/serum 25-hydroxyvitamin D (25(OH)D): reflects body stores (liver and adipose tissue) Plasma/serum 1,25(OH) <sub>2</sub> D: difficult to interpret
<b>Vitamin E</b>	Serum tocopherol:cholesterol ratio
<b>Vitamin K</b>	Coagulation assays (e.g. prothrombin time) Plasma vitamin K
<b>Vitamin B<sub>1</sub> (thiamin)</b>	Whole-blood vitamin B <sub>1</sub> or red blood cell transketolase activity (Treat suspected deficiency without waiting for results)
<b>Vitamin B<sub>2</sub> (riboflavin)</b>	Red blood cell glutathione reductase activity or whole-blood vitamin B <sub>2</sub>
<b>Vitamin B<sub>3</sub> (niacin)</b>	Urinary metabolites: 1-methyl-2-pyridone-5-carboxamide, 1-methylnicotinamide
<b>Vitamin B<sub>6</sub></b>	Plasma pyridoxal phosphate or erythrocyte transaminase activation coefficient
<b>Vitamin B<sub>12</sub></b>	Plasma B <sub>12</sub> : poor measure of overall vitamin B <sub>12</sub> status but will detect severe deficiency Alternatives (methylmalonic acid and holotranscobalamin) are not used routinely
<b>Folate</b>	Red blood cell folate Plasma folate: reflects recent intake but also detects unmetabolised folic acid from foods and supplements
<b>Vitamin C</b>	Leucocyte ascorbic acid: assesses vitamin C tissue stores Plasma ascorbic acid: reflects recent (daily) intake

(Fig. 22.13). In countries where vitamin A deficiency is endemic, pregnant women should be advised to eat dark green, leafy vegetables and yellow fruits (to build up stores of retinol in the fetal liver), and infants should be fed the same. The WHO is according high priority to prevention in communities where xerophthalmia occurs, giving single prophylactic oral doses of 60 mg retinyl palmitate (providing 200 000 U retinol) to pre-school children. This also reduces mortality from gastroenteritis and respiratory infections.

Repeated moderate or high doses of retinol can cause liver damage, hyperostosis and teratogenicity. Women in countries where deficiency is not endemic are therefore advised not to take vitamin A supplements in pregnancy. Acute overdose leads to nausea and headache, increased intracranial pressure and skin desquamation. Excessive intake of carotene causes harmless orange pigmentation of the skin (hypercarotenosis).

### Vitamin D

Vitamin D is required for musculoskeletal health, specifically preventing rickets and osteomalacia. Adequate levels of vitamin D may also be important in some other conditions and may improve immune function. The natural form of vitamin D, cholecalciferol, is formed in the skin by the action of ultraviolet (UV) light on 7-dehydrocholesterol, a metabolite of cholesterol. Vitamin D is converted in the liver to 25-hydroxyvitamin D (25(OH)D), which is further hydroxylated in the kidneys to 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D), the most active form of the vitamin (see Fig. 26.62). This 1,25(OH)<sub>2</sub>D activates specific intracellular receptors that influence calcium metabolism, bone mineralisation and tissue differentiation. The synthetic form, ergocalciferol or vitamin D<sub>2</sub>, is considered to be less potent than endogenous D<sub>3</sub>.

In much of the world, skin exposure to sunlight is the main source. Moving away from the equator, the intensity of UV light decreases, so

**Fig. 22.13** Eye signs of vitamin A deficiency. **A** Bitot spots in xerophthalmia, showing the white triangular plaques (arrows). **B** Keratomalacia in a 14-month-old child. There is liquefactive necrosis affecting the greater part of the cornea, with typical sparing of the superior aspect. (A) Courtesy of Institute of Ophthalmology, Moorfields Eye Hospital, London. (B) From WHO. Report of a joint WHO/USAID meeting, vitamin A deficiency and xerophthalmia (WHO technical report series no. 5W); 1976.

that at a latitude above 50° (including northern Europe) vitamin D is not synthesised in winter, and even above 30° there is seasonal variation. The large body store, in the liver, normally accumulated during the summer, is consumed during the winter. The limited sunlight exposure in the UK has led to recommendations that everyone over the age of 1 should be given 10 µg vitamin D supplement daily, with a lower dose of 8.5–10 µg in breastfed babies under 1 year of age. Formula milk is fortified with vitamin D so further supplements are only necessary when <500 mL of formula milk is consumed daily. Supplementation at these doses is appropriate for babies and people in old age who are confined indoors, and those who habitually cover up their skin when outdoors. The richest food sources are oily fish such as salmon, sardines, herring and mackerel, red meat, liver and eggs. Breakfast cereals, margarines and milk products are widely fortified with vitamin D in some parts of Europe and in North America.

The effects of vitamin D deficiency (calcium deficiency, rickets and osteomalacia) are described on page 1053. An analogue of vitamin D (calcipotriol) is used for treatment of skin conditions such as psoriasis.

Excessive doses of cholecalciferol, ergocalciferol or the hydroxylated metabolites cause hypercalcaemia. Partly because redundant receptors for vitamin D are present in most tissues, commercial agencies have proposed a role for vitamin D in nearly every human disease, and market it in large doses. Randomised trials are required to refute each claim, and they have nearly all been refuted.

## Vitamin E

There are eight related fat-soluble substances with vitamin E activity. The most important dietary form is  $\alpha$ -tocopherol. Vitamin E has many direct metabolic actions:

- It prevents oxidation of polyunsaturated fatty acids in cell membranes by free radicals.
- It helps maintain cell membrane structure.
- It affects DNA synthesis and cell signalling.
- It is involved in the anti-inflammatory and immune systems.

Human deficiency is rare and has been described only in premature infants and in malabsorption, notably with abetalipoproteinaemia. It can cause a mild haemolytic anaemia, ataxia and visual scotomas. Vitamin E intakes of up to 3200 mg/day (1000-fold greater than recommended intakes) are considered safe. Diets rich in vitamin E (e.g. vegetable oils, nuts and seeds) are consumed in countries with lower rates of coronary heart disease, but randomised controlled trials have not demonstrated cardioprotective effects of vitamin E or other antioxidants.

## Vitamin K

Vitamin K is supplied in the diet mainly as vitamin K<sub>1</sub> (phylloquinone) in the UK, or as vitamin K<sub>2</sub> (menaquinone) from fermented products in parts of Asia. Vitamin K<sub>2</sub> is also synthesised by bacteria in the colon. Vitamin K is a co-factor for carboxylation reactions: in particular, the production of  $\gamma$ -carboxyglutamate (gla). Gla residues are found in four of the coagulation factor proteins (II, VII, IX and X; p. 927), conferring their capacity to bind to phospholipid surfaces in the presence of calcium. Other important gla proteins are osteocalcin and matrix gla protein, which are important in bone mineralisation.

Vitamin K deficiency leads to delayed coagulation and bleeding. In obstructive jaundice, dietary vitamin K is not absorbed and it is essential to administer the vitamin in parenteral form before surgery. Warfarin and related anticoagulants act by antagonising vitamin K. Vitamin K is given routinely to newborn babies to prevent haemorrhagic disease. Symptoms of excess have been reported only in infants, with synthetic preparations linked to haemolysis and liver damage.

## Water-soluble vitamins

### Thiamin (vitamin B<sub>1</sub>)

Thiamin is mainly supplied by nuts and seeds, including legumes and whole-grain cereals. Thiamin pyrophosphate (TPP) is a co-factor for enzyme reactions involved in the metabolism of macronutrients (carbohydrate, fat and alcohol), including:

- decarboxylation of pyruvate to acetyl-co-enzyme A, which bridges between glycolysis and the tricarboxylic acid (Krebs) cycle
- transketolase activity in the hexose monophosphate shunt pathway
- decarboxylation of  $\alpha$ -ketoglutarate to succinate in the Krebs cycle.

In thiamin deficiency, cells cannot metabolise glucose aerobically to generate energy as ATP. Neuronal cells are most vulnerable because they depend almost exclusively on glucose for energy requirements. Impaired glucose oxidation also causes an accumulation of pyruvic and lactic acids, which produce vasodilatation and increased cardiac output.

### Deficiency – beri-beri

Thiamin deficiency constitutes a clinical emergency, causing sudden catastrophic and often permanent damage if treatment is delayed. It occurs when sufficient whole-grain cereals or other seeds and nuts are not consumed, classically in the developing world, from diets based on polished rice. It also occurs among people who follow extreme low-carbohydrate diets, for example for weight loss. It is especially encountered in chronic alcohol misusers, among whom poor diet, impaired absorption, storage and phosphorylation of thiamin in the liver, and the increased requirements for thiamin to metabolise ethanol, all contribute to deficiency.

The body has very limited stores of thiamin, so deficiency can develop after only 1 month on a thiamin-free diet. There are two forms of the disease in adults, which may coexist:

- *Dry (or neurological) beri-beri* may manifest with chronic peripheral neuropathy and with wrist and/or foot drop. However its most dramatic presentation is with Wernicke encephalopathy, the triad of ophthalmoplegia, ataxia and confusion, which may progress to permanent Korsakoff psychosis.
- *Wet (or cardiac) beri-beri* causes generalised oedema due to biventricular heart failure with pulmonary congestion and ECG changes.

Wet beri-beri usually recovers full and swiftly with thiamin replacement. However, with dry beri-beri, response to thiamin administration is not uniformly good. Multivitamin and mineral therapy seems to produce some improvement, however, suggesting that other dietary deficiencies may be involved, with zinc particularly incriminated.

Possible thiamin deficiency, and any clinical suggestions of Wernicke encephalopathy or wet beri-beri, should be treated on suspicion, immediately, without waiting for biochemical confirmation of the diagnosis, with intravenous vitamin B and C mixture. Korsakoff psychosis, brain damage with failure to create memory, can develop rapidly, and is irreversible and does not respond to thiamin treatment.

### Riboflavin (vitamin B<sub>2</sub>)

Riboflavin is required for the flavin co-factors involved in oxidation–reduction reactions. It is widely distributed in animal and vegetable foods. Levels are low in staple cereals but germination, e.g. as bean sprouts, increases its content. It is destroyed under alkaline conditions by heat and by exposure to sunlight. Deficiency is rare in developed countries. It mainly affects the tongue and lips and manifests as glossitis, angular stomatitis and cheilosis. The genitals may be involved, as well as the skin areas rich in sebaceous glands, causing nasolabial or facial dyssebacea. Rapid recovery usually follows administration of riboflavin 10 mg daily by mouth.

### Niacin (vitamin B<sub>3</sub>)

Niacin encompasses nicotinic acid and nicotinamide. Nicotinamide is an essential part of the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which play a key role as hydrogen acceptors and donors for many enzymes. Niacin can be synthesised in the body in limited amounts from the amino acid tryptophan.

### Deficiency – pellagra

Pellagra was formerly endemic among poor people who subsisted chiefly on maize, which contains niacytin, a form of niacin that the body is unable to utilise. Pellagra can develop in only 8 weeks in individuals eating diets that are very deficient in niacin and tryptophan. It remains a problem in parts of Africa, and is occasionally seen in alcohol misusers and in patients with chronic small intestinal disease in developed countries. Pellagra can occur in Hartnup disease, a genetic disorder characterised by impaired absorption of several amino acids, including tryptophan. It is also seen occasionally in carcinoid syndrome, when tryptophan is consumed in the excessive production of 5-hydroxytryptamine (5-HT, serotonin). Pellagra is the ‘Disease of the three Ds’:

- *Dermatitis*. Characteristic erythema resembling severe sunburn, appearing symmetrically over the parts of the body exposed to sunlight, particularly the limbs (Fig. 22.14) and especially on the neck but not the face (Casal’s necklace). The skin lesions may progress to vesiculation, cracking, exudation and secondary infection.
- *Diarrhoea*. Often associated with anorexia, nausea, glossitis and dysphagia, reflecting the presence of a non-infective inflammation that extends throughout the gastrointestinal tract.
- *Dementia*. In severe deficiency, delirium occurs acutely and dementia develops if untreated.

**Fig. 22.14** Dermatitis in niacin deficiency (pellagra). There are red, scaly, cracked areas with sharply demarcated borders and surrounding pigmented skin. From Piqué-Duran E, Pérez-Cejudo JA, Cameselle D, et al. Pellagra: A clinical, histopathological, and epidemiological study of 7 cases. *Actas Dermosifiliogr* 2012; 103(1):51–58.

Treatment is with nicotinamide, 100 mg 3 times daily orally or parenterally. The response is usually rapid. Within 24 hours the erythema diminishes, the diarrhoea ceases and a striking improvement occurs in the patient's mental state.

#### Toxicity

Excessive intakes of niacin may lead to reversible hepatotoxicity. Nicotinic acid is a lipid-lowering agent but doses above 200 mg a day cause vasodilatory symptoms ('flushing' and/or hypotension).

#### **Pyridoxine (vitamin B<sub>6</sub>)**

Pyridoxine, pyridoxal and pyridoxamine are different forms of vitamin B<sub>6</sub> that undergo phosphorylation to produce pyridoxal 5-phosphate (PLP). PLP is the co-factor for a large number of enzymes involved in the metabolism of amino acids. Vitamin B<sub>6</sub> is available in most foods.

Deficiency is rare, although certain drugs, such as isoniazid and penicillamine, act as chemical antagonists to pyridoxine. Pyridoxine administration is effective in isoniazid-induced peripheral neuropathy and some cases of sideroblastic anaemia. Large doses of vitamin B<sub>6</sub> have an antiemetic effect in radiotherapy-induced nausea. Although vitamin B<sub>6</sub> supplements have become popular in the treatment of nausea in pregnancy, carpal tunnel syndrome and pre-menstrual syndrome, there is no convincing evidence of benefit. Very high doses of vitamin B<sub>6</sub> taken for several months can cause unpleasant sensory polyneuropathy, which may become permanent.

#### **Biotin**

Biotin is a co-enzyme in the synthesis of fatty acids, isoleucine and valine, and is also involved in gluconeogenesis. Deficiency results from consuming very large quantities of raw egg whites (>30% energy intake) because the avidin they contain binds to and inactivates biotin in the intestine. It may also be seen after long periods of total parenteral nutrition. The clinical features of deficiency include scaly dermatitis, alopecia and paraesthesia.

#### **Folate (folic acid)**

Folates exist in many forms. The main circulating form is 5-methyltetrahydrofolate. The natural forms, in plant foods, are prone to oxidation. Folic acid is the stable synthetic form. Folate works as a methyl donor for cellular methylation and protein synthesis, particularly for haematopoiesis. It is also directly involved in DNA and RNA synthesis, and requirements increase during embryonic development. Deficiency states include dietary insufficiency and also altered folate metabolism, which may be genetic.

The commonest clinical presentation of folate deficiency is as macrocytic anaemia, which may extend to pancytopenia, in people with poor consumption of fruit and green vegetables. It is particularly frequent among alcohol misusers. Folate deficiency in early pregnancy may cause

three major birth defects (spina bifida, anencephaly and encephalocele) resulting from imperfect closure of the neural tube, which takes place 3–4 weeks after conception. Women who have experienced a pregnancy affected by a neural tube defect should take 5 mg of folic acid daily from before conception and throughout the first trimester; this reduces the incidence of these defects by 70%. All women planning a pregnancy are advised to include good sources of folate in their diet, and to take folate supplements throughout the first trimester. Liver is the richest source of folate but an alternative source (e.g. leafy vegetables) is advised in early pregnancy because of the high vitamin A content of liver. Folate deficiency has also been associated with heart disease, dementia and cancer. There is mandatory fortification of flour with folic acid in the United States and voluntary fortification of many foods across Europe. Neural tube defects have declined dramatically, but there are some concerns about increased incidence of colon cancer, through accelerating the growth of polyps.

#### **Hydroxycobalamin (vitamin B<sub>12</sub>)**

Vitamin B<sub>12</sub> is a co-factor in folate co-enzyme recycling and nerve myelination. Vitamin B<sub>12</sub> and folate are particularly important in DNA synthesis in red blood cells. The haematological disorders (macrocytic or megaloblastic anaemias) caused by their deficiency are discussed in Chapter 25. Vitamin B<sub>12</sub>, but not folate, is needed for the integrity of myelin, so that vitamin B<sub>12</sub> deficiency is also associated with neurological disease (see Box 25.33).

In older people and chronic alcohol misusers, or after bowel surgery, vitamin B<sub>12</sub> deficiency arises from insufficient intake and/or from malabsorption, but purely dietary deficiency is rare, as it is synthesised by colonic bacteria. The classic cause is malabsorption through pernicious anaemia. Several drugs, including neomycin, can render vitamin B<sub>12</sub> inactive. Adequate intake of folate maintains erythropoiesis and there is a concern that fortification of foods with folate may delay recognition of underlying vitamin B<sub>12</sub> deficiency.

In severe deficiency there is insidious, diffuse and uneven demyelination. It may be clinically manifest as peripheral neuropathy or spinal cord degeneration affecting both posterior and lateral columns ('subacute combined degeneration of the spinal cord'), or there may be cerebral manifestations (resembling dementia) or optic atrophy. Vitamin B<sub>12</sub> therapy improves symptoms in most cases.

#### **Vitamin C (ascorbic acid)**

Ascorbic acid is a natural antioxidant in fruit and vegetables. It serves as an essential cofactor in the hydroxylation of proline and lysine in procollagen, to hydroxyproline and hydroxylysine in mature collagen. It is also an active reducing agent in the aqueous phase of living tissues, and is involved in intracellular electron transfer. It is very easily destroyed by heat, increased pH and light, and is very soluble in water; hence many traditional cooking methods reduce it. Claims that high-dose vitamin C improves immune function (including resistance to the common cold), prevents cancers or heart disease and cholesterol turnover are unsubstantiated.

#### **Deficiency – scurvy**

Vitamin C deficiency causes defective formation of collagen with impaired healing of wounds, capillary haemorrhage and reduced platelet adhesiveness (normal platelets are rich in ascorbate) (Fig. 22.15). Precipitants and clinical features of scurvy are shown in Box 22.33. A dose of 250 mg vitamin C 3 times daily by mouth should saturate the tissues quickly. The deficiencies in the patient's food choices also need to be corrected, and other vitamin supplements given if necessary, for example for alcohol misusers. Daily intakes above 1 g/day can cause diarrhoea and the formation of renal oxalate stones.

#### **Other bioactive dietary compounds**

There are a number of non-essential organic compounds found in vegetable foods with purported health benefits, such as reducing risk of heart disease or cancers. Groups of compounds such as the flavonoids and phytoestrogens do show bioactivity through their respective antioxidant and oestrogenic or anti-oestrogenic activities. Flavonoids (of which there are many different classes) are potent antioxidants found

### 22.33 Scurvy – vitamin C deficiency

#### Precipitants

##### Increased requirement

- Trauma, surgery, burns, infections
- Smoking
- Drugs (glucocorticoids, aspirin, indometacin, tetracycline)

##### Dietary deficiency

- Lack of dietary fruit and vegetables for > 2 months
- Infants fed exclusively on boiled milk

#### Clinical features

- Swollen gums that bleed easily
- Perifollicular and petechial haemorrhages
- Ecchymoses
- Haemarthrosis
- Gastrointestinal bleeding
- Anaemia
- Poor wound healing

**Fig. 22.15 Scurvy.** **A** Gingival swelling and bleeding. **B** Perifollicular hyperkeratosis. (A,B) From Ho V, Prinsloo P, Ombiga J. Persistent anaemia due to scurvy. *J NZ Med Assoc* 2007; 120:62. Reproduced with permission.

in fruit and vegetables, tea and wine; phytoestrogens are found in soy products (with higher intakes in parts of Asia compared to Europe and the United States) and other pulses. Caffeine and related compounds in tea and coffee, can with habituation improve mental performance in the short term, with adverse effects including agitation and tachycardia at higher intakes. Acute withdrawal of usual caffeine intake (e.g. in a hospital admission) can provoke headaches, indicating its addictive quality. It is added to carbonated beverages and 'tonic wines', ostensibly as a flavouring, but increases their consumption.

## Inorganic micronutrients

A number of inorganic elements are necessary for structure and growth, as electrolytes, or as cofactors in enzymes and are thus essential dietary constituents for humans (Box 22.34). Deficiency is seen when there is inadequate dietary intake or excessive loss from the body. Toxic effects have also been observed from self-medication and disordered absorption or excretion. Examples of clinical toxicity include excess of iron (haemochromatosis or haemosiderosis), fluoride (fluorosis), copper (Wilson's disease) and selenium (selenosis, seen in parts of China). For most minerals,

the available biochemical plasma markers do not accurately reflect whole-body status or dietary intake, and dietary assessment is required.

## Calcium and phosphorus

Calcium is the most abundant cation in the body and powerful homeostatic mechanisms control circulating ionised calcium levels. WHO dietary guidelines for calcium differ between countries, with higher intakes usually recommended in places with higher fracture prevalence. Between 20% and 30% of calcium in the diet is absorbed, depending on vitamin D status and food source. Calcium requirements depend on phosphorus intakes, with an optimum molar ratio (Ca:P) of 1:1. Excessive phosphorus intakes (e.g. 1–1.5g/day) with a Ca:P of 1:3 have been shown to cause hypocalcaemia and secondary hyperparathyroidism.

Calcium absorption may be impaired in vitamin D deficiency and in malabsorption secondary to small intestinal disease. Calcium deficiency causes impaired bone mineralisation and can lead to osteomalacia in adults. The potential benefits of high calcium intake in osteoporosis are discussed on p. 1052. Too much calcium can lead to constipation, and toxicity has been observed in 'milk-alkali syndrome'.

Dietary insufficiency of phosphorus is rare as a cause of deficiency (except in older people with limited diets, and importantly in severe starvation) because it is present in nearly all foods and phosphates are added to a number of processed foods. Phosphate deficiency in adults occurs:

- in patients with renal tubular phosphate loss
- in patients with diabetic ketoacidosis
- in patients receiving a prolonged high dosage of aluminium hydroxide
- in alcohol misusers, sometimes when they are fed with high-carbohydrate foods
- in patients receiving parenteral nutrition if inadequate phosphate is provided.

Deficiency causes hypophosphataemia and muscle weakness secondary to ATP deficiency.

## Iron

Iron is involved in the synthesis of haemoglobin and is required for the transport of electrons within cells and for a number of enzyme reactions. Non-haem iron in cereals and vegetables is poorly absorbed but makes the greater contribution to overall intake, compared to the well-absorbed haem iron from animal products. Fruits and vegetables containing vitamin C enhance iron absorption, while the tannins in tea reduce it. Dietary calcium reduces iron uptake from the same meal, which may precipitate iron deficiency in those with borderline iron stores. There is no physiological mechanism for excretion of iron, so homeostasis depends on the regulation of iron absorption (see Fig. 25.20). This is regulated at the level of duodenal enterocytes by hepcidin (a peptide secreted by hepatocytes in the duodenum). The normal daily loss of iron is 1 mg, arising from desquamated surface cells and intestinal losses. A regular loss of only 2 mL of blood per day doubles the iron requirement. On average, an additional 20 mg of iron is lost during menstruation, so pre-menopausal women require about twice as much iron as men (and more if menstrual losses are heavy).

The major consequence of iron deficiency is anaemia. This is one of the most important nutritional causes of ill health in all parts of the world. In the UK, it is estimated that 10% women are iron-deficient. Dietary iron overload is occasionally observed and results in iron accumulation in the liver and, rarely, cirrhosis. Haemochromatosis results from an inherited increase in iron absorption.

Normally, only a small proportion of dietary iron is absorbed. Iron absorption mechanisms are up-regulated, to absorb a greater proportion if dietary provision is low. Iron shares and competes for a pathway for absorption with zinc. Indiscriminate iron supplementation can therefore impair zinc status. In overdosage, iron supplements are highly toxic and can be fatal for children.

## 22.34 Summary of clinically important minerals

Mineral	Sources <sup>1</sup>		Rich	Important
<b>Calcium</b>	Milk and milk products, tofu	Milk, boned fish, green vegetables, beans	700 mg <sup>2</sup>	
<b>Phosphorus</b>		Most foods contain phosphorus	550 mg <sup>2</sup>	
	Marmite and dry-roasted peanuts	Milk, cereal products, bread and meat		
<b>Magnesium</b>	Whole grains, nuts	Unprocessed and wholegrain foods	300 mg men 270 mg women <sup>2</sup>	
<b>Iron</b>	Liver, red meat (haem iron)	Non-haem iron from vegetables, wholemeal bread	8.7 mg 14.8 mg women <50 years	
<b>Zinc</b>	Red meat, seafood	Dairy produce, wholemeal bread	9.5 mg men 7 mg women <sup>2</sup>	
<b>Iodine</b>	Edible seaweeds	Milk and dairy products	140 µg	
	Sea fish	Sea food products		
<b>Selenium</b>	Fish, food crops grown in selenium-rich soils	Fish	75 µg men 60 µg women <sup>2</sup>	
<b>Copper</b>	Shellfish, liver	Bread, cereal products, vegetables	1.2 mg <sup>2</sup>	
<b>Fluoride</b>	Tea	Drinking water, tea	No RNI. Safe intake: 0.5 mg/kg	
<b>Potassium</b>	Dried fruit, potatoes, coffee	Fresh fruit, vegetables, meat and dairy foods	3500 mg	
<b>Sodium</b>	Table salt, anchovies	Processed foods, bread, bacon	1600 mg	

<sup>1</sup>Rich sources contain the nutrient in high concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are eaten. <sup>2</sup>Increased amounts are required in women during lactation.

### Iodine

Iodine is required, in very small amounts, for synthesis of thyroid hormones and thus for neurodevelopment. It is present in sea fish, seaweed and most plant foods grown near the sea. The amount of iodine in soil and water influences the iodine content of plant foods, and of animals grazing on them. Iodine is lacking, giving rise in older times to endemic goitre and cretinism, in the highest mountainous areas of the world (e.g. the Alps and the Himalayas) and in the soil of frequently flooded plains (e.g. Bangladesh). In the UK, most dietary iodine in human diets until recently came from disinfectant used to wash cows' udders before milking. Milk and sea fish are now the main sources, but many people have inadequate intakes.

About a billion people in the world are estimated to have an inadequate iodine intake and hence are at risk of iodine deficiency disorder. Goitre is the most common manifestation, affecting about 200 million people.

In areas where women have endemic goitre, 1% or more of babies are born with cretinism (characterised by impaired growth and neurological development and physical deformities). There is a higher than usual prevalence of deafness, slowed reflexes and poor learning in the remaining population. The best way of preventing neonatal cretinism is to ensure adequate levels of iodine during pregnancy. This can be achieved by intramuscular injections with 1–2 mL of iodised poppy seed oil (475–950 mg iodine) to women of child-bearing age every 3–5 years, by administration of iodised oil orally at 6-monthly or yearly intervals to adults and children.

In many countries foods are fortified with iodine to avoid iodine deficiency, especially reported among young people who avoid fish and/or dairy products. Iodised salt is most common, but with health advice to minimise sodium consumption, other common foods such as milk and breads can be fortified, provided their cumulative consumption does not become excessive.

### Zinc

Zinc is present in most foods of vegetable and animal origin, and is stored in the liver. It is an essential component of many enzymes, including carbonic anhydrase, alcohol dehydrogenase and alkaline phosphatase.

Acute zinc deficiency has been reported in patients receiving prolonged zinc-free parenteral nutrition and causes diarrhoea, mental apathy, a moist, eczematoid dermatitis, especially around the mouth, and loss of hair. Chronic zinc deficiency occurs in dietary deficiency, malabsorption syndromes, when there are chronic losses (e.g. of exudates from leg ulcers), in alcoholism and in cirrhosis. It causes the clinical features seen in the very rare congenital disorder known as acrodermatitis enteropathica (growth retardation, hair loss and chronic diarrhoea). Zinc deficiency is thought to be responsible for one-third of the world's population not reaching their optimal height. In the Middle East, chronic deficiency has been associated with dwarfism and hypogonadism. In starvation, zinc deficiency causes thymic atrophy; zinc supplements may accelerate the healing of skin lesions, promote general well-being, improve appetite and reduce the morbidity associated with the under-nourished state, and lower the mortality associated with diarrhoea and pneumonia in children.

### Selenium

The family of seleno-enzymes includes glutathione peroxidase, which helps prevent free radical damage to cells, and monodeiodinase, which converts thyroxine to triiodothyronine. North American soil has a higher selenium content than European and Asian soil, and the decreasing reliance of Europe on imported American food in recent decades has resulted in a decline in dietary selenium intake.

Selenium deficiency can cause hypothyroidism, cardiomyopathy in children (Keshan disease) and myopathy in adults. Excess selenium can cause heart disease, and has been linked to industrial pollution.

### Fluoride

Fluoride is an essential nutrient necessary for normal dental enamel, and also incorporated as a component of bone mineral. Fluoride is most important for young children, before the permanent teeth erupt, while their enamel is being laid down, but also for healthy enamel recycling and repair after damage. Fluoride deficiency results in weakened dental enamel, vulnerable to attack by acid produced from sugars by oral bacteria, and thus to dental caries and tooth loss. Fluoride in normal amounts may help strengthen bone and

protect against fractures. Excessive intakes cause a brown mottling of dental enamel, and may compromise bone structure, making them more brittle.

Fluoride is an unusual micronutrient in being supplied almost entirely from drinking water, including local water and that consumed from other areas as bottled or canned drinks. If the water supply contains more than 1 part per million (ppm) of fluoride, the incidence of dental caries is low. Very hard waters may contain over 10 ppm, presenting no problem other than some discoloration of teeth. However, soft waters contain little or no fluoride, so dental caries and loss is very frequent without supplementation. Almost no foods provide significant amounts of fluoride, an exception being tea, permitting strong teeth in areas where both tea and sugar cane are grown and consumed by children.

Adding of traces of fluoride to public water supplies, to maintain a normal healthful concentration of 1 ppm, is now a widespread practice but, where this is not policy, dental health must depend on education, supplementation to children, and provision of fluoride-containing toothpaste.

Chronic fluoride poisoning is occasionally seen where the water supply contains >10 ppm fluoride. It can also occur in workers handling cryolite (aluminium sodium fluoride), used in smelting aluminium. Pitting of teeth is a result of excess fluoride intake as a child.

### Sodium, potassium and magnesium

Most animal and plant foods are low in natural sodium, and rich in potassium and magnesium. Western diets are high in sodium due to the sodium chloride (salt) that is added to processed food. In the UK, it is recommended that daily salt intakes are kept well below 6 g, and potassium and magnesium intakes maintained at levels a little greater than currently, principally to prevent the common gradual rise in blood pressure which occurs if children are weaned onto a lifelong higher sodium diet. The pathophysiological roles of sodium, potassium and magnesium are discussed in [Chapter 14](#).

### Other essential inorganic nutrients

These include chloride (a counter-ion to sodium and potassium), cobalt (required for vitamin B<sub>12</sub>), sulphur (a constituent of methionine and cysteine), manganese (needed for or activates many enzymes) and chromium (necessary for insulin action). Deficiency of chromium presents as hyperglycaemia and has been reported in adults as a rare complication of prolonged parenteral nutrition.

Copper metabolism is abnormal in Wilson's disease. Deficiency occasionally occurs but only in young children, causing microcytic hypochromic anaemia, neutropenia, retarded growth, skeletal rarefaction and dermatosis.

## Multiple Choice Questions

22.1. Which of the following is true? In a clinical setting, overweight/obesity should be assessed using

- A. BMI
- B. Waist circumference
- C. Observation and clinical judgement
- D. Plasma leptin concentration
- E. A composite of BMI and full clinical evaluation

Answer: E.

The recommended approach to assess an individual is to measure BMI (and waist if BMI is  $<35\text{ kg/m}^2$ ), and to monitor progress using body weight and clinical staging based on evaluation of clinical status using a scheme such as Edmonton Obesity Staging System. BMI alone provides a useful benchmark, but BMI has relatively poor correlation with body fat content ( $R^2 = 0.6$ ) and it does not capture the variable link with symptoms or medical conditions mediated by the disease-process of obesity. Waist provides slightly better correlation with body fat content, and of secondary disease risk than BMI, but cannot be used reliably when BMI is above 35. Observation and clinical judgement are valuable, but do not provide a baseline to assess progress. Plasma leptin can now be measured, but only as a research tool. It correlates reasonably strongly with BMI or body fat content but is not accurate for individual assessment. Another technique – bio-impedance measurement – is simple and cheap, widely used in gyms, but it is not more accurate than using scales or a waist-tape measure to estimate body fat content.

22.2. Which of the following is true? Parenteral (intravenous) feeding (TPN)

- A. Is the gold-standard safe clinical practice after any bowel surgery
- B. Can be established routinely using standard feed bags
- C. Requires a central IV access line, which is also useful for blood sampling
- D. Should be set up at weekends to save staff time during weekdays
- E. Requires management by a dedicated nutrition support team

Answer: E.

Evidence shows that case selection and outcomes (particularly line infection rates) are greatly improved when a multidisciplinary Nutrition Support Team is in place. Parenteral feeding incurs many potentially serious complications and should not be used if there is likelihood of a functional gut within 3–5 days. TPN cannot be established routinely using standard feed bags as a full nutritional assessment is required in order to determine the requirements of each individual patient. TPN requires a central line, but this should never be used for other procedures, such as blood testing, because of high risks of introducing infection. Setting up parenteral feeding is time-consuming and requires planning and full multidisciplinary coordination, which is rarely possible outside normal work hours and starting at a weekend is not advisable.

22.3. Which of the following is true? Vitamin C (ascorbic acid)

- A. In large doses is effective for preventing colds
- B. Is destroyed by cooking
- C. Allows improved absorption of iron from foods
- D. Contributes to antioxidant vitamin (ACE) treatment for prevention of heart disease
- E. Is stored in the liver, to provide a buffer against periods of low intake

Answer: C.

When the iron content of foods is low, or when greater iron absorption is needed to counteract deficiency, consuming foods that contain iron and vitamin C together improves iron availability. There is weak evidence that suggests mega-doses of vitamin C might reduce duration of minor cold symptoms to a very small degree. Vitamin C content of foods is reduced but not entirely destroyed by cooking. Boiled potatoes are a major food source for many people. There is consistent evidence that antioxidant treatments with vitamins A, C and E do not reduce heart disease. Indeed this treatment actually increases mortality in large randomised trials. Vitamin C is a water-soluble vitamin, and as such has little or no storage in the body. Daily consumption is needed, from fruits and vegetables.

**4 Abdominal examination: possible findings**

**6 Rectal examination: common findings**

Diseases of the gastrointestinal tract are a major cause of morbidity and mortality. Around 10% of all consultations in primary care are for gastroenterological problems, split equally between the upper and lower gastrointestinal tract. Infective diarrhoea and malabsorption are responsible for much ill health and many deaths in low- and middle-income countries. The gastrointestinal tract is the most common site for cancer development. Colorectal cancer is the third most common cancer in men and second most common in women, with population-based screening programmes existing in many countries. Functional gastrointestinal disorders account for at least 40% of all referrals to gastroenterology services and consume considerable health-care resources. The inflammatory bowel diseases, Crohn's disease and ulcerative colitis, together affect 1 in 250 people in the Western world, with substantial associated morbidity.

## Functional anatomy and physiology

### Oesophagus, stomach and duodenum

The oesophagus is a muscular tube that extends 25 cm from the cricoid cartilage to the cardiac orifice of the stomach, with the gastroesophageal junction being 40 cm from the incisors. The oesophagus has both an upper and a lower sphincter. A peristaltic swallowing wave propels the food bolus into the stomach (Fig. 23.1).

The stomach acts as a 'hopper', retaining and grinding food, and then actively propelling it into the upper small bowel (Fig. 23.2).

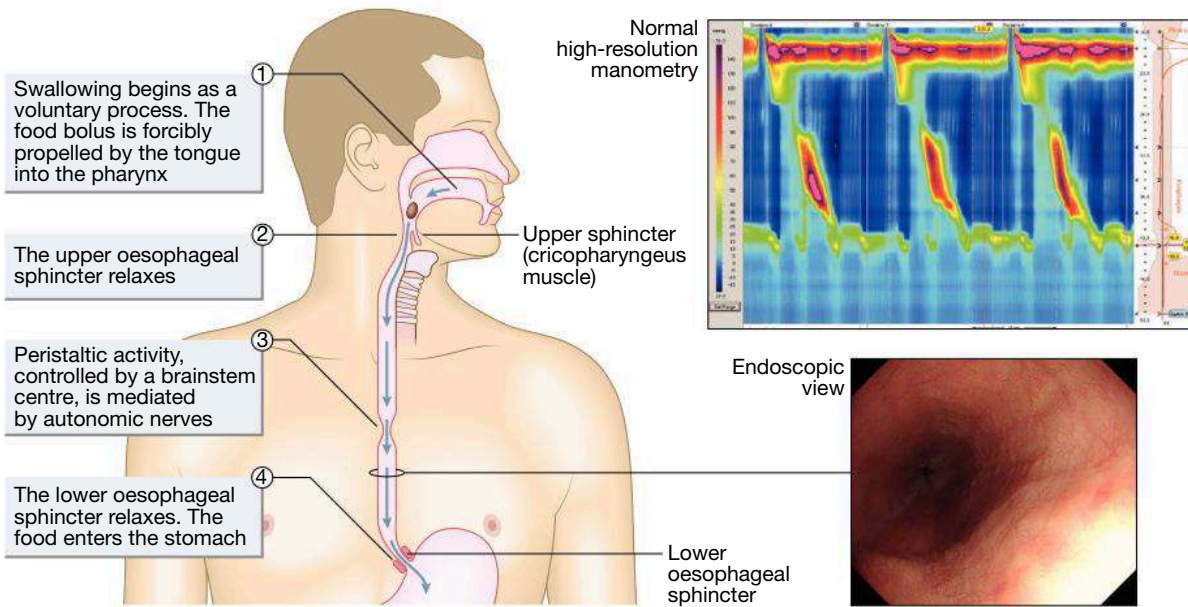

Fig. 23.1 The oesophagus: anatomy and function. The swallowing wave.

Fig. 23.2 Normal gastric and duodenal anatomy.

## Gastric secretion

Gastrin, histamine and acetylcholine are the key stimulants of acid secretion. Hydrogen and chloride ions are secreted from the apical membrane of gastric parietal cells into the lumen of the stomach by a hydrogen–potassium adenosine triphosphatase (ATPase) ('proton pump') (Fig. 23.3). The hydrochloric acid sterilises the upper gastrointestinal tract and converts the zymogen pepsinogen, which is secreted by chief cells, to pepsin, which digests proteins to polypeptides. The glycoprotein intrinsic factor, secreted in parallel with acid, is necessary for vitamin B<sub>12</sub> absorption in the terminal ileum.

## Gastrin, somatostatin and ghrelin

The hormone gastrin is produced by G cells mainly in the gastric antrum, with somatostatin being secreted from D cells throughout the gastrointestinal tract. Gastrin stimulates acid secretion and mucosal growth while somatostatin suppresses it. Ghrelin, secreted from oxyntic glands, stimulates acid secretion, as well as appetite and gastric emptying.

## Protective factors

Bicarbonate ions, stimulated by prostaglandins, mucins and trefoil factor family (TFF) peptides, together protect the gastroduodenal mucosa from the ulcerative properties of acid and pepsin.

## Small intestine

The jejunum extends from the ligament of Treitz to the ileocaecal valve (Fig. 23.4). During fasting, a wave of peristaltic activity passes down the

**Fig. 23.3 Control of acid secretion.** Gastrin released from antral G cells in response to food (protein) binds to cholecystikinin receptors (CCK-2R) on the surface of enterochromaffin-like (ECL) cells, which in turn release histamine. The histamine binds to H<sub>2</sub> receptors on parietal cells and this leads to secretion of hydrogen ions in exchange for potassium ions at the apical membrane. Parietal cells also express CCK-2R and it is thought that activation of these receptors by gastrin is involved in regulatory proliferation of parietal cells. Cholinergic (vagal) activity and gastric distension also stimulate acid secretion; somatostatin, vasoactive intestinal polypeptide (VIP) and gastric inhibitory polypeptide (GIP) may inhibit it. (ACh-R = acetylcholine receptor; ATPase = adenosine triphosphatase)

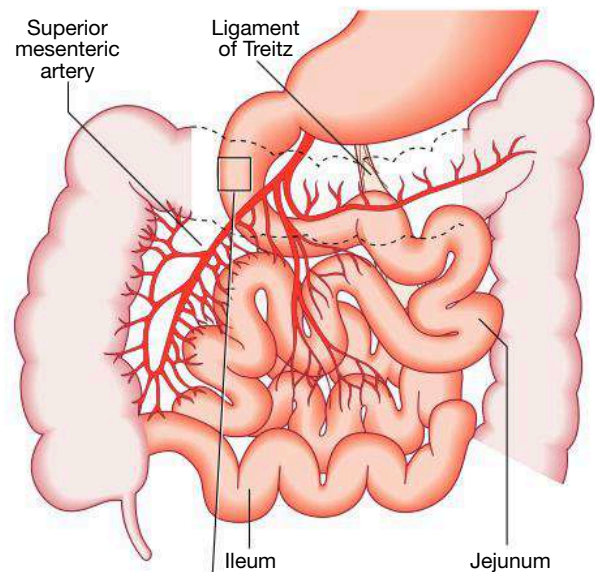

small bowel every 1–2 hours. Entry of food into the gastrointestinal tract stimulates small bowel peristaltic activity. Functions of the small intestine are:

- digestion (mechanical, enzymatic and peristaltic)
- absorption – the products of digestion, water, electrolytes and vitamins
- protection against ingested toxins
- immune regulation.

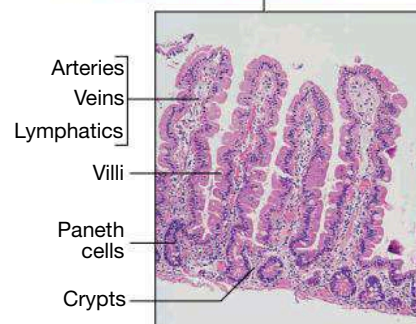

## Digestion and absorption

### Fat

Dietary lipids comprise long-chain triglycerides, cholesterol esters and lecithin. Lipids are insoluble in water and undergo lipolysis and incorporation into mixed micelles before they can be absorbed into enterocytes

### Duodenal villi

**Fig. 23.4 Small intestine: anatomy.** Epithelial cells are formed in crypts and differentiate as they migrate to the tip of the villi to form enterocytes (absorptive cells) and goblet cells.

**Fig. 23.5 Fat digestion.** *Step 1: Luminal phase.* Fatty acids stimulate cholecystokinin (CCK) release from the duodenum and upper jejunum. The CCK stimulates release of amylase, lipase, colipase and proteases from the pancreas, causes gallbladder contraction and relaxes the sphincter of Oddi, allowing bile to flow into the intestine. *Step 2: Fat solubilisation.* Bile acids and salts combine with dietary fat to form mixed micelles, which also contain cholesterol and fat-soluble vitamins. *Step 3: Digestion.* Pancreatic lipase, in the presence of its co-factor, colipase, cleaves long-chain triglycerides, yielding fatty acids and monoglycerides. *Step 4: Absorption.* Mixed micelles diffuse to the brush border of the enterocytes. Within the brush border, long-chain fatty acids bind to proteins, which transport the fatty acids into the cell, whereas cholesterol, short-chain fatty acids, phospholipids and fat-soluble vitamins enter the cell directly. The bile salts remain in the small intestinal lumen and are actively transported from the terminal ileum into the portal circulation and returned to the liver (the enterohepatic circulation). *Step 5: Re-esterification.* Within the enterocyte, fatty acids are re-esterified to form triglycerides. Triglycerides combine with cholesterol ester, fat-soluble vitamins, phospholipids and apoproteins to form chylomicrons. *Step 6: Transport.* Chylomicrons leave the enterocytes by exocytosis, enter mesenteric lymphatics, pass into the thoracic duct and eventually reach the systemic circulation.

along with the fat-soluble vitamins A, D, E and K. The lipids are processed within enterocytes and pass via lymphatics into the systemic circulation. Fat absorption and digestion can be considered as a stepwise process, as outlined in [Figure 23.5](#),

### Carbohydrates

Starch is hydrolysed by salivary and pancreatic amylases to:

- $\alpha$ -limit dextrins containing 4–8 glucose molecules
- the disaccharide maltose
- the trisaccharide maltotriose.

Disaccharides are digested by enzymes fixed to the microvillous membrane to form the monosaccharides glucose, galactose and fructose. Glucose and galactose enter the cell by an energy-requiring process involving a carrier protein, and fructose enters by simple diffusion.

### Protein

The steps involved in protein digestion are shown in [Figure 23.6](#). Intra-gastric digestion by pepsin is quantitatively modest, but important, because the resulting polypeptides and amino acids stimulate cholecystokinin (CCK) release from the mucosa of the proximal jejunum, which in turn stimulates release of pancreatic proteases, including trypsinogen, chymotrypsinogen, pro-elastases and procarboxypeptidases, from the pancreas. On exposure to brush border enterokinase, inert trypsinogen is converted to the active proteolytic enzyme trypsin, which activates

the other pancreatic pro-enzymes. Trypsin digests proteins to produce oligopeptides, peptides and amino acids. Oligopeptides are further hydrolysed by brush border enzymes to yield dipeptides, tripeptides and amino acids. These small peptides and the amino acids are actively transported into the enterocytes, where intracellular peptidases further digest peptides to amino acids. Amino acids are then actively transported across the basal cell membrane of the enterocyte into the portal circulation and the liver.

### Water and electrolytes

Absorption and secretion of electrolytes and water occur throughout the intestine. Electrolytes and water are transported by two pathways:

- *the paracellular route*, in which passive flow through tight junctions between cells is a consequence of osmotic, electrical or hydrostatic gradients
- *the transcellular route* across apical and basolateral membranes by energy-requiring specific active transport carriers (pumps).

In healthy individuals, fluid balance is tightly controlled, such that only 100 mL of the 8 litres of fluid entering the gastrointestinal tract daily is excreted in stools ([Fig. 23.7](#)).

### Vitamins and trace elements

Water-soluble vitamins are absorbed throughout the intestine. The absorption of folic acid, vitamin B<sub>12</sub>, calcium and iron is described in [Chapter 25](#).

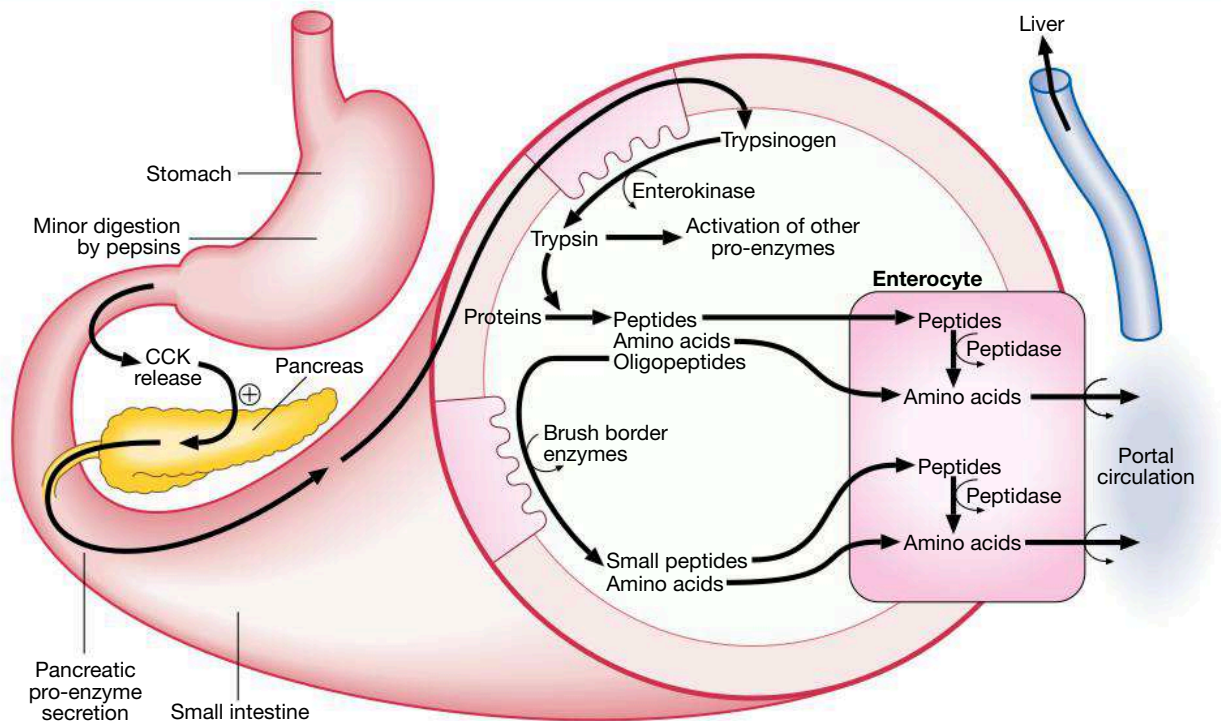

Fig. 23.6 Protein digestion. (CCK = cholecystokinin)

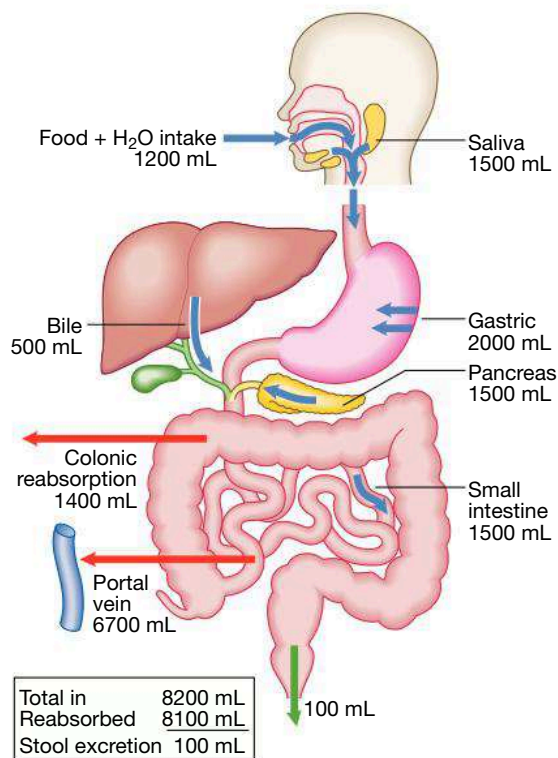

Fig. 23.7 Fluid homeostasis in the gastrointestinal tract.

## Protective function of the small intestine

### Physical defence mechanisms

There are several levels of defence in the small bowel (Fig. 23.8). Firstly, the gut lumen contains host bacteria, mucins and secreted antibacterial products, including defensins and immunoglobulins that help combat pathogenic infections. Secondly, epithelial cells have relatively

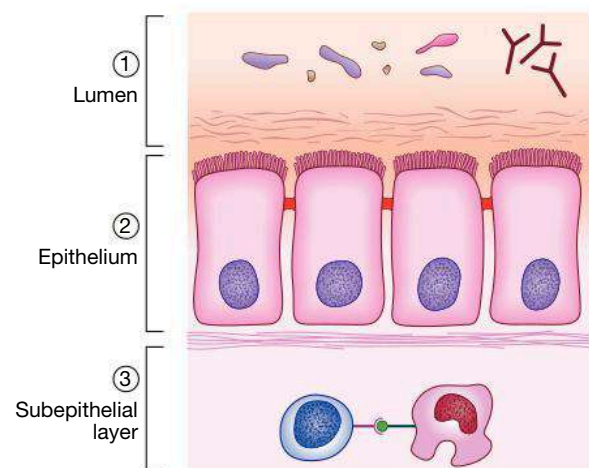

Fig. 23.8 Intestinal defence mechanisms. See text for details.

impermeable brush border membranes and passage between cells is prevented by tight and adherens junctions. These cells can react to foreign peptides ('innate immunity') using pattern recognition receptors found on cell surfaces (Toll receptors) or intracellularly. Lastly, in the sub-epithelial layer, immune responses occur under control of the adaptive immune system in response to pathogenic compounds.

### Immunological defence mechanisms

Gastrointestinal mucosa-associated lymphoid tissue (MALT) constitutes 25% of the total lymphatic tissue of the body and is at the heart of adaptive immunity. Within Peyer's patches, B lymphocytes differentiate to plasma cells following exposure to antigens and these migrate to mesenteric lymph nodes to enter the blood stream via the thoracic duct. The plasma cells return to the lamina propria of the gut through the circulation and release immunoglobulin A (IgA), which is transported into the lumen of the intestine. Intestinal T lymphocytes help localise plasma cells to the site of antigen exposure, as well as producing inflammatory mediators. Macrophages in the gut phagocytose foreign materials and secrete a

range of cytokines, which mediate inflammation. Similarly, activation of mast-cell surface IgE receptors leads to degranulation and release of other molecules involved in inflammation.

## Pancreas

The exocrine pancreas (Box 23.1) is necessary for the digestion of fat, protein and carbohydrate. Pro-enzymes are secreted from pancreatic acinar cells in response to circulating gastrointestinal hormones (Fig. 23.9) and are activated by trypsin. Bicarbonate-rich fluid is secreted from ductular cells to produce an optimum alkaline pH for enzyme activity. The endocrine pancreas is discussed in Chapters 20 and 21.

## Colon

The colon (Fig. 23.10) absorbs water and electrolytes. It also acts as a storage organ and has contractile activity. Two types of contraction occur. The first of these is segmentation (ring contraction), which leads to mixing but not propulsion; this promotes absorption of water and electrolytes. Propulsive (peristaltic contraction) waves occur several times a day and propel faeces to the rectum. All activity is stimulated after meals through the gastrocolic reflex in response to release of hormones such as 5-hydroxytryptamine (5-HT, serotonin), motilin and CCK. Faecal continence depends on maintenance of the anorectal angle and tonic contraction of the external anal sphincters. On defecation, there is relaxation

23.1 Pancreatic enzymes		
Enzyme	Substrate	Product
Amylase	Starch and glycogen	Limit dextrans Maltose Maltotriose
Lipase Colipase	Triglycerides	Monoglycerides and free fatty acids
Proteolytic enzymes Trypsinogen Chymotrypsinogen Pro-elastase Pro-carboxypeptidases	Proteins and polypeptides	Short polypeptides

**Fig. 23.9 Pancreatic structure and function.** Ductular cells secrete alkaline fluid in response to secretin. Acinar cells secrete digestive enzymes from zymogen granules in response to a range of secretagogues. The photograph shows a normal pancreatic duct (PD) and side branches, as defined at magnetic resonance cholangiopancreatography (MRCP). Note the incidental calculi in the gallbladder and common bile duct (arrow). (CCK = cholecystokinin; VIP = vasoactive intestinal polypeptide)

of the anorectal muscles, increased intra-abdominal pressure from the Valsalva manoeuvre and contraction of abdominal muscles, and relaxation of the anal sphincters.

## Intestinal microbiota

The human microbiota comprises  $10^{14}$  microbial residents in the human body, vastly outnumbering host cells. Indeed, the number of bacterial genes in the microbiota genome exceeds that of the host by 100-fold or more. This represents a vast ecosystem that is central to health and homeostasis, and is disordered in disease. In terms of nomenclature, 'microbiota' refers to the microorganisms that live in a particular niche, while 'microbiome' refers to the collective genomes of these microbiota. There is a degree of heritability of this microbiota, but it is clear that there are many environmental factors that can affect it, including diet, drugs, physical activity, smoking, stress and natural ageing. Generally, the adult intestinal microbiota is acquired by the age of 2 years. A dysbiosis or imbalance between the different components of the intestinal microbiota has been associated with diseases of the gastrointestinal tract, such as inflammatory bowel disease and colorectal cancer; liver disease, including hepatocellular carcinoma; and pathologies outside the gastrointestinal tract, such as diabetes, obesity, cardiovascular disorders, cerebrovascular disorders, asthma and psychiatric disorders, such as depression. Many challenges remain in understanding the intestinal microbiota and how it impacts on health and disease.

## Control of gastrointestinal function

Secretion, absorption, motor activity, growth and differentiation of the gut are all modulated by a combination of neuronal and hormonal factors.

## The nervous system and gastrointestinal function

The central nervous system (CNS), the autonomic system (ANS) and the enteric nervous system (ENS) interact to regulate gut function. The ANS comprises:

- *parasympathetic pathways* (vagal and sacral efferent), which are cholinergic, and increase smooth muscle tone and promote sphincter relaxation
- *sympathetic pathways*, which release noradrenaline (norepinephrine), reduce smooth muscle tone and stimulate sphincter contraction.

### The enteric nervous system

In conjunction with the ANS, the ENS senses gut contents and conditions, and regulates motility, fluid exchange, secretion, blood flow and other key gut functions. It comprises two major networks intrinsic to the gut wall. The myenteric (Auerbach's) plexus in the smooth muscle layer regulates motor control; and the submucosal (Meissner's) plexus exerts secretory control over the epithelium, entero-endocrine cells and submucosal vessels. Together, these plexuses form a two-layered neuronal mesh along the length of the gut. Although connected centrally via the ANS, the ENS can function autonomously using a variety of transmitters, including acetylcholine, noradrenaline (norepinephrine), 5-HT, nitric oxide, substance P and calcitonin gene-related peptide (CGRP). There are local reflex loops within the ENS but also loops involving the coeliac and mesenteric ganglia and the paravertebral ganglia. The parasympathetic system generally stimulates motility and secretion, while the sympathetic system generally acts in an inhibitory manner.

### Peristalsis

Peristalsis is a reflex triggered by gut wall distension, which consists of a wave of circular muscle contraction to propel contents from the oesophagus to the rectum. It can be influenced by innervation but functions independently. It results from a basic electrical rhythm originating from the interstitial cells of Cajal in the circular layer of intestinal smooth muscle. These are stellate cells of mesenchymal origin with smooth muscle features, which act as the 'pacemaker' of the gut.

### Migrating motor complexes

Migrating motor complexes (MMCs) are waves of contraction spreading from the stomach to the ileum, occurring at a frequency of about 5 per minute every 90 minutes or so, between meals and during fasting. They may serve to sweep intestinal contents distally in preparation for the next meal and are inhibited by eating.

### Gut hormones

The origin, action and control of the major gut hormones, peptides and non-peptide signalling transmitters are summarised in [Box 23.2](#).

## Investigation of gastrointestinal disease

A wide range of tests is available for the investigation of patients with gastrointestinal symptoms. These can be classified broadly into tests of structure, tests for infection and tests of function.

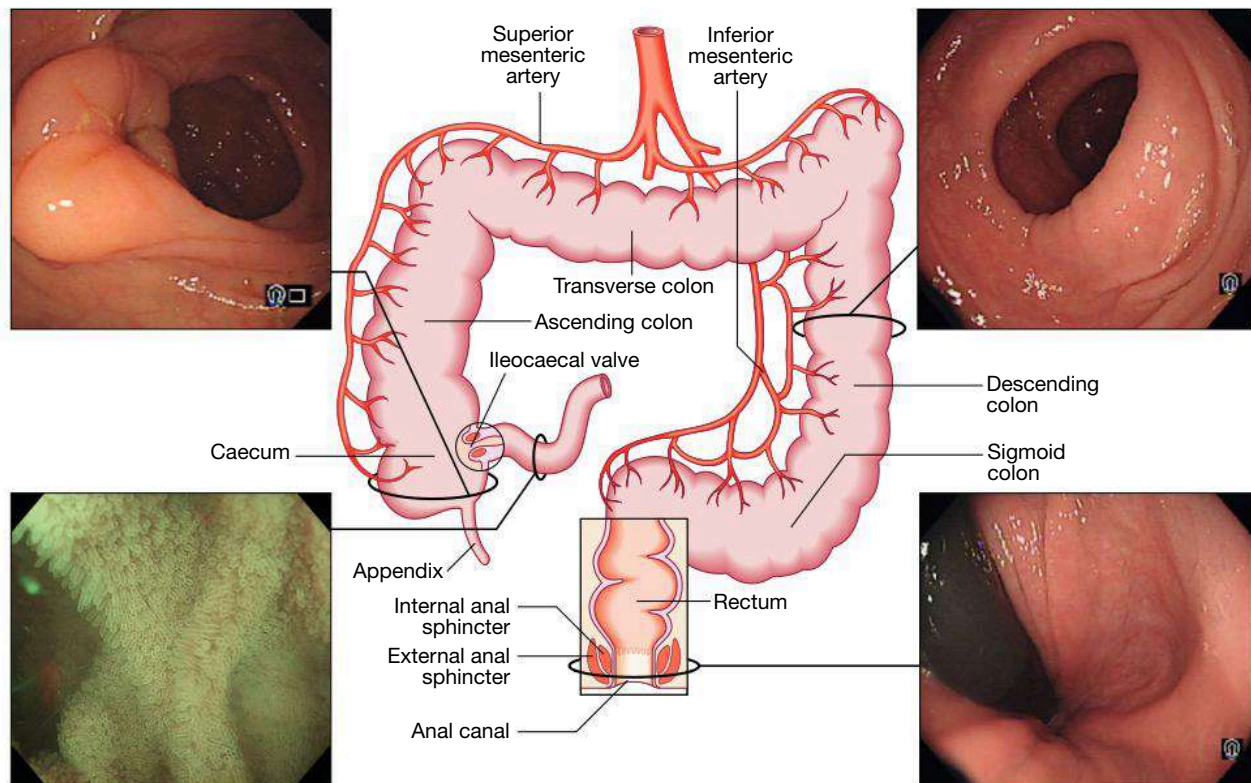

### Imaging

#### Plain X-rays

Plain X-rays of the abdomen are useful in the diagnosis of intestinal obstruction or paralytic ileus, where dilated loops of bowel and (in the erect position) fluid levels may be seen ([Fig. 23.11](#)). Calcified lymph nodes, gallstones and renal stones can also be detected. Chest X-ray (performed with the patient in erect position) is useful in the diagnosis of suspected perforation, as it shows subdiaphragmatic free air (see [Fig. 23.11](#)).

#### Contrast studies

X-rays with contrast medium are usually performed to assess not only anatomical abnormalities but also motility. Barium sulphate provides good mucosal coating and excellent opacification but can precipitate impaction proximal to an obstructive lesion. Water-soluble contrast is used to opacify bowel prior to abdominal computed tomography and in cases of suspected perforation. The double contrast technique improves mucosal visualisation by using gas to distend the barium-coated

**Fig. 23.10** The normal colon, rectum and anal canal.

23.2 Gut hormones and peptides			
Hormone	Origin	Stimulus	Action
<b>Gastrin</b>	Predominantly stomach (G cell)	Products of protein digestion Suppressed by acid and somatostatin	Stimulates gastric acid secretion Stimulates growth of gastrointestinal mucosa
<b>Somatostatin</b>	Throughout gastrointestinal tract (D cell)	Fat ingestion	Inhibits gastrin and insulin secretion Decreases acid secretion Decreases absorption Inhibits pancreatic secretion
<b>Cholecystokinin (CCK)</b>	Duodenum and jejunum (I cells); also ileal and colonic nerve endings	Products of protein digestion Fat and fatty acids Suppressed by trypsin	Stimulates pancreatic enzyme secretion Stimulates gallbladder contraction Relaxes sphincter of Oddi Modulates satiety Decreases gastric acid secretion Reduces gastric emptying Regulates pancreatic growth
<b>Secretin</b>	Duodenum and jejunum (S cells)	Duodenal acid Fatty acids	Stimulates pancreatic fluid and bicarbonate secretion Decreases acid secretion Reduces gastric emptying
<b>Motilin</b>	Duodenum, small intestine and colon (Mo cells)	Fasting Dietary fat	Regulates peristaltic activity, including migrating motor complexes (MMCs)
<b>Gastric inhibitory polypeptide (GIP)</b>	Duodenum (K cells) and jejunum	Glucose and fat	Stimulates insulin release (also known as glucose-dependent insulinotropic polypeptide) Inhibits acid secretion Enhances satiety
<b>Glucagon-like peptide-1 (GLP-1)</b>	Ileum and colon (L cells)	Carbohydrates, protein and fat	Stimulates insulin release Inhibits acid secretion and gastric emptying Enhances satiety
<b>Vasoactive intestinal peptide (VIP)</b>	Nerve fibres throughout gastrointestinal tract	Unknown	Has vasodilator action Relaxes smooth muscle Stimulates water and electrolyte secretion
<b>Ghrelin</b>	Stomach	Fasting Inhibited by eating	Stimulates appetite, acid secretion and gastric emptying
<b>Peptide YY</b>	Ileum and colon	Feeding	Modulates satiety

**Fig. 23.11** Examples of plain X-rays. **A** Abdominal X-ray showing dilatation of loops of small bowel (arrows), which are indicative of obstruction (in this case due to adhesions from previous surgery). **B** Chest X-ray showing free air under both hemi-diaphragms (arrows), which is indicative of acute perforation of an abdominal viscus.

intestinal surface. Contrast studies are useful for detecting filling defects, such as tumours, strictures, ulcers and motility disorders, but are inferior to endoscopic procedures and more sophisticated cross-sectional imaging techniques, such as computed tomography and magnetic resonance imaging. The major uses and limitations of various contrast studies are shown in [Box 23.3](#) and [Figure 23.12](#).

### Ultrasound, computed tomography and magnetic resonance imaging

Ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI) are key tests in the evaluation of intra-abdominal disease. They are non-invasive and offer detailed images of the abdominal

contents; portable ultrasound devices are increasingly used at the bedside to provide rapid diagnostic information, e.g. in acute abdominal pain and to assist with investigations such as paracentesis. Fluorodeoxyglucose-positron emission tomography (FDG-PET) is used in the staging of malignancies and images may be fused with CT to enhance localisation. Their main applications are summarised in Box 23.4 and Figure 23.13.

### 23.3 Contrast radiology in the investigation of gastrointestinal disease

	Barium swallow/meal	Barium follow-through	Barium enema
<b>Indications and major uses</b>	Motility disorders (achalasia and gastroparesis) Perforation or fistula (non-ionic contrast)	Diarrhoea and abdominal pain of small bowel origin Possible obstruction by strictures Suspected malabsorption Assessment of Crohn's disease	Altered bowel habit Evaluation of strictures or diverticular disease Megacolon
<b>Limitations</b>	Risk of aspiration Poor mucosal detail Low sensitivity for early cancer Inability to biopsy	Time-consuming nature Radiation exposure Relative insensitivity	Difficulty in frail or incontinent patients Sigmoidoscopy needed to see rectum Low sensitivity for lesions < 1 cm

### Endoanal ultrasound and anorectal manometry

Endoanal ultrasound is primarily used in the evaluation of anal fistula and anal sphincter pathology, in individuals presenting with faecal incontinence. In conjunction with this, anorectal manometry is commonly performed to detect abnormalities of sphincter function and recto-anal coordination. Anorectal manometry is also commonly used to assess constipation, particularly when thought due to obstructive defecation.

### Endoscopy

Videoendoscopes provide high-definition imaging and accessories can be passed down the endoscope to allow both diagnostic and therapeutic procedures, some of which are illustrated in Figure 23.14. Endoscopes with magnifying lenses allow almost microscopic detail to be observed, and imaging modalities, such as confocal endomicroscopy, autofluorescence and 'narrow-band imaging', are increasingly used to detect subtle abnormalities not visible by standard 'white light' endoscopy. The implications of endoscopic procedures in older people are shown in Box 23.5.

### Upper gastrointestinal endoscopy

This is performed under light sedation, or using only local anaesthetic throat spray after the patient has fasted for at least 4 hours. With the patient in the left lateral position, the entire oesophagus (excluding pharynx), stomach and first two parts of duodenum can be seen. Indications, contraindications and complications are given in Box 23.6. While upper gastrointestinal endoscopy is mainly performed via the transoral route, transnasal endoscopy is becoming an emerging alternative in some units.

**Fig. 23.12** Examples of contrast radiology. **A** Barium swallow showing a large pharyngeal pouch (P) with retained contrast creating an air–fluid level. **B** Barium follow-through. There are multiple diverticula (arrows) in this patient with jejunal diverticulosis. **C** Barium enema showing severe diverticular disease. There is tortuosity and narrowing of the sigmoid colon with multiple diverticula (arrows).

**Fig. 23.13** Examples of ultrasound, CT and MRI. **A** Ultrasound showing large gallstone (arrow) with acoustic shadowing. **B** Multidetector coronal CT showing large solid and cystic malignant tumour in the pancreatic tail (arrow). (PV = portal vein; L = liver) **C** Pelvic MRI showing large pelvic abscess (arrow) posterior to the rectum in a patient with Crohn's disease. **D** Fused CT-PET image showing two liver metastases (arrows).

i 23.4 Imaging in gastroenterology				
	Ultrasound	Computed tomography (CT)	Magnetic resonance imaging (MRI)	Positron emission tomography-CT (PET-CT)
<b>Indications and major uses</b>	Abdominal masses Organomegaly Ascites Biliary tract dilatation Gallstones Guided biopsy of lesions Small bowel imaging	Assessment of pancreatic disease Hepatic tumour deposits CT colonography ('virtual colonoscopy') Tumour staging Assessment of lesion vascularity Abscesses and collections	Hepatic tumour staging MRCP Pelvic/perianal disease Crohn's fistulae Small bowel visualisation	Detection of metastases not seen on ultrasound or CT Images can be fused with CT to form composite image
<b>Limitations</b>	Low sensitivity for small lesions Little functional information Operator-dependent Gas and obesity may obscure view	Cost Radiation dose	Claustrophobic patients Contraindicated in presence of metallic prostheses, cardiac pacemaker, cochlear implants	Signal detection depends on metabolic activity within tumour – not all are metabolically active

(MRCP = magnetic resonance cholangiopancreatography)

i 23.5 Endoscopy in old age	
<ul style="list-style-type: none"> <li>• <b>Tolerance:</b> endoscopic procedures are generally well tolerated, even in very old people.</li> <li>• <b>Side-effects from sedation:</b> older people are more sensitive, and respiratory depression, hypotension and prolonged recovery times are more common.</li> <li>• <b>Bowel preparation for colonoscopy:</b> can be difficult in frail, immobile people. Sodium phosphate-based preparations can cause dehydration or hypotension and should be avoided in those with underlying cardiac or renal failure. Minimal-preparation CT colonograms provide an excellent alternative in these individuals.</li> <li>• <b>Antiperistaltic agents:</b> hyoscine should be avoided in those with glaucoma and can also cause tachyarrhythmias. Glucagon is preferred if an antiperistaltic agent is needed.</li> </ul>	

(CT = computed tomography)

### Endoscopic ultrasound

Endoscopic ultrasound (EUS) combines endoscopy with intraluminal ultrasonography using a high-frequency transducer to produce high-resolution ultrasound images. This allows visualisation through the wall of the gastrointestinal tract and into surrounding tissues, e.g. the pancreas or lymph nodes. It can therefore be used to perform fine needle aspiration or biopsy of mass lesions. EUS is helpful in the diagnosis of pancreatic tumours, chronic pancreatitis, pancreatic cysts, cholangiocarcinoma, common bile duct stones, ampullary lesions and submucosal tumours. It also plays an important role in the staging of certain cancers, e.g. those of oesophagus and pancreas. The role of EUS as a therapeutic modality has increased, and can be used in the drainage of pancreatic fluid collections and coeliac plexus block for pain management. Possible complications of EUS include bleeding, infection, cardiopulmonary events and perforation.

### Capsule endoscopy

Capsule endoscopy (Fig. 23.15) uses a capsule containing an imaging device, battery, transmitter and antenna; as it traverses the small intestine, it transmits images to a battery-powered recorder worn on a belt round the patient's waist. After approximately 8 hours, the capsule is excreted. Images from the capsule are analysed as a video sequence and it is usually possible to localise the segment of small bowel where lesions are seen. Abnormalities detected usually require enteroscopy for confirmation and therapy. Indications, contraindications and complications are listed in Box 23.7.

i 23.6 Upper gastrointestinal endoscopy	
<b>Indications</b>	<ul style="list-style-type: none"> <li>• Dyspepsia in patients &gt; 55 years of age or with alarm symptoms</li> <li>• Atypical chest pain</li> <li>• Dysphagia</li> <li>• Vomiting</li> <li>• Weight loss</li> <li>• Acute or chronic gastrointestinal bleeding</li> <li>• Screening for oesophageal varices in chronic liver disease</li> <li>• Abnormal CT scan or barium meal</li> <li>• Duodenal biopsies in the investigation of malabsorption and confirmation of a diagnosis of coeliac disease prior to commencement of gluten-free diet</li> <li>• Therapy, including treatment of bleeding lesions, banding/injection of varices, dilatation of strictures, insertion of stents, placement of percutaneous gastrostomies, ablation of Barrett's oesophagus and resection of high-grade dysplastic lesions and early neoplasia in the upper gastrointestinal tract</li> </ul>
<b>Contraindications</b>	<ul style="list-style-type: none"> <li>• Severe shock</li> <li>• Recent myocardial infarction, unstable angina, cardiac arrhythmia</li> <li>• Severe respiratory disease*</li> <li>• Atlantoaxial subluxation*</li> <li>• Possible visceral perforation</li> </ul>
<b>Complications</b>	<ul style="list-style-type: none"> <li>• Cardiorespiratory depression due to sedation</li> <li>• Aspiration pneumonia</li> <li>• Perforation</li> </ul>
<p>*These are 'relative' contraindications; in experienced hands, endoscopy can be safely performed. (CT = computed tomography)</p>	

### Enteroscopy – push enteroscopy/double balloon enteroscopy

While upper gastrointestinal endoscopy can reach the proximal small intestine in most patients, enteroscopy is an endoscopic technique that allows more extensive evaluation of the small intestine, extending into the jejunum and/or ileum. Push enteroscopy uses a long endoscope to examine up to the proximal jejunum. Deeper evaluation of the small bowel can be assessed by using a technique called double balloon enteroscopy, which uses a long endoscope with a flexible overtube. Sequential and repeated inflation and deflation of balloons on the tip of the overtube and endoscope allow the operator to push and pull along the entire length of the small intestine to the terminal ileum, to diagnose or treat small bowel lesions detected by capsule endoscopy or other imaging modalities. This technique can be performed via an ante-grade approach (via the mouth) or retrograde approach (via the anus),

Fig. 23.14 Examples of therapeutic techniques in endoscopy.

dependent upon the site of the lesion. Indications, contraindications and complications are listed in [Box 23.8](#).

### Sigmoidoscopy and colonoscopy

Sigmoidoscopy can be carried out either in the outpatient clinic using a rigid plastic sigmoidoscope or in the endoscopy suite using a colonoscope following bowel preparation. When sigmoidoscopy is combined with proctoscopy, accurate detection of haemorrhoids, ulcerative colitis and distal colorectal neoplasia is possible. After full bowel cleansing, it is possible to examine the entire colon and the terminal ileum using a colonoscope. Indications, contraindications and complications of colonoscopy are listed in [Box 23.9](#).

### Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) has largely replaced endoscopic retrograde cholangiopancreatography (ERCP) in the evaluation of obstructive jaundice since it produces comparable images of the biliary tree and pancreas, providing information that complements that obtained from CT and EUS.

### Endoscopic retrograde cholangiopancreatography

Using a side-viewing duodenoscope, it is possible to cannulate the main pancreatic duct and common bile duct. ERCP is used mainly in the treatment of a range of biliary and pancreatic diseases that have been identified by other imaging techniques such as MRCP, EUS and CT. Indications for and risks of ERCP are listed in [Box 23.10](#).

## Histology

Biopsy material obtained endoscopically or percutaneously can provide useful information ([Box 23.11](#)).

## Tests of infection

### Bacterial cultures

Stool cultures are essential in the investigation of diarrhoea, especially when it is acute or bloody, in order to identify pathogenic organisms (see [Ch. 13](#)).

### Serology

Detection of antibodies plays a limited role in the diagnosis of gastrointestinal infection caused by organisms such as *Helicobacter pylori*, *Salmonella* species and *Entamoeba histolytica*.

### Breath tests

Non-invasive breath tests for *H. pylori* infection are discussed on page 814 and breath tests for suspected small intestinal bacterial overgrowth on page 822.

## Tests of function

A number of dynamic tests can be used to investigate aspects of gut function, including digestion, absorption, inflammation and epithelial permeability. Some of the more common ones are listed in [Box 23.12](#). In the assessment of suspected malabsorption, blood tests (full blood count, erythrocyte sedimentation rate (ESR)), and measurement of C-reactive protein (CRP), folate, vitamin B<sub>12</sub>, iron status, albumin, calcium and phosphate) are essential, and endoscopy is undertaken to obtain mucosal biopsies. Faecal calprotectin is very sensitive at detecting mucosal inflammation.

**Fig. 23.15** Wireless capsule endoscopy. **A** Examples of capsules. **B** Capsule endoscopy image of scalloping of the small bowel suggestive of coeliac disease.

i 23.7 Wireless capsule endoscopy
<b>Indications</b> <ul style="list-style-type: none"> <li>• Obscure gastrointestinal bleeding</li> <li>• Small bowel Crohn's disease</li> <li>• Assessment of coeliac disease and its complications</li> <li>• Screening and surveillance in familial polyposis syndromes</li> </ul>
<b>Contraindications</b> <ul style="list-style-type: none"> <li>• Known or suspected small bowel stricture (risk of capsule retention)</li> <li>• Caution in people with pacemakers or implantable defibrillators</li> </ul>
<b>Complications</b> <ul style="list-style-type: none"> <li>• Capsule retention (&lt; 1%)</li> </ul>

i 23.8 Double balloon enteroscopy
<b>Indications</b>
<b>Diagnostic</b> <ul style="list-style-type: none"> <li>• Obscure gastrointestinal bleeding</li> <li>• Malabsorption or unexplained diarrhoea</li> <li>• Suspicious radiological findings</li> <li>• Suspected small bowel tumour</li> <li>• Surveillance of polyposis syndromes</li> </ul>
<b>Therapeutic</b> <ul style="list-style-type: none"> <li>• Coagulation/diathermy of bleeding lesions</li> <li>• Jejunostomy placement</li> </ul>
<b>Contraindications</b> <ul style="list-style-type: none"> <li>• As for upper gastrointestinal endoscopy</li> </ul>
<b>Complications</b> <ul style="list-style-type: none"> <li>• As for upper gastrointestinal endoscopy</li> <li>• Post-procedure abdominal pain (<math>\leq 20\%</math>)</li> <li>• Pancreatitis (1%–3%)</li> <li>• Perforation (especially after resection of large polyps)</li> </ul>

## Oesophageal motility

A barium swallow can give useful information about oesophageal motility. Videofluoroscopy, with joint assessment by a speech and language therapist and a radiologist, may be necessary in difficult cases. High resolution oesophageal manometry (see Fig. 23.1), often in conjunction with 24-hour pH measurements, is of value in diagnosing cases of refractory gastro-oesophageal reflux, achalasia and non-cardiac chest pain. Oesophageal impedance testing is useful for detecting non-acid or gas reflux events, especially in patients with atypical symptoms or those who respond poorly to acid suppression.

i 23.9 Colonoscopy
<b>Indications*</b> <ul style="list-style-type: none"> <li>• Suspected inflammatory bowel disease</li> <li>• Chronic diarrhoea</li> <li>• Altered bowel habit</li> <li>• Rectal bleeding or iron deficiency anaemia</li> <li>• Assessment of abnormal CT colonogram or barium enema</li> <li>• Colorectal cancer screening</li> <li>• Colorectal adenoma and carcinoma follow-up</li> <li>• Therapeutic procedures, including endoscopic resection, dilatation of strictures, laser, stent insertion and argon plasma coagulation</li> </ul>
<b>Contraindications</b> <ul style="list-style-type: none"> <li>• Acute severe ulcerative colitis (unprepared flexible sigmoidoscopy is preferred)</li> <li>• As for upper gastrointestinal endoscopy</li> </ul>
<b>Complications</b> <ul style="list-style-type: none"> <li>• Cardiorespiratory depression due to sedation</li> <li>• Perforation</li> <li>• Bleeding following polypectomy</li> </ul>
<p>*Colonoscopy is not useful in the investigation of constipation. (CT = computed tomography)</p>

i 23.10 Endoscopic retrograde cholangiopancreatography (ERCP)
<b>Indications</b>
<b>Diagnostic</b> <ul style="list-style-type: none"> <li>• Biliary or pancreatic disease where other imaging is equivocal or contraindicated</li> <li>• Ampullary biopsy or biliary cytology</li> </ul>
<b>Therapeutic</b> <ul style="list-style-type: none"> <li>• Biliary disease: <ul style="list-style-type: none"> <li>• Removal of common bile duct calculi*</li> <li>• Palliation of malignant biliary obstruction</li> <li>• Management of biliary leaks/damage complicating surgery</li> <li>• Dilatation of benign strictures</li> <li>• Primary sclerosing cholangitis</li> </ul> </li> <li>• Pancreatic disease: <ul style="list-style-type: none"> <li>• Drainage of pancreatic pseudocysts and fistulae</li> <li>• Removal of pancreatic calculi (selected cases)</li> </ul> </li> </ul>
<b>Contraindications</b> <ul style="list-style-type: none"> <li>• Severe cardiopulmonary comorbidity</li> <li>• Coagulopathy</li> </ul>
<b>Complications</b> <ul style="list-style-type: none"> <li>• Occur in 5%–10% with a 30-day mortality of 0.5%–1%</li> </ul>
<b>General</b> <ul style="list-style-type: none"> <li>• As for upper endoscopy</li> </ul>
<b>Specific</b> <ul style="list-style-type: none"> <li>• Biliary disease: <ul style="list-style-type: none"> <li>• Bleeding following sphincterotomy</li> <li>• Cholangitis (if biliary obstruction is not relieved by ERCP)</li> <li>• Gallstone impaction</li> </ul> </li> <li>• Pancreatic disease: <ul style="list-style-type: none"> <li>• Acute pancreatitis</li> <li>• Infection of pseudocyst</li> </ul> </li> </ul>
<p>*Laparoscopic surgery is preferred in fit individuals who also require cholecystectomy.</p>

i 23.11 Reasons for biopsy or cytological examination
<ul style="list-style-type: none"> <li>• Suspected malignant lesions</li> <li>• Assessment of mucosal abnormalities</li> <li>• Diagnosis of infection (<i>Candida</i>, <i>Helicobacter pylori</i>, <i>Giardia lamblia</i>)</li> <li>• Analysis of genetic mutations</li> </ul>

### 23.12 Tests of gastrointestinal function

Process	Test	Principle	Comments
<b>Absorption</b>			
Lactose	Lactose H <sub>2</sub> breath test	Measurement of breath H <sub>2</sub> content after 50 g oral lactose. Undigested sugar is metabolised by colonic bacteria in hypolactasia and expired hydrogen is measured	Non-invasive and accurate. May provoke pain and diarrhoea in sufferers
Fructose	Fructose H <sub>2</sub> breath test	Measurement of breath H <sub>2</sub> content after 25–50 g oral fructose. Unabsorbed fructose is fermented by colonic bacteria with expired hydrogen measured	Results can be difficult to interpret as breath testing does not reflect fructose ingestion in everyday life
Bile acids	<sup>75</sup> SeHCAT test Serum 7 $\alpha$ -hydroxycholestenone	Isotopic quantification of 7-day whole-body retention of oral dose <sup>75</sup> Se-labelled homochoyltaurine (>15% = normal, 5%–15% borderline, <5% = abnormal) Intermediate metabolite of the bile acid synthetic pathway. Serum levels indicate activity of the pathway and are elevated in bile acid diarrhoea	Accurate and specific but requires two visits and involves radiation. Results can be equivocal. Serum 7 $\alpha$ -hydroxycholestenone is almost as sensitive and specific Simple test to perform and only marginally less sensitive and specific than <sup>75</sup> SeHCAT test
<b>Pancreatic exocrine function</b>	Faecal elastase	Immunoassay of pancreatic enzymes on stool sample	Simple, quick and avoids urine collection. Does not detect mild disease
<b>Mucosal inflammation/permeability</b>	Faecal calprotectin or lactoferrin	Proteins secreted non-specifically by neutrophils into the colon in response to inflammation or neoplasia	Useful screening test for gastrointestinal inflammation and for monitoring patients with Crohn's disease and ulcerative colitis. Poor sensitivity for cancer

(<sup>75</sup>SeHCAT = <sup>75</sup>Se-homochoylic acid taurine)

### Gastric emptying

This involves administering a test meal containing solids and liquids labelled with different radioisotopes and measuring the amount retained in the stomach afterwards (Box 23.13). It is useful in the investigation of suspected delayed gastric emptying (gastroparesis), when other studies are normal.

### Colonic and anorectal motility

A plain abdominal X-ray taken on day 5 after ingestion of different-shaped inert plastic pellets on days 1–3 gives an estimate of whole-gut transit time. The test is useful in the evaluation of chronic constipation, when the position of any retained pellets can be observed, and helps to differentiate cases of slow transit from those due to dyssynergic defecation. The mechanism of defecation and anorectal function can be assessed by anorectal manometry, electrophysiological tests and defecating proctography.

### Radioisotope tests

Many different radioisotope tests are used (Boxes 23.12 and 23.13). In some, structural information is obtained, such as the localisation of a Meckel's diverticulum. Others provide functional information, such as the rate of gastric emptying or ability to reabsorb bile acids. Others are tests of infection and rely on the presence of bacteria to hydrolyse a radio-labelled test substance followed by detection of the radioisotope in expired air, such as the urea breath test for *H. pylori*.

### Gut hormone testing

Excess gut hormone secretion by some gastrointestinal and pancreatic neuro-endocrine tumours can be assessed by measuring levels in blood. Commonly measured hormones include gastrin, somatostatin, vasoactive intestinal polypeptide (VIP) and pancreatic polypeptide.

## Presenting problems in gastrointestinal disease

### Dysphagia

Dysphagia is defined as difficulty in swallowing. It may coexist with heartburn or vomiting but should be distinguished from both globus sensation

### 23.13 Tests involving radioisotopes

Test	Isotope	Major uses and principle of test
<b>Gastric emptying study</b>	<sup>99m</sup> Tc-sulphur <sup>111</sup> In-DTPA	Assessment of gastric emptying, particularly for possible gastroparesis
<b>Urea breath test</b>	<sup>13</sup> C-urea	Non-invasive diagnosis of <i>Helicobacter pylori</i> . Bacterial urease enzyme splits urea to ammonia and CO <sub>2</sub> , which is detected in expired air
<b>Meckel's scan</b>	<sup>99m</sup> Tc-pertechnetate	Diagnosis of Meckel's diverticulum in cases of obscure gastrointestinal bleeding. Isotope is injected intravenously and localises in ectopic parietal mucosa within diverticulum
<b>Somatostatin receptor scintigraphy (SRS)</b>	<sup>111</sup> In-DTPA-octreotide <sup>99m</sup> Tc-tekrotyd	Staging neuro-endocrine tumours. Labelled somatostatin analogues bind to cell surface somatostatin receptors on neuro-endocrine cancer cells
<b>Positron emission tomography-CT (PET-CT)</b>	<sup>18</sup> F-FDG <sup>68</sup> Ga-labelled somatostatin analogue	Staging high-grade cancers More sensitive and specific than SRS for staging neuro-endocrine tumours

(C = carbon; DTPA = diethylenetriaminepentaacetic acid; FDG = fluorodeoxyglucose; In = indium; Tc = technetium)

(in which anxious people feel a lump in the throat without organic cause) and odynophagia (pain during swallowing, usually from gastro-oesophageal reflux or candidiasis).

Dysphagia can occur due to problems in the oropharynx or oesophagus (Fig. 23.16). Oropharyngeal disorders affect the initiation of swallowing at the pharynx and upper oesophageal sphincter. The patient has difficulty initiating swallowing and complains of choking, nasal regurgitation or tracheal aspiration. Drooling, dysarthria, hoarseness and cranial nerve or other neurological signs may be present. Oesophageal disorders cause dysphagia by obstructing the lumen or by affecting motility. Patients with oesophageal disease complain of food 'sticking' after

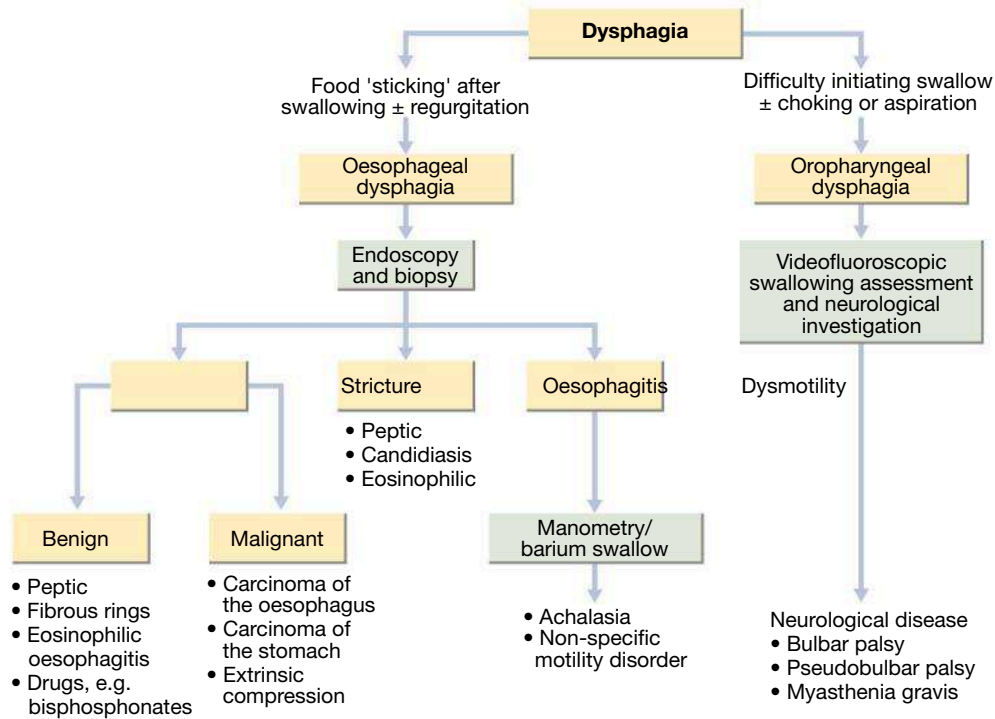

Fig. 23.16 Investigation of dysphagia.

swallowing, although the level at which this is felt correlates poorly with the true site of obstruction. Swallowing of liquids is normal until strictures become extreme.

### Investigations

Dysphagia should always be investigated urgently. Endoscopy is the investigation of choice because it allows biopsy and dilatation of strictures. Even if the appearances are normal, biopsies should be taken to look for eosinophilic oesophagitis. If no abnormality is found, then barium swallow with videofluoroscopic swallowing assessment can be used to detect major motility disorders. In some cases, high-resolution oesophageal manometry is required, allowing accurate classification of abnormalities. Figure 23.16 summarises a diagnostic approach to dysphagia and lists the major causes.

## Dyspepsia

Dyspepsia describes symptoms such as discomfort, bloating and nausea, which are thought to originate from the upper gastrointestinal tract. There are many causes (Box 23.14), including some arising outside the digestive system. Heartburn and other 'reflux' symptoms are separate entities and are considered elsewhere. Although symptoms often correlate poorly with the underlying diagnosis, a careful history is important to detect 'alarm' features requiring urgent investigation (Box 23.15) and to detect atypical symptoms that might be due to problems outside the gastrointestinal tract.

Dyspepsia affects up to 80% of the population at some time in life and most patients have no serious underlying disease. People who present with new dyspepsia at an age of more than 55 years and younger patients unresponsive to empirical treatment require investigation to exclude serious disease. An algorithm for the investigation of dyspepsia is outlined in Figure 23.17.

## Heartburn and regurgitation

Heartburn describes retrosternal, burning discomfort, often rising up into the chest and sometimes accompanied by regurgitation of acidic or bitter fluid into the throat. These symptoms often occur after meals, on lying down or with bending, straining or heavy lifting. They are classical

23.14 Causes of dyspepsia	
<b>Upper gastrointestinal disorders</b>	
<ul style="list-style-type: none"> <li>• Peptic ulcer disease</li> <li>• Acute gastritis</li> <li>• Gallstones</li> </ul>	<ul style="list-style-type: none"> <li>• Oesophageal spasm</li> <li>• Non-ulcer dyspepsia</li> <li>• Irritable bowel syndrome</li> </ul>
<b>Other gastrointestinal disorders</b>	
<ul style="list-style-type: none"> <li>• Pancreatic disease (cancer, chronic pancreatitis)</li> <li>• Colonic carcinoma</li> </ul>	<ul style="list-style-type: none"> <li>• Hepatic disease (hepatitis, metastases)</li> </ul>
<b>Systemic disease</b>	
<ul style="list-style-type: none"> <li>• Renal failure</li> </ul>	<ul style="list-style-type: none"> <li>• Hypercalcaemia</li> </ul>
<b>Drugs</b>	
<ul style="list-style-type: none"> <li>• Non-steroidal anti-inflammatory drugs (NSAIDs)</li> <li>• Glucocorticoids</li> </ul>	<ul style="list-style-type: none"> <li>• Iron and potassium supplements</li> <li>• Digoxin</li> </ul>
<b>Others</b>	
<ul style="list-style-type: none"> <li>• Psychological (anxiety, depression)</li> </ul>	<ul style="list-style-type: none"> <li>• Alcohol</li> </ul>

23.15 Alarm features in dyspepsia
<ul style="list-style-type: none"> <li>• Unintentional weight loss</li> <li>• Anaemia</li> <li>• Persistent vomiting</li> <li>• Haematemesis and/or melaena</li> <li>• Dysphagia</li> <li>• Palpable abdominal mass</li> </ul>

symptoms of gastro-oesophageal reflux but up to 50% of patients present with other symptoms, such as chest pain, belching, halitosis, chronic cough or sore throats. In young patients with typical symptoms and a good response to dietary changes, antacids or acid suppression investigation is not required, but patients aged over 55 years and those with alarm symptoms or atypical features need urgent endoscopy.

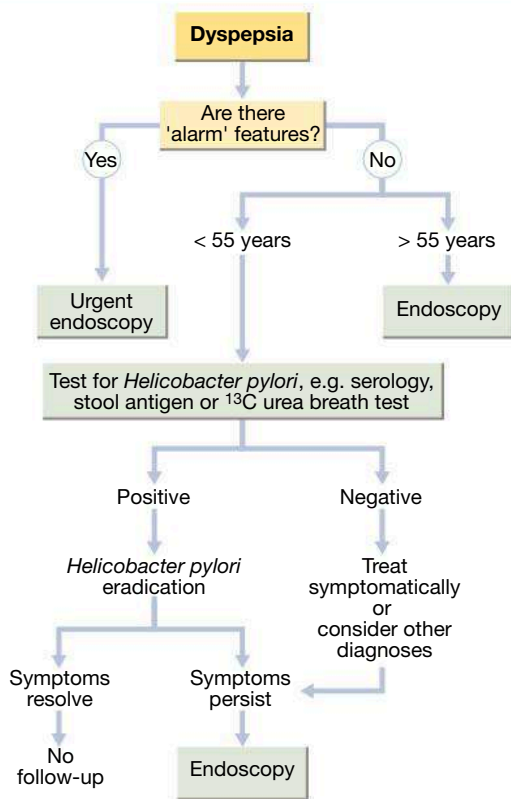

Fig. 23.17 Investigation of dyspepsia.

## Vomiting

Vomiting is a complex reflex involving both autonomic and somatic neural pathways. Synchronous contraction of the diaphragm, intercostal muscles and abdominal muscles raises intra-abdominal pressure and, combined with relaxation of the lower oesophageal sphincter, results in forcible ejection of gastric contents. It is important to distinguish true

vomiting from regurgitation and to elicit whether the vomiting is acute or chronic (recurrent), as the underlying causes may differ. The major causes are shown in Figure 23.18.

## Gastrointestinal bleeding

### Acute upper gastrointestinal bleeding

This is the most common gastrointestinal emergency, with an estimated incidence of 134 per 100 000 of the population in the UK; the mortality of patients admitted to hospital is around 10%. Risk scoring systems have been developed to stratify the risk of needing endoscopic therapy or of having a poor outcome (Box 23.16). The advantage of the Blatchford score is that it may be used before endoscopy to predict the need for intervention to treat bleeding. Low scores (2 or less) are associated with a very low risk of adverse outcome. The common causes are shown in Figure 23.19.

#### Clinical assessment

Haematemesis is red with clots when bleeding is rapid and profuse, or black ('coffee grounds') when less severe. Syncope may occur and is caused by hypotension from intravascular volume depletion. Symptoms of anaemia suggest chronic bleeding. Melaena is the passage of black, tarry stools containing altered blood; it is usually caused by bleeding from the upper gastrointestinal tract, although haemorrhage from the right side of the colon is occasionally responsible. The characteristic colour and smell are the result of the action of digestive enzymes and of bacteria on haemoglobin. Severe acute upper gastrointestinal bleeding can sometimes cause maroon or bright red stool.

#### Management

The principles of emergency management of non-variceal bleeding are discussed in detail below. Management of variceal bleeding is discussed on page 882.

#### 1. Intravenous access

The first step is to gain intravenous access, ideally using two large-bore cannulae.

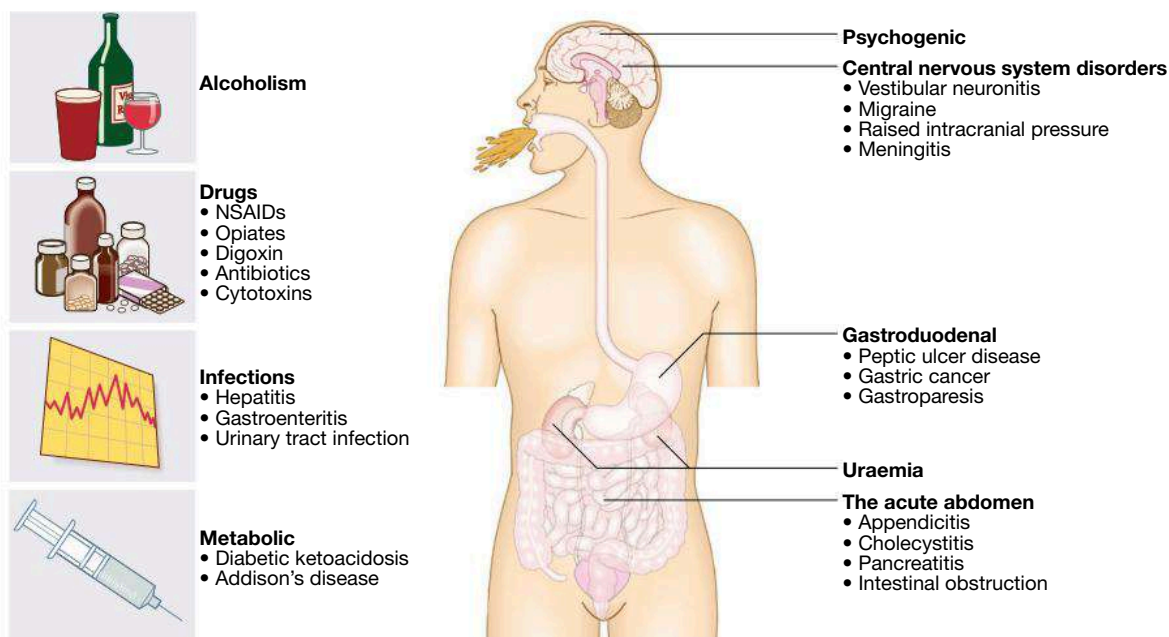

Fig. 23.18 Causes of vomiting. (NSAIDs = non-steroidal anti-inflammatory drugs)

23.16 Modified Blatchford score: risk stratification in acute upper gastrointestinal bleeding	
Admission risk marker	Score component value
<b>Blood urea</b>	
≥ 25 mmol/L (70 mg/dL)	6
10–25 mmol/L (28–70 mg/dL)	4
8–10 mmol/L (22.4–28 mg/dL)	3
6.5–8 mmol/L (18.2–22.4 mg/dL)	2
< 6.5 mmol/L (18.2 mg/dL)	0
<b>Haemoglobin for men</b>	
< 100 g/L (10 g/dL)	6
100–119 g/L (10–11.9 g/dL)	3
120–129 g/L (12–12.9 g/dL)	1
≥ 130 g/L (13 g/dL)	0
<b>Haemoglobin for women</b>	
< 100 g/L (10 g/dL)	6
100–119 g/L (10–11.9 g/dL)	1
≥ 120 g/L (12 g/dL)	0
<b>Systolic blood pressure</b>	
< 90 mmHg	3
90–99 mmHg	2
100–109 mmHg	1
> 109 mmHg	0
<b>Other markers</b>	
Presentation with syncope	2
Hepatic disease	2
Cardiac failure	2
Pulse ≥ 100 beats/min	1
Presentation with melaena	1
None of the above	0

## 2. Initial clinical assessment

- *Define circulatory status.* Severe bleeding causes tachycardia, hypotension and oliguria. The patient is cold and sweating, and may be agitated.
- *Seek evidence of liver disease* (p. 860). Jaundice, cutaneous stigmata, hepatosplenomegaly and ascites may be present in decompensated cirrhosis.
- *Identify comorbidity.* The presence of cardiorespiratory, cerebrovascular or renal disease is important, both because these may be worsened by acute bleeding and because they increase the hazards of endoscopy and surgical operations. These comorbidities are, therefore, a common cause of death following acute gastrointestinal haemorrhage, even after successful haemostasis.

## 3. Basic investigations

- *Full blood count.* Chronic or subacute bleeding leads to anaemia, but the haemoglobin concentration may be normal after sudden, major bleeding until haemodilution occurs. Thrombocytopenia may be a clue to the presence of hypersplenism in chronic liver disease.
- *Urea and electrolytes.* This test may show evidence of renal failure. The blood urea rises as the absorbed products of luminal blood are metabolised by the liver; an elevated blood urea with normal creatinine concentration implies severe bleeding.
- *Liver function tests.* These may show evidence of chronic liver disease.
- *Prothrombin time.* Check when there is a clinical suggestion of liver disease or patients are anticoagulated.
- *Cross-matching.* At least 2 units of blood should be cross-matched if a significant bleed is suspected.

## 4. Resuscitation

Intravenous crystalloid fluids should be given to raise the blood pressure, with a 500 ml bolus recommended over less than 15 minutes in haemodynamically unstable patients. In most patients, blood should be transfused when haemoglobin is less than 70 g/L, although transfusion should be considered at higher levels in those with haemodynamic instability or ischaemic heart disease.

Fig. 23.19 Causes of acute upper gastrointestinal haemorrhage. Frequency is given in parentheses. (NSAIDs = non-steroidal anti-inflammatory drugs)

## 5. Oxygen

Oxygen saturations should be monitored with pulse oximetry, with a target saturation of 94%–98% and oxygen prescribed as required.

## 6. Antithrombotic drugs

An increasing number of individuals present with an upper gastrointestinal bleed while using antithrombotic medication. Aspirin can be continued during an upper gastrointestinal bleed. P2Y<sub>12</sub>-receptor antagonists (e.g. clopidogrel) should be temporarily stopped (unless prescribed following coronary artery stenting), as well as warfarin and direct oral anti-coagulant therapy. However, early reintroduction of these medications should occur after haemostasis has been achieved to reduce thrombotic events and death.

## 7. Proton pump inhibitor (PPI) therapy

Intravenous PPI infusion should be given in non-variceal bleeding, in individuals who have a high-risk ulcer post endoscopy (e.g. ulcers with a clot and/or requiring endoscopic haemostasis). PPIs work by reducing gastric acid secretion, neutralising intragastric pH, promoting clot stability by reducing pepsin-induced clot lysis and increasing platelet aggregation. While intravenous PPI infusion is most frequently used, intermittent intravenous PPI and oral high-dose PPI can be considered as alternatives. [Box 23.17](#) outlines some common PPIs used.

23.17 Common proton pump inhibitors (PPIs) and dosage for peptic ulcer disease		
Oral administration		
	Standard dose	High dose
Lansoprazole	30 mg OD	30 mg BD
Omeprazole	20 mg OD	40 mg OD
Pantoprazole	40 mg OD	40 mg BD
Rabeprazole	20 mg OD	20 mg BD
Esomeprazole	20 mg OD	40 mg OD
Intravenous infusion		
	Dose	
Omeprazole Pantoprazole Esomeprazole	80 mg IV bolus, followed by 8 mg/hr for 72 hrs	
(BD = twice daily; IV = intravenous; OD = once daily)		

## 8. Endoscopy

This should be carried out after adequate resuscitation, ideally within 24 hours; it yields a diagnosis in approximately 80% of cases. Patients with major endoscopic stigmata of recent haemorrhage ([Fig. 23.20](#)) can be treated endoscopically using a thermal or mechanical modality, such as a 'heater probe' or endoscopic clips, combined with injection of dilute adrenaline (epinephrine) into the bleeding point ('dual therapy'). A biologically inert haemostatic mineral powder (TC325, 'haemospray') can be used as rescue therapy when standard therapy fails. This may stop active bleeding and combined with PPI therapy may prevent rebleeding, thus avoiding the need for surgery. Newer techniques, such as 'over-the-scope clips', may also be used as a rescue therapy when standard therapy fails, treating large vessels or fibrotic lesions. Patients found to have bled from varices should be treated by band ligation (p. 883); balloon tamponade is another option if this fails, while arrangements are made for a transjugular intrahepatic portosystemic shunt (TIPSS). Balloon tamponade can be associated with serious complications, and newer techniques, such as removable, self-expanding, covered metal oesophageal stents may be used as an alternative option.

## 9. Monitoring

Patients should be closely observed, with hourly measurements of pulse, blood pressure, oxygen saturations and urine output.

## 10. Radiology and surgery

Patients who have recurrent bleeding, where endoscopic attempts at haemostasis have failed, should be considered for radiological or surgical intervention. If available, angiographic control of bleeding is generally preferred to surgery in older, frail patients. If surgery is required, the choice of operation depends on the site and diagnosis of the bleeding lesion. Duodenal ulcers are treated by under-running, with or without pyloroplasty. Under-running for gastric ulcers can also be carried out (a biopsy must be taken to exclude carcinoma). Local excision may be performed, but when neither is possible, partial gastrectomy is required.

## 11. Eradication

Following treatment for ulcer bleeding, all patients should avoid non-steroidal anti-inflammatory drugs (NSAIDs) and those who test positive for *H. pylori* infection should receive eradication therapy (p. 814). Successful eradication should be confirmed by urea breath or faecal antigen testing.

**Fig. 23.20** Major stigmata of recent haemorrhage and endoscopic treatment. **A** Active bleeding from a duodenal ulcer. **B** Haemostasis is achieved after endoscopic injection of adrenaline (epinephrine) and application of a heater probe.

## Lower gastrointestinal bleeding

The incidence of lower gastrointestinal bleeding is around 30–90 per 100 000 of the population in the UK, with an in-hospital mortality of around 4%. This may be caused by haemorrhage from the colon, anal canal or small bowel. It is useful to distinguish those patients who present with profuse, acute bleeding from those who present with chronic or subacute bleeding of lesser severity (see [Box 23.18](#)).

### Severe acute lower gastrointestinal bleeding

This presents with profuse red or maroon diarrhoea and with hypovolaemic shock. If available, CT angiography should be performed initially to localise the site of blood loss. If the bleeding source is identified, then catheter angiography with embolisation should be performed. If no source of bleeding is found then a colonoscopy should be performed. Some patients presenting with an apparent severe lower GI bleed are ultimately found to have a significant upper GI bleed.

The commonest cause of lower GI bleeding is diverticular disease, with up to two-thirds of cases being classified as severe. Bleeding from diverticular disease is often due to erosion of an artery within the mouth of a diverticulum. Multiple endoscopic options are available, with endoscopic clipping either alone or after the injection of dilute adrenaline (epinephrine) considered as first-line treatment in the UK. Angiodysplasia is a disease of older adults, in which vascular malformations develop within the GI tract, commonly in the caecum. Bleeding can be acute and profuse; it usually stops spontaneously, but commonly recurs. Diagnosis is often difficult. Colonoscopy may reveal characteristic vascular spots and, in the acute phase, angiography can show bleeding into the intestinal lumen and an abnormal large, draining vein. The treatment of choice is endoscopic thermal ablation, but resection of the affected bowel may be required if bleeding continues. Bowel ischaemia due to occlusion of the inferior mesenteric artery can present with abdominal colic and rectal bleeding. It should be considered in patients (particularly older patients) who have evidence of generalised atherosclerosis. The diagnosis is made at colonoscopy. Resection is required only in the presence of peritonitis. Meckel's diverticulum with ectopic gastric epithelium may ulcerate and erode into a major artery. The diagnosis should be considered in children or adolescents who present with profuse or recurrent lower gastrointestinal bleeding. A Meckel's <sup>99m</sup>Tc-pertechnetate scan is sometimes positive, but the diagnosis is commonly made only by laparotomy, at which time the diverticulum is excised.

### Subacute or chronic lower gastrointestinal bleeding

This can occur at all ages and is usually due to haemorrhoids or anal fissure. Haemorrhoidal bleeding is bright red and occurs during or after defecation. Proctoscopy can be used to make the diagnosis, but individuals who have altered bowel habit and those who present over the age of 40 years should undergo colonoscopy to exclude coexisting colorectal cancer. Anal fissure should be suspected when fresh rectal bleeding and anal pain occur during defecation.

## i

### 23.18 Causes of lower gastrointestinal bleeding

#### Severe acute

- Diverticular disease
- Angiodysplasia
- Ischaemia
- Meckel's diverticulum
- Inflammatory bowel disease (rarely)

#### Moderate, chronic/subacute

- Fissure
- Haemorrhoids
- Inflammatory bowel disease
- Carcinoma
- Large polyps
- Angiodysplasia
- Radiation enteritis
- Solitary rectal ulcer

## Major gastrointestinal bleeding of unknown cause

In some patients who present with major gastrointestinal bleeding, upper endoscopy, colonoscopy and CT angiography may fail to reveal a diagnosis. Wireless capsule endoscopy is increasingly used in such patients. The diagnostic yield is highest when performed as close as possible to the bleeding episode, particularly within the first 48 hours of presenting with bleeding. Wireless capsule endoscopy is often used to define a source of bleeding prior to enteroscopy ([Fig. 23.21](#)), with push or double balloon enteroscopy being used to visualise the small intestine and treat the bleeding source. When all else fails, laparotomy with on-table endoscopy is indicated.

## Chronic occult gastrointestinal bleeding

In this context, occult means that blood or its breakdown products are present in the stool but cannot be seen by the naked eye. Occult bleeding may reach 200 mL per day and cause iron deficiency anaemia. Any cause of gastrointestinal bleeding may be responsible, but the most important is colorectal cancer, particularly carcinoma of the caecum, which may produce no gastrointestinal symptoms. In clinical practice, investigation of the upper and lower gastrointestinal tract should be considered whenever a patient presents with unexplained iron deficiency anaemia.

## Diarrhoea

Diarrhoea is defined as the passage of three or more loose or liquid stools per day. Stool weight was previously used to define diarrhoea (> 200 g stool per day), but is no longer recommended as normal stool volumes can exceed this value. The most severe symptom in many patients is urgency of defecation, while faecal incontinence can occur in acute and chronic diarrhoeal illnesses.

## Acute diarrhoea

This is extremely common and is usually caused by faecal–oral transmission of bacteria or their toxins, viruses or parasites (see [Ch. 13](#)). Infective diarrhoea is usually short-lived and patients who present with a history of diarrhoea lasting more than 10 days rarely have an infective cause. A variety of drugs, including antibiotics, cytotoxic drugs, PPIs and NSAIDs, may be responsible.

**Fig. 23.21** Angiodysplastic lesion noted on capsule endoscopy.

### 23.19 Chronic or relapsing diarrhoea

	Colonic	Malabsorption	Small bowel
<b>Clinical features</b>	Blood and mucus in stool Cramping lower abdominal pain	Steatorrhoea Undigested food in the stool Weight loss and nutritional disturbances	Large-volume, watery stool Abdominal bloating Cramping mid-abdominal pain
<b>Some causes</b>	Inflammatory bowel disease Microscopic colitis Neoplasia Ischaemia Irritable bowel syndrome	Pancreatic: Chronic pancreatitis Cancer of pancreas Cystic fibrosis Enteropathy: Coeliac disease Tropical sprue Lymphoma Lymphangiectasia	Crohn's disease Neuro-endocrine tumour Small bowel carcinoid VIPoma Drug-induced: NSAIDs Aminosalicylates SSRIs
<b>Investigations</b>	Faecal calprotectin Ileocolonoscopy with biopsies	Faecal elastase Ultrasound, CT and MRCP Small bowel biopsy Barium follow-through or small bowel MRI	Faecal calprotectin Stool volume Serum gut hormone profile and 24 hr urine 5HIAA Barium follow-through or small bowel MRI

(CT = computed tomography; 5HIAA = 5-hydroxyindoleacetic acid; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; NSAIDs = non-steroidal anti-inflammatory drugs; SSRIs = selective serotonin re-uptake inhibitors; VIP = vasoactive intestinal polypeptide)

### Chronic or relapsing diarrhoea

Chronic diarrhoea can be categorised as being caused by disease of the colon or small bowel, or due to malabsorption (Box 23.19). Clinical presentation, examination of the stool, routine blood tests and imaging reveal a diagnosis in many cases. Young patients (< 40 years) with typical symptoms of a functional bowel disorder, with negative initial investigations, may have a diagnosis of irritable bowel syndrome (p. 847).

### Malabsorption

Diarrhoea and weight loss in patients with a normal diet are likely to be caused by malabsorption. The symptoms are diverse in nature and variable in severity. A few patients have apparently normal bowel habit, but diarrhoea usually occurs and may be watery and voluminous. Bulky, pale and offensive stools that float in the toilet (steatorrhoea) signify fat malabsorption. Abdominal distension, borborygmi, cramps, weight loss and undigested food in the stool may be present. Some patients complain only of malaise and lethargy. In others, symptoms related to deficiencies of specific vitamins, trace elements and minerals may occur (Fig. 23.22).

### Pathophysiology

Malabsorption results from abnormalities of the three processes that are essential to normal digestion:

- *Intraluminal maldigestion* occurs when deficiency of bile or pancreatic enzymes results in inadequate solubilisation and hydrolysis of nutrients. Fat and protein malabsorption results. This may also occur with small bowel bacterial overgrowth.
- *Mucosal malabsorption* results from small bowel resection or conditions that damage the small intestinal epithelium, thereby diminishing the surface area for absorption and depleting brush border enzyme activity.
- *'Post-mucosal' lymphatic obstruction* prevents the uptake and transport of absorbed lipids into lymphatic vessels. Increased pressure in these vessels results in leakage into the intestinal lumen, leading to protein-losing enteropathy.

### Investigations

Investigations should be performed both to confirm the presence of malabsorption and to determine the underlying cause. Routine blood tests may show one or more of the abnormalities listed in Box 23.20. Tests to confirm fat and protein malabsorption should be performed (see Box 23.12). An approach to the investigation of malabsorption is shown in Figure 23.23.

### Weight loss

Weight loss may be physiological, due to dieting, exercise, starvation, or the decreased nutritional intake that accompanies old age. Weight loss of more than 5% of usual body weight over 6–12 months is clinically important and can indicate the presence of an underlying disease. Hospital and general practice weight records may be valuable in confirming that weight loss has occurred, as may reweighing patients at intervals; sometimes weight is regained or stabilises in those with no obvious cause. Pathological weight loss can be due to psychiatric illness, systemic disease, gastrointestinal causes or advanced disease of many organ systems (Fig. 23.24).

### Physiological causes

Weight loss can occur in the absence of serious disease in healthy individuals who have changes in physical activity or social circumstances. It may be difficult to be sure of this diagnosis in older patients, when the dietary history may be unreliable, and professional help from a dietician may be required.

### Psychiatric illness

Features of anorexia nervosa, bulimia and affective disorders (see Ch. 31) may be apparent only after formal psychiatric input. Patients with alcohol dependence lose weight as a consequence of self-neglect and poor dietary intake. Depression may cause weight loss.

### Systemic disease

Chronic infections, including tuberculosis (Ch. 17), recurrent urine or chest infections, and a range of parasitic and protozoan infections (Ch. 13), should be considered. A history of foreign travel, high-risk activities and specific features, such as fever, night sweats, rigors, productive cough and dysuria, must be sought. High-risk sexual activity and recreational drug misuse may suggest human immunodeficiency virus (HIV)-related illness (Ch. 14). Weight loss is a late feature of disseminated malignancy, but by the time the patient presents, other features of cancer are often present. Chronic inflammatory diseases, such as rheumatoid arthritis and polymyalgia rheumatica (Ch. 26), are often associated with weight loss.

### Gastrointestinal disease

Almost any disease of the gastrointestinal tract can cause weight loss. Dysphagia and gastric outflow obstruction (p. 816) cause weight loss by

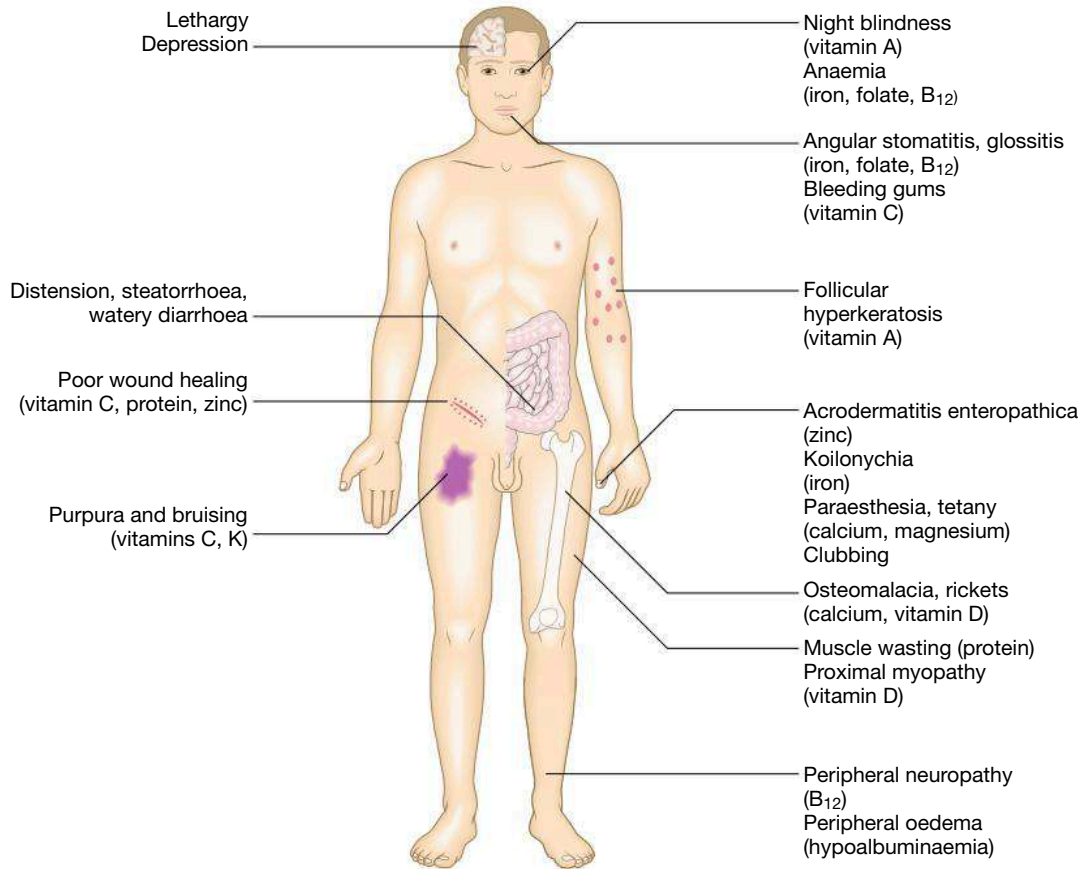

Fig. 23.22 Possible physical consequences of malabsorption.

23.20 Routine blood test abnormalities in malabsorption	
<b>Haematology</b>	<ul style="list-style-type: none"> <li>• Microcytic anaemia (iron deficiency)</li> <li>• Macrocytic anaemia (folate or B<sub>12</sub> deficiency)</li> <li>• Increased prothrombin time (vitamin K deficiency)</li> </ul>
<b>Biochemistry</b>	<ul style="list-style-type: none"> <li>• Hypoalbuminaemia</li> <li>• Hypocalcaemia</li> <li>• Hypomagnesaemia</li> <li>• Hypophosphataemia</li> <li>• Low serum zinc</li> </ul>

reducing food intake. Malignancy at any site may cause weight loss by mechanical obstruction, anorexia or cytokine-mediated systemic effects. Malabsorption from pancreatic diseases (p. 850) or small bowel causes may lead to profound weight loss with specific nutritional deficiencies (p. 766). Inflammatory diseases, such as Crohn's disease or ulcerative colitis (p. 835), cause anorexia, fear of eating and loss of protein, blood and nutrients from the gut.

#### Metabolic disorders and miscellaneous causes

Weight loss may occur in association with metabolic disorders, such as a new presentation of type 1 diabetes or thyrotoxicosis, as well as end-stage respiratory and cardiac disease.

#### Investigations

In cases where the cause of weight loss is not obvious after thorough history-taking and physical examination, or where an existing condition is considered unlikely, the following investigations are indicated: urinalysis for glucose, protein and blood; blood tests, including liver

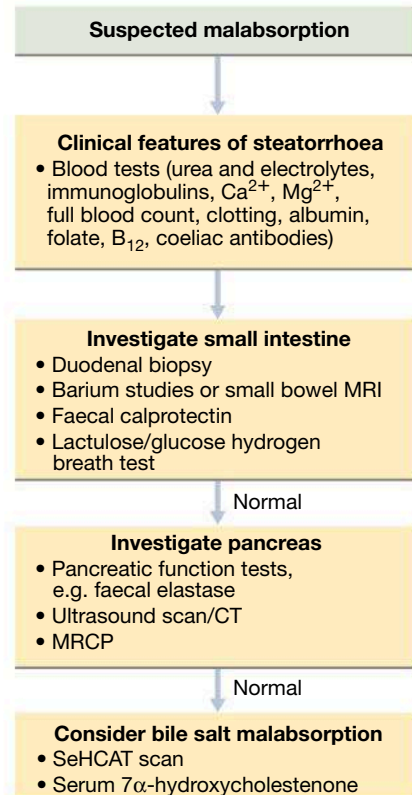

Fig. 23.23 Investigation for suspected malabsorption. (CT = computed tomography; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; <sup>75</sup>SeHCAT = <sup>75</sup>Se-homocholeic acid taurine)

**Fig. 23.24** Some important causes of weight loss.

function tests, random blood glucose and thyroid function tests; CRP and ESR (may be raised in unsuspected infections, such as tuberculosis, connective tissue disorders and malignancy); and faecal calprotectin. Where the cause of weight loss is still unclear, chest X-ray, whole-body CT imaging and/or endoscopic investigation may be required. Rarely, tests such as bone marrow aspiration or liver biopsy may be necessary to identify conditions like cryptic miliary tuberculosis (Ch. 17). Before embarking on invasive or very costly investigations, it is always worth revisiting the patient's history and reweighing at intervals.

## Constipation

Constipation is defined as infrequent passage of hard stools. Patients may also complain of straining, a sensation of incomplete evacuation and either perianal or abdominal discomfort. Constipation can be acute, typically lasting less than 1 week, or chronic, lasting greater than 4 weeks. Chronic constipation is normally due to a primary cause, such as dietary intake (e.g. insufficient fibre), lifestyle factors (e.g. sedentary lifestyle) or disorders of rectal evacuation.

Secondary causes of chronic constipation are numerous, including drugs such as opiates. [Box 23.21](#) outlines causes of constipation.

### Clinical assessment and management

The onset, duration and characteristics are important; for example, a neonatal onset suggests Hirschsprung's disease, while a recent change in bowel activity in middle age should raise the suspicion of an organic disorder, such as colonic carcinoma. The presence of rectal bleeding, pain and weight loss is important, as are excessive straining, symptoms suggestive of irritable bowel syndrome, a history of childhood constipation and emotional distress.

Careful examination contributes more to the diagnosis than extensive investigation. A search should be made for general medical disorders, as well as signs of intestinal obstruction. Neurological disorders, especially spinal cord lesions, should be sought. Perineal inspection and rectal examination are essential and may reveal abnormalities of the pelvic floor (abnormal descent, impaired sensation), anal canal or rectum (masses, faecal impaction, prolapse).

It is neither possible nor appropriate to investigate every person with constipation. For those with chronic constipation, investigation will usually proceed along the lines described below.

### Initial investigations

A thorough history and physical examination should be performed. Careful digital rectal examination and inspection of the perineum is essential, and useful in the assessment of pelvic floor abnormalities. A full blood count, routine biochemistry, including serum calcium and thyroid function tests, should be carried out. If these are normal, then dietary and lifestyle modifications should be advised, such as increased fluid intake, dietary fibre supplementation and exercise. Laxatives should be commenced if individuals fail to respond. Organic causes should be explored using colonoscopy in individuals with concerning symptoms (e.g. rectal bleeding, pain or weight loss).

### Further investigations

If no cause is found and disabling symptoms are present, then specialist referral for investigation of possible dysmotility may be necessary. The problem may be due to delayed transit of stool in the colon (slow transit constipation) or from functional abnormalities in the pelvic floor and anal sphincter muscles (dyssynergic defecation). Intestinal marker studies, anorectal manometry, electrophysiological studies and magnetic resonance proctography can all be used to define the problem.

## Abdominal pain

There are four types of abdominal pain:

- Visceral.** Gut organs are insensitive to stimuli such as burning and cutting but are sensitive to distension, contraction, twisting and stretching. Pain from unpaired structures is usually, but not always, felt in the midline.
- Parietal.** The parietal peritoneum is innervated by somatic nerves and its involvement by inflammation, infection or neoplasia causes sharp, well-localised and lateralised pain.
- Referred pain.** Gallbladder pain, for example, may be referred to the back or shoulder tip.
- Psychogenic.** Cultural, emotional and psychosocial factors influence everyone's experience of pain. In some patients, no organic cause can be found despite investigation, and psychogenic causes (depression or somatisation disorder) may be responsible (see Ch. 31).

The causes, assessment and management of acute abdominal pain are discussed in [Chapter 9](#).

### Chronic or recurrent abdominal pain

It is essential to take a detailed history, paying particular attention to features of the pain and any associated symptoms ([Boxes 23.22](#) and [23.23](#)).

Note should be made of the patient's general demeanour, mood and emotional state, signs of weight loss, fever, jaundice or anaemia. If a thorough abdominal and rectal examination is normal, a careful search should be made for evidence of disease affecting other structures, particularly the vertebral column, spinal cord, lungs and cardiovascular system.

23.22 Extra-intestinal causes of chronic or recurrent abdominal pain	
<b>Retroperitoneal</b>	
<ul style="list-style-type: none"> <li>Aortic aneurysm</li> <li>Malignancy</li> </ul>	<ul style="list-style-type: none"> <li>Lymphadenopathy</li> <li>Abscess</li> </ul>
<b>Psychogenic</b>	
<ul style="list-style-type: none"> <li>Depression</li> <li>Anxiety</li> </ul>	<ul style="list-style-type: none"> <li>Hypochondriasis</li> <li>Somatisation</li> </ul>
<b>Locomotor</b>	
<ul style="list-style-type: none"> <li>Vertebral compression/fracture</li> </ul>	<ul style="list-style-type: none"> <li>Abdominal muscle strain</li> </ul>
<b>Metabolic/endocrine</b>	
<ul style="list-style-type: none"> <li>Diabetes mellitus</li> <li>Acute intermittent porphyria</li> </ul>	<ul style="list-style-type: none"> <li>Hypercalcaemia</li> </ul>
<b>Drugs/toxins</b>	
<ul style="list-style-type: none"> <li>Glucocorticoids</li> <li>Azathioprine</li> </ul>	<ul style="list-style-type: none"> <li>Lead</li> <li>Alcohol</li> </ul>
<b>Haematological</b>	
<ul style="list-style-type: none"> <li>Sickle-cell disease</li> </ul>	<ul style="list-style-type: none"> <li>Haemolytic disorders</li> </ul>
<b>Neurological</b>	
<ul style="list-style-type: none"> <li>Spinal cord lesions</li> <li>Tabes dorsalis</li> </ul>	<ul style="list-style-type: none"> <li>Radiculopathy</li> </ul>

23.23 How to assess abdominal pain	
<ul style="list-style-type: none"> <li>Duration</li> <li>Site and radiation</li> <li>Severity</li> <li>Precipitating and relieving factors (food, drugs, alcohol, posture, movement, defecation)</li> <li>Nature (colicky, constant, sharp or dull, wakes patient at night)</li> <li>Pattern (intermittent or continuous)</li> <li>Associated features (vomiting, dyspepsia, altered bowel habit)</li> </ul>	

Investigations will depend on the clinical features elicited during the history and examination:

- Endoscopy and ultrasound are indicated for epigastric pain, and for dyspepsia and symptoms suggestive of gallbladder disease.
- Colonoscopy is indicated for patients with altered bowel habit, rectal bleeding or features of obstruction suggesting colonic disease.
- CT or MR angiography should be considered when pain is provoked by food in a patient with widespread atherosclerosis, as this may indicate mesenteric ischaemia.
- Persistent symptoms require exclusion of colonic or small bowel disease. However, young patients with pain related to defecation, bloating and alternating bowel habit are more likely to have irritable bowel syndrome (p. 847). Simple investigations (blood tests, faecal calprotectin and sigmoidoscopy) are sufficient in the absence of rectal bleeding, weight loss and abnormal physical findings.
- Ultrasound, CT and faecal elastase are required for patients with upper abdominal pain radiating to the back. A history of alcohol misuse, weight loss and diarrhoea suggests chronic pancreatitis or pancreatic cancer.
- Recurrent attacks of pain in the loins radiating to the flanks with urinary symptoms should prompt investigation for renal or ureteric stones by abdominal X-ray, ultrasound and computed tomography of the kidneys, ureters and bladder (CT KUB).
- Chronic abdominal wall pain (CAWP) should be considered when pain is clearly related to movement, with the commonest cause being anterior cutaneous nerve entrapment syndrome. A positive Carnett's sign (abdominal pain is unchanged or worsened when abdominal muscles are tensed, e.g. by asking the patient to lift their head and shoulders from the examination couch) may point towards

the diagnosis. CAWP is frequently overlooked and patients are often mis-diagnosed as having a functional disorder.

- A past history of psychiatric disturbance, repeated negative investigations or vague symptoms that do not fit any disease or organ pattern suggest a psychological origin for the pain. Careful review of case notes and previous investigations, along with open and honest discussion with the patient, reduces the need for further cycles of unnecessary and invasive tests. Care must always be taken, however, not to miss rare pathology, such as acute intermittent porphyria (p. 644) or atypical presentations of common diseases.

### Constant abdominal pain

Patients with chronic pain that is constant or nearly always present usually have features to suggest the underlying diagnosis. No cause will be found in a minority, despite thorough investigation, leading to consideration of functional causes of abdominal pain. Centrally mediated abdominal pain syndrome is characterised by severe constant or frequent abdominal pain that is rarely related to gut function, thought to result from abnormal CNS processing of normal visceral afferent sensory input and psychosocial factors are often operative (see Ch. 31). The management is reliant on establishing an effective patient–physician relationship, psychological support and the appropriate use of drugs such as tricyclic antidepressants to minimise the effects of the pain on social, personal and occupational life. Narcotic bowel syndrome may also present with constant abdominal pain, and is associated with increased or continuous use of opioids, with opioid-induced hyperalgesia thought to be the cause for symptoms. Patients tend to have an improvement in pain on withdrawal of opiates.

## Disorders of the mouth and salivary glands

### Aphthous ulceration

Aphthous ulcers are superficial and painful; they occur in any part of the mouth. Recurrent ulcers occur in around 20% of the population and are particularly common in women prior to menstruation. The cause is unknown, but in severe cases other causes of oral ulceration must be considered (Box 23.24). Biopsy is occasionally necessary for diagnosis.

Treatment is generally not required. Acute episodes may be treated with topical glucocorticoids (such as 0.1% triamcinolone in Orabase) or choline salicylate (8.7%) gel. Symptomatic relief is achieved using local anaesthetic mouthwashes. Rarely, patients with very severe, recurrent aphthous ulcers may need oral glucocorticoids.

### Oral cancer

Squamous carcinoma of the oral cavity is common worldwide and is more common in males. Five-year survival is around 50%, largely as a result of late diagnosis. Poor diet, alcohol excess and smoking or tobacco chewing are the traditional risk factors but high-risk, oncogenic strains of human papillomavirus (HPV-16 and HPV-18) have been identified as being responsible for much of the recent increase in incidence, especially in cases affecting the base of tongue, soft palate and tonsils. In parts of Asia, the disease is common among people who chew areca nuts wrapped in leaves of the betel plant ('betel nuts').

Oral cancer may present in many ways (Box 23.25) and a high index of suspicion is required. All possible sources of local trauma or infection should be treated in patients with suspicious lesions and they should be reviewed after 2 weeks, with biopsy if the lesion persists. Small cancers can be resected but extensive surgery, with neck dissection to remove involved lymph nodes, may be necessary. Some patients can be treated with radical radiotherapy alone, and sometimes chemoradiotherapy is also given after surgery to treat microscopic residual disease. Some tumours may be amenable to photodynamic therapy (PDT), avoiding the need for surgery. Recurrent or metastatic disease may require treatment with the monoclonal antibody cetuximab

### 23.24 Causes of oral ulceration

#### Aphthous

- Idiopathic
- Premenstrual

#### Infection

- Fungal (candidiasis)
- Bacterial, including syphilis, tuberculosis
- Viral (herpes simplex, HIV)

#### Gastrointestinal diseases

- Crohn's disease
- Coeliac disease

#### Dermatological conditions

- Lichen planus
- Dermatitis herpetiformis
- Immunobullous disorders (Ch. 27)
- Erythema multiforme

#### Drugs

- Nicorandil, NSAIDs, methotrexate, penicillamine, losartan, ACE inhibitors
- Stevens–Johnson syndrome (Ch. 27)
- Cytotoxic drugs

#### Systemic diseases

- Systemic lupus erythematosus (Ch. 26)
- Behçet's disease (Ch. 26)

#### Neoplasia

- Carcinoma
- Kaposi's sarcoma
- Leukaemia

(ACE = angiotensin-converting enzyme; HIV = human immunodeficiency virus; NSAIDs = non-steroidal anti-inflammatory drugs)

### 23.25 Symptoms and signs of oral cancer

- Solitary ulcer without precipitant, e.g. local trauma
- Solitary white patch ('leukoplakia') that fails to wipe off
- Solitary red patch
- Fixed lump
- Lip numbness in absence of trauma or infection
- Trismus (pain/difficulty in opening the mouth)
- Cervical lymphadenopathy

(an epidermal growth factor receptor inhibitor), in combination with chemotherapy.

### Candidiasis

The yeast *Candida albicans* is a normal mouth commensal, but it may proliferate to cause thrush. This occurs in babies, debilitated patients, people receiving glucocorticoid or antibiotic therapy, individuals with diabetes and immunosuppressed patients, especially those receiving cytotoxic therapy and those with HIV infection. White patches are seen on the tongue and buccal mucosa. Odynophagia or dysphagia suggests pharyngeal and oesophageal candidiasis. A clinical diagnosis is sufficient to instigate therapy, although brushings or biopsies can be obtained for mycological examination. Oral thrush can be treated using topical treatments such as miconazole or nystatin. Resistant cases or immunosuppressed patients may require oral fluconazole.

### Parotitis

Parotitis is caused by viral or bacterial infection. Mumps causes a self-limiting acute parotitis (p. 284). Bacterial parotitis usually occurs as a complication of major surgery. It is a consequence of dehydration and poor oral hygiene, and can be avoided by good post-operative care. Patients present with painful parotid swelling and this can be complicated by abscess formation. Broad-spectrum antibiotics are required, while surgical drainage is necessary for abscesses. Other causes of salivary gland enlargement are listed in Box 23.26 and implications of oral health in older people are discussed in Box 23.27.

## i

## 23.26 Causes of salivary gland swelling

- Infection:
  - Mumps
  - Bacterial (post-operative)
- Calculi
- Sjögren syndrome (Ch. 26)
- Sarcoidosis
- Tumours:
  - Benign: pleomorphic adenoma (95% of cases)
  - Intermediate: mucoepidermoid tumour
  - Malignant: carcinoma

## 23.27 Oral health in old age

- **Dry mouth:** affects around 40% of healthy older people.
- **Gustatory and olfactory sensation:** declines and chewing power is diminished.
- **Salivation:** baseline salivary flow falls, but stimulated salivation is unchanged.
- **Root caries and periodontal disease:** common partly because oral hygiene deteriorates with increasing frailty.
- **Bacteraemia and sepsis:** may complicate Gram-negative anaerobic infection in the periodontal pockets of the very frail.

## Disorders of the oesophagus

## Gastro-oesophageal reflux disease

Gastro-oesophageal reflux resulting in heartburn affects approximately 15% of the general population.

## Pathophysiology

Occasional episodes of gastro-oesophageal reflux are common in healthy individuals. Reflux is normally followed by oesophageal peristaltic waves that efficiently clear the gullet, alkaline saliva neutralises residual acid and symptoms do not occur. Gastro-oesophageal reflux disease develops when the oesophageal mucosa is exposed to gastroduodenal contents for prolonged periods of time, resulting in symptoms and, in a proportion of cases, oesophagitis. Several factors are known to be involved in the development of gastro-oesophageal reflux disease and these are shown in [Figure 23.25](#).

## Abnormalities of the lower oesophageal sphincter

The lower oesophageal sphincter is tonically contracted under normal circumstances, relaxing only during swallowing (see [Fig. 23.1](#)).

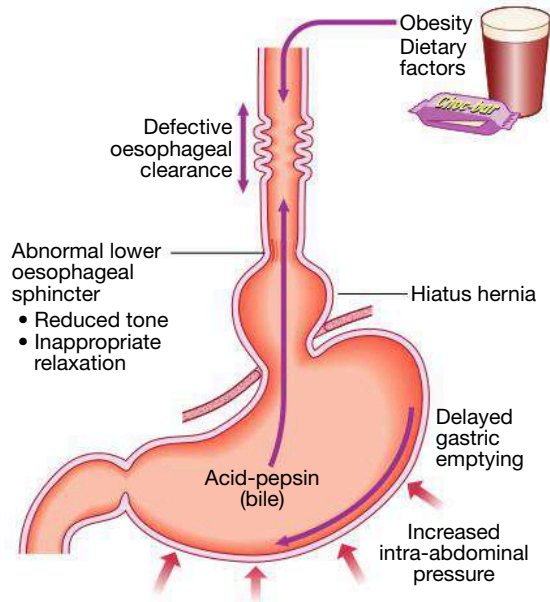

Some patients with gastro-oesophageal reflux disease have reduced lower oesophageal sphincter tone, permitting reflux when intra-abdominal pressure rises. In others, basal sphincter tone is normal, but reflux occurs in response to frequent episodes of inappropriate sphincter relaxation.

## Hiatus hernia

Hiatus hernia ([Box 23.28](#) and [Fig. 23.26](#)) causes reflux because the pressure gradient is lost between the abdominal and thoracic cavities, which normally pinches the hiatus. In addition, the oblique angle between the cardia and oesophagus disappears. Many patients who have large hiatus hernias develop reflux symptoms but the relationship between the presence of a hernia and symptoms is poor. Nevertheless, almost all patients who develop oesophagitis, Barrett's oesophagus or peptic strictures are found to have a hiatus hernia.

## Delayed oesophageal clearance

Defective oesophageal peristaltic activity is commonly found in patients who have oesophagitis. It is a primary abnormality, since it persists after

**Fig. 23.25** Factors associated with the development of gastro-oesophageal reflux disease.

## i

## 23.28 Important features of hiatus hernia

- Herniation of the stomach through the diaphragm into the chest
- Occurs in 30% of the population over the age of 50 years
- Often asymptomatic
- Heartburn and regurgitation can occur
- Gastric volvulus may complicate large hernias

oesophagitis has been healed by acid-suppressing drug therapy. Poor oesophageal clearance leads to increased acid exposure time.

## Gastric contents

Gastric acid is the most important oesophageal irritant and there is a close relationship between acid exposure time and symptoms. Pepsin and bile also contribute to mucosal injury.

## Defective gastric emptying

Gastric emptying is delayed in patients with gastro-oesophageal reflux disease. The reason is unknown.

## Increased intra-abdominal pressure

Pregnancy and obesity are established predisposing causes. Weight loss may improve symptoms.

## Dietary and environmental factors

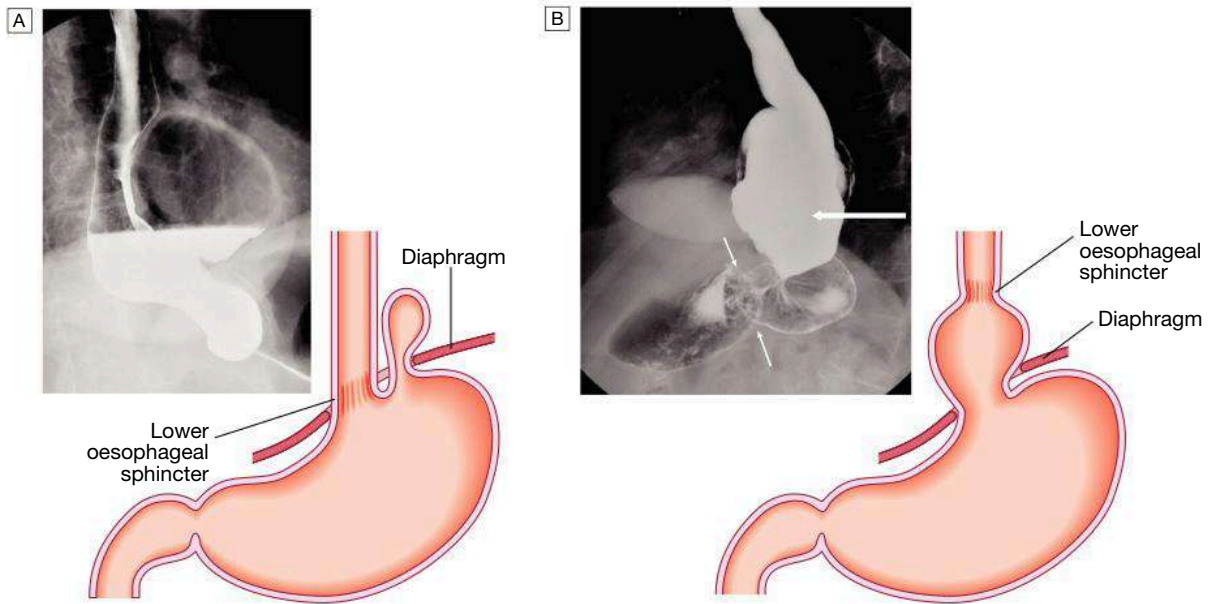

Dietary fat, chocolate, alcohol, tea and coffee relax the lower oesophageal sphincter and may provoke symptoms. The foods that trigger symptoms vary widely between affected individuals.

## Patient factors

Visceral sensitivity and patient vigilance play a role in determining symptom severity and consulting behaviour in individual patients.

## Clinical features

The major symptoms are heartburn and regurgitation, often provoked by bending, straining or lying down. 'Waterbrash', which is salivation due to reflex salivary gland stimulation as acid enters the gullet, is often present. Gastro-oesophageal reflux is commoner in older people ([Box 23.29](#)) and in those who are overweight. Some patients are woken at night by

**Fig. 23.26** Types of hiatus hernia. **A** Rolling or para-oesophageal. *Inset:* Barium meal showing a large para-oesophageal hernia with intrathoracic stomach. **B** Sliding. *Inset:* Barium meal showing a gastric volvulus (small arrows) complicating a sliding hiatus hernia (large arrow).

**23.29 Gastro-oesophageal reflux disease in old age**

- **Prevalence:** higher.
- **Severity of symptoms:** does not correlate with the degree of mucosal inflammation.
- **Complications:** late complications, such as peptic strictures or bleeding from oesophagitis, are more common.
- **Recurrent pneumonia:** consider aspiration from occult gastro-oesophageal reflux disease.

choking as refluxed fluid irritates the larynx. Others develop odynophagia or dysphagia. A variety of other features have been described, such as atypical chest pain that may be severe and can mimic angina; it may be due to reflux-induced oesophageal spasm. Others include hoarseness ('acid laryngitis'), recurrent chest infections, chronic cough and asthma. The true relationship of these features to gastro-oesophageal reflux disease remains unclear.

### Complications

#### Oesophagitis

A range of endoscopic findings is recognised, from mild redness to severe bleeding ulceration with stricture formation, although appearances may be completely normal (Fig. 23.27). There is a poor correlation between symptoms and histological and endoscopic findings.

#### Barrett's oesophagus

Barrett's oesophagus is a pre-malignant condition, in which the normal squamous lining of the lower oesophagus is replaced by columnar mucosa (columnar lined oesophagus; CLO) that may contain areas of intestinal metaplasia (Fig. 23.28). Patients are often asymptomatic until discovered, and can present with oesophageal cancer. Barrett's oesophagus is an adaptive response to chronic gastro-oesophageal reflux and is found in 10% of patients undergoing gastroscopy for reflux symptoms. The estimated prevalence in Western countries is 1%–2% of the population. The relative risk of oesophageal cancer is increased 40–120-fold, but the absolute risk is low (0.1%–0.5% per year). The epidemiology and aetiology of Barrett's oesophagus are poorly understood. The prevalence

**Fig. 23.27** Severe reflux oesophagitis. There is near-circumferential superficial ulceration and inflammation extending up the gullet.

is increasing, and it is more common in men (especially of European ancestry), the obese (central obesity in particular) and those over 50 years of age. Cigarette smoking is a moderate risk factor, while there is a less clear association with alcohol. The risk of cancer seems to relate to the severity and duration of reflux rather than the presence of Barrett's oesophagus per se, and it has been suggested that duodenogastro-oesophageal reflux of bile, pancreatic enzymes and pepsin, as well as gastric acid, may be important in the pathogenesis. The molecular events underlying progression of Barrett's oesophagus to dysplasia and cancer are incompletely understood, but inactivation of the tumour suppression protein p16 by loss of heterozygosity or promoter hypermethylation is a key event, followed by somatic inactivation of *TP53*, which promotes aneuploidy and tumour progression. Studies are in progress to develop biomarkers that will allow detection of those at higher cancer risk, but are currently not used in clinical practice.

**Fig. 23.28** Barrett's oesophagus. Tongues of pink columnar mucosa are seen extending upwards above the oesophago-gastric junction.

### Diagnosis

Endoscopy is the gold standard for diagnosis. Multiple systematic biopsies are taken, in addition to sampling any visible lesions, to maximise the chance of detecting intestinal metaplasia and/or dysplasia.

### Management

Neither potent acid suppression nor anti-reflux surgery stops progression or induces regression of Barrett's oesophagus, and treatment is indicated only for symptoms of reflux or complications, such as stricture. Endoscopic therapies can induce regression and at present may be used for those with dysplasia and mucosal oesophageal adenocarcinoma. Regular endoscopic surveillance can detect dysplasia at an early stage and may improve survival but, because most Barrett's oesophagus is undetected until cancer develops, surveillance strategies are unlikely to influence the overall mortality rate of oesophageal cancer. Surveillance is expensive and the cost-effectiveness of this approach is debatable. Currently, surveillance intervals for Barrett's oesophagus are risk stratified by the length of the Barrett's oesophagus segment, and by the presence and grade of dysplasia.

For those with high-grade dysplasia or intramucosal carcinoma, the treatment options are either oesophagectomy or endoscopic therapy, with a combination of endoscopic resection of any visibly abnormal areas and radiofrequency ablation (RFA) of the remaining Barrett's mucosa, as an 'organ-preserving' alternative to surgery. Promising alternative ablative therapies to RFA are in development, such as cryoablation, but further studies are required before recommending these as a second-line option for patients who fail to respond to RFA.

### Anaemia

Iron deficiency anaemia can occur as a consequence of occult blood loss from long-standing oesophagitis. Most patients have a large hiatus hernia and bleeding can stem from subtle erosions in the neck of the sac ('Cameron lesions'). Nevertheless, hiatus hernia is very common and other causes of blood loss, particularly colorectal cancer, must be considered in anaemic patients, even when endoscopy reveals oesophagitis.

### Benign oesophageal stricture

Fibrous strictures can develop as a consequence of long-standing oesophagitis, especially in older people and those with poor oesophageal peristaltic activity. The typical presentation is with dysphagia that is worse for solids than for liquids. Bolus obstruction following ingestion of meat causes absolute dysphagia. A history of heartburn is common but not invariable; many patients presenting in old age with strictures have no preceding heartburn.

Diagnosis is by endoscopy, when biopsies of the stricture can be taken to exclude malignancy. Endoscopic balloon dilatation or bougienage is helpful. Subsequently, long-term therapy with a PPI at full dose should be started to reduce the risk of recurrent oesophagitis and stricture formation. The patient should be advised to chew food thoroughly and it is important to ensure adequate dentition.

### Gastric volvulus

Occasionally, a massive intrathoracic hiatus hernia may twist on itself, leading to a gastric volvulus. This gives rise to complete oesophageal or gastric obstruction and the patient presents with severe chest pain, vomiting and dysphagia. The diagnosis is made by chest X-ray (air bubble in the chest) and barium swallow (see Fig. 23.26B). A nasogastric tube is normally inserted in the acute phase to facilitate decompression, with surgery usually advised after the acute episode. Endoscopic decompression may be an alternative option in selected patients in old age.

### Investigations

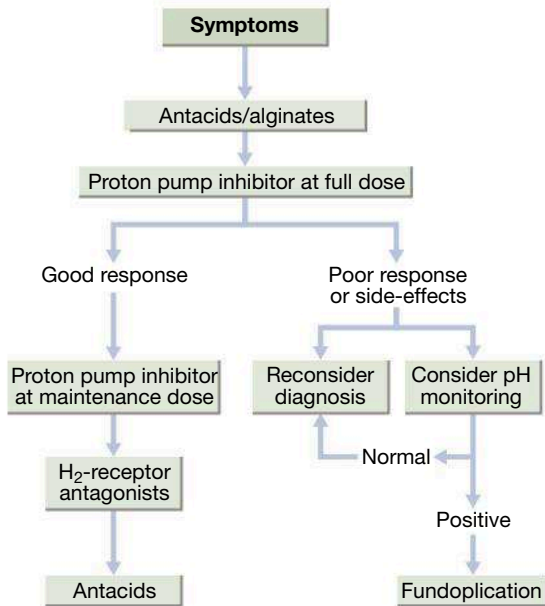

Young patients who present with typical symptoms of gastro-oesophageal reflux, without worrying features such as dysphagia, weight loss or anaemia, can be treated empirically without investigation. Investigation is advisable if patients present over the age of 50–55 years, if symptoms are atypical or if a complication is suspected. Endoscopy is the investigation of choice. This is performed to exclude other upper gastrointestinal diseases that can mimic gastro-oesophageal reflux and to identify complications. A normal endoscopy in a patient with compatible symptoms should not preclude treatment for gastro-oesophageal reflux disease.

Oesophageal pH monitoring is indicated if the diagnosis is unclear or surgical intervention is under consideration. This involves tethering a slim catheter with a terminal radiotelemetry pH-sensitive probe above the gastro-oesophageal junction; wireless oesophageal pH monitoring is available in some centres for those intolerant of catheter-based monitoring. Intraluminal pH is recorded while the patient undergoes normal activities, and episodes of symptoms are noted and related to pH. An oesophageal pH of less than 4 for more than 6% of the study time is considered diagnostic for reflux disease. In patients with difficult reflux, impedance testing can detect weakly acidic or alkaline reflux that is not revealed by standard pH testing.

### Management

A treatment algorithm for gastro-oesophageal reflux is outlined in Figure 23.29. Lifestyle advice should be given, including weight loss, avoidance of dietary items that worsen symptoms, elevation of the bed head in those who experience nocturnal symptoms, avoidance of late meals and cessation of smoking. Patients who fail to respond to these measures should be offered PPIs, which are usually effective in resolving symptoms and healing oesophagitis. Recurrence of symptoms is common when therapy is stopped and some patients require life-long treatment at the lowest acceptable dose. When dysmotility features are prominent, prokinetics such as domperidone (not available in the United States) or metoclopramide can be helpful. There is no evidence that *H. pylori* eradication has any therapeutic value. Proprietary antacids and alginates can also provide symptomatic benefit.  $H_2$ -receptor antagonist drugs relieve symptoms without healing oesophagitis.

Long-term PPI therapy can lead to the development of parietal cell hyperplasia and hypertrophy, leading to acid rebound on withdrawal of PPIs after long-term usage. PPI therapy is also associated with reduced absorption of iron,  $B_{12}$  and magnesium. The drugs may also predispose to enteric infections with *Salmonella*, *Campylobacter* and possibly *Clostridioides difficile*. They may have an undesirable impact on the composition of the gut microbiota, although the clinical importance of this is unclear. An association between microscopic colitis and PPIs has also been suggested, as well as with acute interstitial nephritis. Long-term therapy increases the risk of *Helicobacter*-associated progression of gastric mucosal atrophy (see below) and *H. pylori* eradication is advised in patients requiring PPIs for more than 1 year. The risks described with PPIs are relatively modest, but patients should receive the lowest dose of PPIs to manage their symptoms.

**Fig. 23.29** Treatment of gastro-oesophageal reflux disease: a 'step-down' approach.

Patients who fail to respond to medical therapy, those who are unwilling to take long-term PPIs and those whose major symptom is severe regurgitation should be considered for laparoscopic fundoplication (see this book's companion text, *Principles and Practice of Surgery*); endoscopic anti-reflux procedures are currently in development.

## Other causes of oesophagitis

### Infection

Oesophageal candidiasis occurs in debilitated patients and those taking broad-spectrum antibiotics or cytotoxic drugs. It is a particular problem in patients with HIV/AIDS, who are also susceptible to a spectrum of other oesophageal infections (p. 359).

### Corrosives

Suicide attempt by ingestion of caustic acid (e.g. vinegar) or alkaline agents (e.g. bleach) is followed by painful burns of the mouth and pharynx and by extensive erosive oesophagitis (p. 234). Late complications include oesophageal strictures, which may require endoscopic dilatation or stent insertion, or surgery in severe cases.

### Drugs

Potassium supplements and NSAIDs may cause oesophageal ulcers when the tablets are trapped above an oesophageal stricture. Liquid preparations of these drugs should be used in such patients. Bisphosphonates cause oesophageal ulceration and should be used with caution in patients with known oesophageal disorders. Tetracyclines, such as doxycycline, can also cause oesophagitis.

### Eosinophilic oesophagitis

This is an increasingly recognised condition, that affects both children and adults, and is more common in males. It occurs more often in atopic individuals and is characterised by eosinophilic infiltration of the oesophageal mucosa. Children commonly present with vomiting, difficulty feeding or failure to thrive. In contrast, adults present with dysphagia or food bolus obstruction more often than heartburn, while other symptoms, such as chest pain may be present. Endoscopy is usually normal, but mucosal rings, longitudinal furrows, exudates, oedema, strictures or a narrow-calibre oesophagus can occur (Fig. 23.30). To obtain a diagnosis, multiple biopsies should be taken from different levels of the oesophagus.

**Fig. 23.30** Endoscopic features suggestive of eosinophilic oesophagitis.

One of the features noted on histology is an increase in eosinophil density ( $\geq 15$  eosinophils per high-powered field (HPF)).

Dietary modifications are an effective first-line treatment for this condition, and include elemental and elimination diets. Adherence to these diets can be challenging, particularly in adults. In terms of pharmacological management, an empiric 8-week trial of high-dose PPI can be used in the first instance. Around one-third of patients will respond to this, known as PPI-responsive oesophageal eosinophilia. In patients who do not respond, 8–12 weeks of therapy with topical glucocorticoids can be used, such as fluticasone and budesonide. Fluticasone is delivered by spraying into the mouth via a metered-dose inhaler, and swallowed rather than inhaled. Budesonide is administered as an oral viscous solution. There are few pharmacological options beyond this, with biologic agents currently experimental. Endoscopic oesophageal dilatation may be considered in individuals with strictures or mucosal rings that have failed to respond to medical therapy.

## Benign oesophageal stricture

Benign oesophageal stricture is usually a consequence of gastro-oesophageal reflux disease (Box 23.30) and occurs most often in older adults who have poor oesophageal clearance. Rings, caused by sub-mucosal fibrosis, are found at the oesophago-gastric junction ('Schatzki ring') and cause intermittent dysphagia, often starting in middle age. A post-cricoid web is a rare complication of iron deficiency anaemia (Paterson–Kelly or Plummer–Vinson syndrome), and may be complicated by the development of squamous carcinoma. Benign strictures can be treated by endoscopic dilatation, in which wire-guided bougies or balloons are used to disrupt the fibrous tissue of the stricture.

## Tumours of the oesophagus

### Benign tumours

The most common is a leiomyoma. This is usually asymptomatic, but may cause bleeding or dysphagia.

### Carcinoma of the oesophagus

Squamous oesophageal cancer (Box 23.31) accounts for 90% of oesophageal cancers globally, being more common in Iran, areas of Africa and China. Squamous cancer can occur in any part of the oesophagus, although almost all tumours in the upper oesophagus are squamous cancers. Adenocarcinomas typically arise in the lower third

## i

**23.30 Causes of oesophageal stricture**

- Gastro-oesophageal reflux disease
- Webs and rings
- Carcinoma of the oesophagus or cardia
- Eosinophilic oesophagitis
- Extrinsic compression from bronchial carcinoma
- Corrosive ingestion
- Post-operative scarring following oesophageal resection
- Following radiotherapy
- Following long-term nasogastric intubation
- Bisphosphonates

## i

**23.31 Squamous carcinoma: aetiological factors**

- Smoking
- Alcohol excess
- Chewing betel nuts or tobacco
- Achalasia of the oesophagus
- Coeliac disease
- Post-cricoid web
- Post-caustic stricture
- Tylosis (familial hyperkeratosis of palms and soles)

of the oesophagus from Barrett's oesophagus or from the cardia of the stomach, and are more common in America, Australia and Europe. The incidence is increasing possibly as a result of the high prevalence of gastro-oesophageal reflux and Barrett's oesophagus in Western populations. Despite modern treatment, the overall 5-year survival of patients presenting with oesophageal cancer is less than 20%.

**Clinical features**

Most patients have a history of progressive, painless dysphagia for solid foods. Others present acutely because of food bolus obstruction. In the late stages, weight loss is often extreme; chest pain or hoarseness suggests mediastinal invasion. Fistulation between the oesophagus and the trachea or bronchial tree leads to coughing after swallowing, pneumonia and pleural effusion. Physical signs may be absent but, even at initial presentation, cachexia, cervical lymphadenopathy or other evidence of metastatic spread is common.

**Investigations**

The investigation of choice is upper gastrointestinal endoscopy (Fig. 23.31) with biopsy. Once a diagnosis has been made, investigations should be performed to stage the tumour and define operability. Thoracic and abdominal CT, often combined with positron emission tomography (PET-CT), should be carried out to identify metastatic spread and local invasion (Fig. 23.32). Invasion of the aorta, major airways or coeliac axis usually precludes surgery, but patients with resectable disease on imaging should undergo EUS to determine the depth of penetration of the tumour into the oesophageal wall and to detect locoregional lymph node involvement (Fig. 23.33). These investigations will define the TNM (tumour, node, metastases) stage of the disease (Box 7.3).

**Management**

Endoscopic management is an option in specialist centres for very early superficial tumours. Techniques such as endoscopic mucosal resection or endoscopic submucosal dissection with or without radiofrequency ablation, have become established for Barrett's oesophagus and, in particular, adenocarcinoma. Oesophagectomy is the treatment of choice for limited and locally advanced tumours where resection is possible. For locally advanced tumours, neoadjuvant and perioperative chemotherapy or chemoradiotherapy (e.g. cisplatin and capecitabine) can reduce the tumour bulk and increase the chances of complete (R0) surgical resection. Neoadjuvant therapy can also relieve dysphagia and improve nutritional status. Some patients with squamous carcinoma can have a

**Fig. 23.31 Adenocarcinoma of the lower oesophagus.** A polypoidal adenocarcinoma in association with Barrett's oesophagus.

**Fig. 23.32 Positron emission tomography–computed tomography (PET-CT) staging of oesophageal carcinoma.** Whole-body PET scan showing avid uptake in the primary tumour (thick arrow) but also in distant paratracheal (superior thin arrow) and gastro-oesophageal (inferior thin arrow) lymph nodes.

complete response following definitive chemoradiotherapy, with a subset not requiring surgery initially but close surveillance. All cases should be discussed within a multidisciplinary oesophageal cancer team (MDT).

Approximately 70% of patients have extensive disease at presentation; in these, treatment is palliative and should focus on relief of dysphagia and pain. Palliative radiotherapy or stent placement can be used for symptom control. Palliative chemotherapy can be used for selected patients, particularly for those with adenocarcinoma. Quality of life can be improved by nutritional support and appropriate analgesia.

**Perforation of the oesophagus**

Oesophageal perforation is a rare but potentially life-threatening clinical condition. The most common cause is iatrogenic endoscopic perforation complicating dilatation or intubation. Malignant, corrosive or post-radiotherapy strictures are more likely to be perforated than peptic strictures.

**Fig. 23.33** Endoscopic ultrasound staging of oesophageal carcinoma. There is a superficial adenocarcinoma of the oesophagus (T). The submucosa (white band, white arrows) is not involved but there is a small involved local lymph node (white arrow, inset). The tumour is therefore staged T1a, N1.

Spontaneous oesophageal perforation ('Boerhaave syndrome') results from forceful vomiting and retching, accounting for around 15% of cases. Severe chest pain and shock occur as oesophago-gastric contents enter the mediastinum and thoracic cavity. Subcutaneous emphysema, pleural effusions and pneumothorax develop. The diagnosis can be made using a water-soluble contrast swallow but, in difficult cases, both CT and careful endoscopy (usually in an intubated patient) may be required. Delay in diagnosis is a key factor in the high mortality associated with this condition.

Surgery remains the mainstay of treatment for oesophageal perforation. However, an increasing subgroup of patients are being managed via non-operative measures, such as individuals with small well-defined tears. Non-operative options include conservative management involving broad spectrum antibiotics and parental nutrition, and endoscopic management such as clip placement.

## Oesophageal motility disorders

### Pharyngeal pouch

This occurs because of incoordination of swallowing within the pharynx, which leads to herniation through the cricopharyngeus muscle and formation of a pouch. It is rare, affecting 1 in 100 000 people; it occurs predominantly in men, and is most common in the seventh and eighth decades of life. Many patients have no symptoms, but regurgitation, halitosis and dysphagia can be present. Some notice gurgling in the throat after swallowing. The investigation of choice is a barium swallow (see Fig. 23.12A), which demonstrates the pouch and reveals incoordination of swallowing, often with pulmonary aspiration. Treatment is indicated in symptomatic patients, and can be via a surgical approach, such as cricopharyngeus myotomy (diverticulotomy), with or without resection of the pouch. Recently, there has been the development of minimally invasive endoscopic approaches, such as endoscopic diverticulectomy.

### Achalasia of the oesophagus

#### Pathophysiology

Achalasia is characterised by:

- a hypertonic lower oesophageal sphincter, which fails to relax in response to the swallowing wave
- failure of propagated oesophageal contraction, leading to progressive dilatation of the gullet.

The cause is unknown. It is associated with autoimmune diseases, such as type 1 diabetes mellitus, systemic lupus erythematosus, rheumatoid arthritis and Sjögren syndrome. Defective release of nitric oxide by inhibitory neurons in the lower oesophageal sphincter has been reported, and there is degeneration of ganglion cells within the sphincter and the body of the oesophagus. Loss of the dorsal vagal nuclei within the brainstem can be demonstrated in later stages. Infection with *Trypanosoma cruzi* in Chagas' disease (Ch. 13) causes a syndrome that is clinically indistinguishable from achalasia.

#### Clinical features

The presentation is with dysphagia, typically to solids and liquids. Regurgitation to saliva and food can also occur, as well as some patients experiencing episodes of chest pain due to oesophageal spasm. Around one-third of patients can experience weight loss. As the disease progresses, dysphagia worsens, the oesophagus empties poorly and nocturnal pulmonary aspiration develops. Achalasia predisposes to squamous carcinoma of the oesophagus.

#### Investigations

Endoscopy should always be carried out because carcinoma of the cardia can mimic the presentation and radiological and manometric features of achalasia ('pseudo-achalasia'). A barium swallow shows tapered narrowing of the lower oesophagus and, in late disease, the oesophageal body is dilated, aperistaltic and food-filled (Fig. 23.34A). Manometry confirms the high-pressure, non-relaxing lower oesophageal sphincter with poor contractility of the oesophageal body (Fig. 23.34B).

#### Management

##### Endoscopic

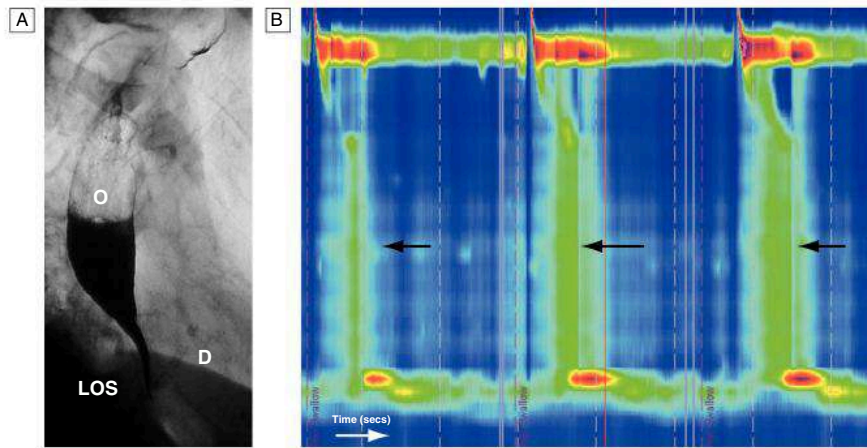

Forceful pneumatic dilatation using a 30–35 mm-diameter, fluoroscopically positioned balloon disrupts the oesophageal sphincter and improves symptoms in 80% of patients. Some patients require more than one dilatation, but those needing frequent dilatation are best treated surgically. Endoscopically directed injection of botulinum toxin into the lower oesophageal sphincter induces clinical remission, but relapse is common, with worsening response on repeated treatments. It tends to be reserved for frail individuals in old age where other treatments are too risky. Peroral endoscopic myotomy (POEM) is a newer advanced endoscopic technique for the management of achalasia, but is currently only performed in specialist centres (Fig. 23.35).

##### Surgical

Surgical myotomy (Heller's operation), commonly performed laparoscopically or as an open operation, is effective but is more invasive than endoscopic dilatation. Both pneumatic dilatation and myotomy may be complicated by gastro-oesophageal reflux, and this can lead to severe oesophagitis because oesophageal clearance is so poor. For this reason, Heller's myotomy is accompanied by a partial fundoplication anti-reflux procedure. PPI therapy is often necessary after surgery.

#### Other oesophageal motility disorders

Distal oesophageal spasm presents in late middle age with episodic chest pain that may mimic angina, but is sometimes accompanied by transient dysphagia. Some cases occur in response to gastro-oesophageal reflux. Treatment is based on the use of PPIs when gastro-oesophageal reflux is present. Oral or sublingual nitrates or nifedipine may relieve attacks of pain. The results of drug therapy are often disappointing, as are the alternatives such as pneumatic dilatation and surgical myotomy. 'Nutcracker' oesophagus is a condition in which extremely forceful peristaltic activity leads to episodic chest pain and dysphagia. Treatment is with nitrates or nifedipine. Some patients present with oesophageal motility disorders that do not fit into a specific disease entity. The patients usually present in old age and with dysphagia and chest pain. Manometric abnormalities occur, ranging from poor peristalsis to spasm. Treatment is with dilatation and/or vasodilators for chest pain.

**Fig. 23.34 Achalasia.** **A** X-ray showing a dilated, barium-filled oesophagus (O) with fluid level and distal tapering, and a closed lower oesophageal sphincter (LOS). (D = diaphragm) **B** High-resolution manometry in achalasia showing absence of peristaltic swallowing wave in oesophageal body (black arrows) and raised LOS pressure with failure of relaxation on swallowing (white arrow). Compare with normal appearances in [Figure 23.1](#).

### Secondary causes of oesophageal dysmotility

In systemic sclerosis or CREST syndrome (p. 1040) the muscle of the oesophagus is replaced by fibrous tissue, which causes failure of peristalsis leading to heartburn and dysphagia. Oesophagitis is often severe and benign fibrous strictures occur. These patients require long-term therapy with PPIs. If patients remain symptomatic, endoscopic dilatation may be considered. Dermatomyositis, rheumatoid arthritis and myasthenia gravis may also cause dysphagia.

## Disorders of the stomach and duodenum

### Gastritis

Gastritis is a histological diagnosis, although it can also be recognised at endoscopy.

#### Acute gastritis

Acute gastritis is often erosive and haemorrhagic. Neutrophils are the predominant inflammatory cell in the superficial epithelium. Many cases result from alcohol, aspirin or NSAID ingestion ([Box 23.32](#)). Acute gastritis often produces no symptoms, but may cause dyspepsia, anorexia, nausea or vomiting, and haematemesis or melaena. Many cases resolve quickly and do not merit investigation; in others, endoscopy and biopsy may be necessary to exclude peptic ulcer or cancer. Treatment should be directed at the underlying cause. Short-term symptomatic therapy with antacids, and acid suppression using PPIs, prokinetics (domperidone) or antiemetics (metoclopramide) may be necessary.

#### Chronic gastritis due to *Helicobacter pylori* infection

This is the most common cause of chronic gastritis (see [Box 23.32](#)). The predominant inflammatory cells are lymphocytes and plasma cells. Correlation between symptoms and endoscopic or pathological findings is poor. Most patients are asymptomatic and do not require treatment, but patients with dyspepsia may benefit from *H. pylori* eradication.

#### Autoimmune chronic gastritis

This involves the body of the stomach but spares the antrum; it results from autoimmune damage to parietal cells. The histological features are diffuse chronic inflammation, atrophy and loss of fundic glands, intestinal metaplasia and sometimes hyperplasia of enterochromaffin-like (ECL)

cells. Circulating antibodies to parietal cell and intrinsic factor may be present. In some patients, the degree of gastric atrophy is severe and loss of intrinsic factor secretion leads to pernicious anaemia (p. 954). The gastritis itself is usually asymptomatic. Some patients have evidence of other organ-specific autoimmunity, particularly thyroid disease. In the long-term, there is a two- to threefold increase in the risk of gastric cancer (see below).

### Ménétrier's disease

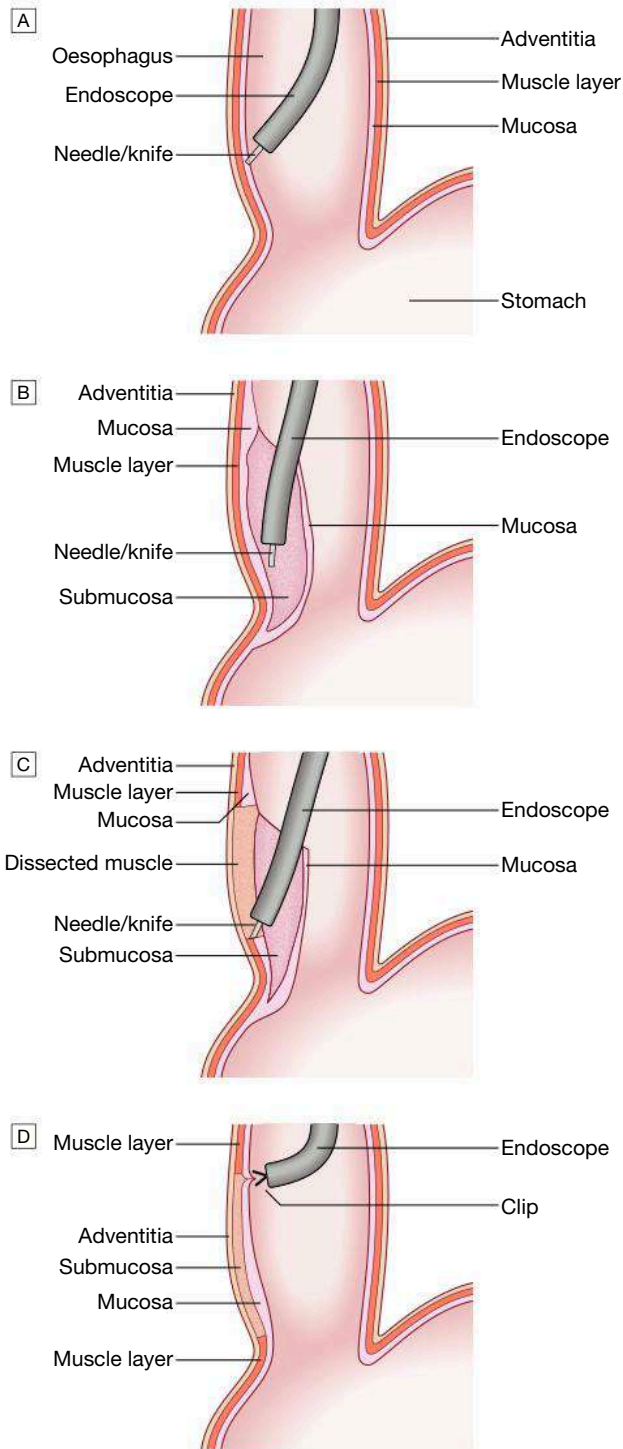

In this rare condition, the gastric pits are elongated and tortuous, with replacement of the parietal and chief cells by mucus-secreting cells. The cause is unknown but there is excessive production of transforming growth factor alpha (TGF- $\alpha$ ). As a result, the mucosal folds of the body and fundus are greatly enlarged. Most patients are hypochlorhydric. While some patients have upper gastrointestinal symptoms, the majority present in middle or old age with protein-losing enteropathy (p. 824) due to exudation from the gastric mucosa. Endoscopy shows enlarged, nodular and coarse folds, although biopsies may not be deep enough to show all the histological features. Treatment with antisecretory drugs, such as PPIs with or without octreotide, may reduce protein loss and *H. pylori* eradication may be effective, but unresponsive patients require partial gastrectomy.

### Peptic ulcer disease

Peptic ulcers are most commonly located in the stomach or duodenum, but can also occur in the lower oesophagus, in the jejunum after surgical anastomosis to the stomach or, rarely, in the ileum adjacent to a Meckel's diverticulum. Ulcers in the stomach or duodenum may be acute or chronic; both penetrate the muscularis mucosae, but the acute ulcer shows no evidence of fibrosis. Erosions do not penetrate the muscularis mucosae.

### Gastric and duodenal ulcer

The lifetime prevalence of peptic ulcer is around 5%–10%. The incidence is decreasing in many high-income societies as a result of widespread use of *Helicobacter pylori* eradication therapy. The male-to-female ratio for duodenal ulcer varies from 5:1 to 2:1, while that for gastric ulcer is 2:1 or less. Chronic gastric ulcer is usually single; 90% are situated on the lesser curve within the antrum or at the junction between body and antral mucosa. Chronic duodenal ulcer usually occurs in the first part of the duodenum and 50% are on the anterior wall. Gastric and duodenal ulcers coexist in 10% of patients and more than one peptic ulcer is found in 10%–15% of patients.

**Fig. 23.35** Per-oral endoscopic myotomy. **A** Mucosal surface opened to access submucosal space. **B** A submucosal tunnel is created. **C** Circular muscle is dissected – endoscopic myotomy. **D** The entry site is closed with clips.

## Pathophysiology

### *Helicobacter pylori*

Peptic ulceration is strongly associated with *H. pylori* infection. The prevalence of the infection in high-income societies rises with age and in the UK approximately 50% of people over the age of 50 years are infected. In low- and middle-income countries, infection is more common, affecting up to 90% of adults. These infections are probably acquired in childhood by person-to-person contact. The vast majority of colonised people

## 23.32 Common causes of gastritis

### Acute gastritis (often erosive and haemorrhagic)

- Aspirin, NSAIDs
- *Helicobacter pylori* (initial infection)
- Alcohol
- Other drugs, e.g. iron preparations
- Severe physiological stress, e.g. burns, multi-organ failure, central nervous system trauma
- Bile reflux, e.g. following gastric surgery
- Viral infections, e.g. CMV, herpes simplex virus in HIV/AIDS (Ch. 14)

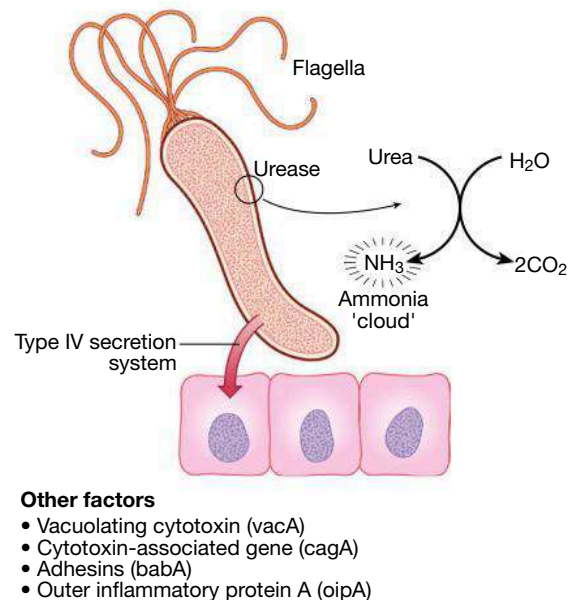

### Chronic non-specific gastritis

- *H. pylori* infection
- Autoimmune (pernicious anaemia)
- Post-gastrectomy

### Chronic 'specific' forms (rare)

- Infections, e.g. CMV, tuberculosis
- Gastrointestinal diseases, e.g. Crohn's disease
- Systemic diseases, e.g. sarcoidosis, graft-versus-host disease
- Idiopathic, e.g. granulomatous gastritis

(CMV = cytomegalovirus; HIV/AIDS = human immunodeficiency virus/acquired immunodeficiency syndrome; NSAIDs = non-steroidal anti-inflammatory drugs)

**Fig. 23.36** Factors that influence the virulence of *Helicobacter pylori*.

remain healthy and asymptomatic, and only a minority develop clinical disease. Around 90% of duodenal ulcer patients and 70% of gastric ulcer patients are infected with *H. pylori*.

*H. pylori* is Gram-negative and spiral, and has multiple flagella at one end, which make it motile, allowing it to burrow and live beneath the mucus layer adherent to the epithelial surface. It uses an adhesin molecule (BabA) to bind to the Lewis b antigen on epithelial cells. Here the surface pH is close to neutral and any acidity is buffered by the organism's production of the enzyme urease. This produces ammonia from urea and raises the pH around the bacterium and between its two cell membrane layers. *H. pylori* exclusively colonises gastric-type epithelium and is found in the duodenum only in association with patches of gastric metaplasia. It causes chronic gastritis by provoking a local inflammatory response in the underlying epithelium (Fig. 23.36). This depends on numerous factors, notably expression of bacterial CagA and VacA genes. The CagA gene product is injected into epithelial cells, interacting with numerous cell-signalling pathways involved in cell replication and apoptosis. *H. pylori* strains expressing

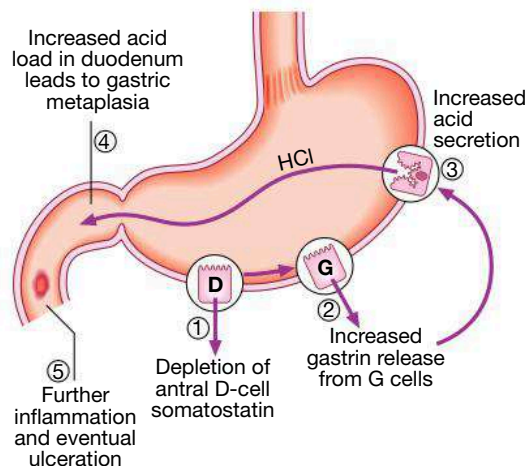

Fig. 23.37 Sequence of events in the pathophysiology of duodenal ulceration.

CagA (CagA<sup>+</sup>) are more often associated with disease than CagA<sup>-</sup> strains. Most strains also secrete a large pore-forming protein called VacA, which causes increased cell permeability, efflux of micronutrients from the epithelium, induction of apoptosis and suppression of local immune cell activity. Several forms of VacA exist and pathology is most strongly associated with the s1/ml form of the toxin.

The distribution and severity of *H. pylori*-induced gastritis determine the clinical outcome. In most people, *H. pylori* causes a mild pangastritis with little effect on acid secretion and the majority develop no significant clinical outcomes. In a minority (up to 10% in the West), the infection causes an antral-predominant pattern of gastritis characterised by hypergastrinaemia and a very exaggerated acid production by parietal cells, which could lead to duodenal ulceration (Fig. 23.37). In a much smaller number of infected people, *H. pylori* causes a corpus-predominant pattern of gastritis leading to gastric atrophy and hypochlorhydria. This phenotype is much more common in Asian countries, particularly Japan, China and Korea. The hypochlorhydria allows other bacteria to proliferate within the stomach; these other bacteria continue to drive the chronic inflammation and produce mutagenic nitrites from dietary nitrates, predisposing to the development of gastric cancer (Fig. 23.38). The effects of *H. pylori* are more complex in gastric ulcer patients compared to those with duodenal ulcers. The ulcer probably arises because of impaired mucosal defence resulting from a combination of *H. pylori* infection, NSAIDs and smoking, rather than excess acid.

### NSAIDs

There has been an increase in the use of NSAIDs and aspirin; these drugs account for 10% of peptic ulcers. NSAIDs increase the risk of complication of peptic ulcer disease four-fold, due to impairment of mucosal defences, as discussed on page 1009.

### Smoking

Smoking confers an increased risk of gastric ulcer and, to a lesser extent, duodenal ulcer. Once the ulcer has formed, it is more likely to cause complications and less likely to heal if the patient continues to smoke.

### Clinical features

Peptic ulcer disease is a chronic condition with spontaneous relapses and remissions lasting for decades, if not for life. The most common presentation is with recurrent abdominal pain that has three notable characteristics: localisation to the epigastrium, relationship to food and episodic occurrence. Occasional vomiting occurs in about 40% of ulcer subjects; persistent daily vomiting suggests gastric outlet obstruction. In one-third, the history is less characteristic, especially in older people or those taking NSAIDs (Box 23.33). In this situation, pain may be absent or so slight that it is experienced only as a vague sense of epigastric unease. Occasionally, the only symptoms are

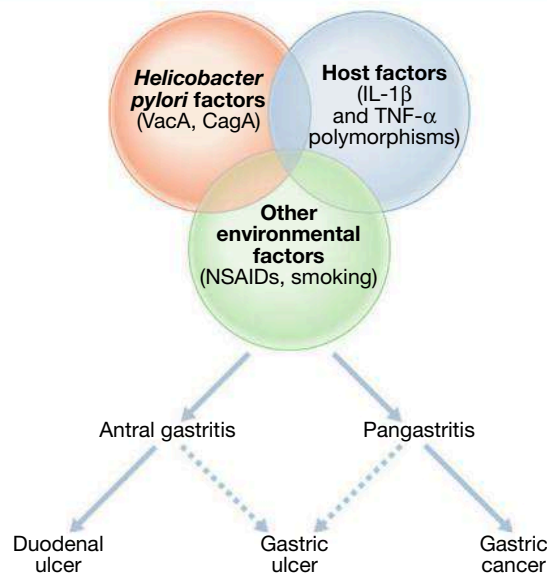

Fig. 23.38 Consequences of *Helicobacter pylori* infection. (CagA = cytotoxin-associated gene; IL-1 $\beta$  = interleukin-1 beta; NSAIDs = non-steroidal anti-inflammatory drugs; TNF- $\alpha$  = tumour necrosis factor alpha; VacA = vacuolating cytotoxin)

### 23.33 Peptic ulcer disease in old age

- **Gastroduodenal ulcers:** have a greater incidence, admission rate and mortality.
- **Causes:** high prevalence of *Helicobacter pylori*, use of non-steroidal anti-inflammatory drugs and impaired defence mechanisms.
- **Atypical presentations:** pain and dyspepsia are frequently absent or atypical. Older people often develop complications, such as bleeding or perforation, without a dyspeptic history.
- **Bleeding:** older patients require more intensive management because they have more limited reserve to withstand hypovolaemia.

anorexia and nausea, or early satiety after meals. In some patients, the ulcer is completely 'silent', presenting for the first time with anaemia from chronic undetected blood loss, as abrupt haematemesis or as acute perforation; in others, there is recurrent acute bleeding without ulcer pain. The diagnostic value of individual symptoms for peptic ulcer disease is poor; the history is therefore a poor predictor of the presence of an ulcer.

### Investigations

Endoscopy is the preferred investigation (Fig. 23.39). Gastric ulcers may occasionally be malignant and therefore must always be biopsied and followed up to ensure healing. Patients should be tested for *H. pylori* infection. The current options available are listed in Box 23.34. Some are invasive and require endoscopy; others are non-invasive. They vary in sensitivity and specificity. Breath tests or faecal antigen tests are best because of accuracy, simplicity and non-invasiveness.

### Management

The aims of management are to relieve symptoms, induce healing and prevent recurrence. *H. pylori* eradication is the cornerstone of therapy for peptic ulcers, as this will successfully prevent relapse and eliminate the need for long-term therapy in the majority of patients.

### *H. pylori* eradication

All patients with proven ulcers who are *H. pylori*-positive should be offered eradication as primary therapy. Treatment is based on a PPI taken simultaneously with two antibiotics (from amoxicillin, clarithromycin and metronidazole) for at least 7 days. High-dose, twice-daily PPI therapy

**Fig. 23.39** Endoscopic identification of a duodenal ulcer. The ulcer has a clean base and there are no stigmata of recent haemorrhage.

### 23.34 Methods for the diagnosis of *Helicobacter pylori* infection

Test	Advantages	Disadvantages
<b>Non-invasive</b>		
Serology	Rapid office kits available Good for population studies	Lacks specificity Cannot differentiate current from past infection
<sup>13</sup> C-urea breath test	High sensitivity and specificity	Requires expensive mass spectrometer
Faecal antigen test	Cheap, specific (> 95%)	Acceptability
<b>Invasive (antral biopsy)</b>		
Histology	Specificity	False negatives Takes several days to process
Rapid urease test	Cheap, quick, specific (> 95%)	Sensitivity 85%
Microbiological culture	'Gold standard' Defines antibiotic sensitivity	Slow and laborious Lacks sensitivity

increases efficacy of treatment, as does extending treatment to 10–14 days. Success used to be achieved in greater than 90% of patients, but this has now fallen to below 70% in many countries as a result of antibiotic resistance. In addition, adherence and side effects (Box 23.35) may influence success of eradication.

*H. pylori* and NSAIDs are independent risk factors for ulcer disease and patients requiring long-term NSAID therapy should first undergo eradication therapy to reduce ulcer risk. Subsequent co-prescription of a PPI along with the NSAID is advised, but is not always necessary for patients being given low-dose aspirin, in whom the risk of ulcer complications is lower.

Other indications for *H. pylori* testing are shown in Box 23.36. Eradication of the infection has proven benefits in several extragastric disorders, including unexplained B<sub>12</sub> deficiency and iron deficiency anaemia, once sources of gastrointestinal bleeding have been looked for and excluded. Platelet counts improve and may normalise after eradication therapy in patients with idiopathic thrombocytopenic purpura (p. 981); the mechanism for this is unclear.

### 23.35 Common side-effects of *Helicobacter pylori* eradication therapy

- Diarrhoea: 30%–50% of patients; usually mild, but *Clostridioides difficile*-associated diarrhoea can occur
- Flushing and vomiting when taken with alcohol (metronidazole)
- Nausea, vomiting
- Abdominal cramps
- Headache
- Rash

### 23.36 Indications for *Helicobacter pylori* testing

#### Definite

- Active or past history of peptic ulcer disease
- Extranodal marginal-zone lymphomas of MALT type
- Previous endoscopic resection for early gastric cancer
- Dyspepsia
- Long-term NSAID or low-dose aspirin users
- Extragastric disorders:
  - Idiopathic thrombocytopenic purpura
  - Unexplained iron deficiency anaemia
- Unexplained Vitamin B<sub>12</sub> deficiency

#### Not indicated

- Gastro-oesophageal reflux disease
- Asymptomatic people

(MALT = mucosa-associated lymphoid tissue; NSAID = non-steroidal anti-inflammatory drug)

### 23.37 Indications for surgery in peptic ulcer

#### Emergency

- Perforation
- Haemorrhage

#### Elective

- Gastric outflow obstruction
- Persistent ulceration despite adequate medical therapy
- Recurrent ulcer following gastric surgery

#### General measures

Cigarette smoking, aspirin and NSAIDs should be avoided. Alcohol in moderation is not harmful and no special dietary advice is required.

#### Maintenance treatment

Continuous maintenance treatment should not be necessary after successful *H. pylori* eradication. For the minority who do require it, the lowest effective dose of PPI should be used.

#### Surgical treatment

Surgery is now rarely required for peptic ulcer disease, but it is needed in some cases (Box 23.37).

#### Complications of gastric resection or vagotomy

Up to 50% of patients who undergo gastric surgery for peptic ulcer experience long-term adverse effects. In most cases these are minor, but in 10% they significantly impair quality of life.

#### Dumping

Symptoms of dumping syndrome can be either early or late. Early dumping is more common, and occurs within 30 minutes following a meal. Rapid gastric emptying leads to distension of the proximal small intestine as the hypertonic contents draw fluid into the lumen. This leads to

abdominal discomfort and diarrhoea after eating. Autonomic reflexes release a range of gastrointestinal hormones that provoke vasomotor features, such as flushing, palpitations, sweating, tachycardia and hypotension. Patients should therefore avoid large meals with high carbohydrate content. Late dumping occurs 1–3 hours following a meal, with symptoms related to reactive hypoglycaemia, such as nausea, tremor and sweating, which are relieved by eating more food.

#### **Chemical (bile reflux) gastropathy**

Duodenogastric bile reflux leads to chronic gastropathy. Treatment with ursodeoxycholic acid may be effective. A few patients require revisional surgery with creation of a Roux en Y loop to prevent bile reflux.

#### **Diarrhoea and maldigestion**

Diarrhoea may develop after any peptic ulcer operation and usually occurs 1–2 hours after eating. Poor mixing of food in the stomach, with rapid emptying, inadequate mixing with pancreaticobiliary secretions, rapid transit and bacterial overgrowth, may lead to malabsorption. Diarrhoea often responds to small, dry meals with a reduced intake of refined carbohydrates. Antidiarrhoeal drugs, such as codeine phosphate (15–30 mg 4–6 times daily) or loperamide (2 mg after each loose stool), are helpful.

#### **Weight loss**

Most patients lose weight shortly after surgery and 30%–40% are unable to regain all the weight that is lost. The usual cause is reduced intake because of a small gastric remnant, but diarrhoea and mild steatorrhoea also contribute.

#### **Anaemia**

Anaemia is common many years after subtotal gastrectomy. Iron deficiency is the most common cause; folic acid and B<sub>12</sub> deficiency are much less frequent. Inadequate dietary intake of iron and folate, lack of acid and intrinsic factor secretion, mild chronic low-grade blood loss from the gastric remnant and recurrent ulceration are responsible.

#### **Metabolic bone disease**

Both osteoporosis and osteomalacia can occur as a consequence of calcium and vitamin D malabsorption.

#### **Gastric cancer**

An increased risk of gastric cancer has been reported from several epidemiological studies. Surgery itself is an independent risk factor for late development of malignancy in the gastric remnant, but the risk is higher in those with hypochlorhydria, duodenogastric reflux of bile, smoking and *H. pylori* infection. Although the relative risk is increased, the absolute risk of cancer remains low and endoscopic surveillance is not indicated following gastric surgery.

### **Complications of peptic ulcer disease**

#### **Perforation**

When perforation occurs, the contents of the stomach escape into the peritoneal cavity, leading to peritonitis. This is more common in duodenal than in gastric ulcers and is usually found with ulcers on the anterior wall. About one-quarter of all perforations occur in acute ulcers and NSAIDs are often incriminated. Perforation can be the first sign of ulcer and a history of recurrent epigastric pain is uncommon. The most striking symptom is sudden, severe pain; its distribution follows the spread of the gastric contents over the peritoneum. The pain initially develops in the upper abdomen and rapidly becomes generalised; shoulder tip pain is caused by irritation of the diaphragm. The pain is accompanied by shallow respiration, due to limitation of diaphragmatic movements, and by shock. The abdomen is held immobile and there is generalised 'board-like' rigidity. Bowel sounds are absent and liver dullness to percussion decreases due to the presence of gas under the diaphragm. After some hours, symptoms may improve, although abdominal rigidity remains.

### **23.38 Differential diagnosis and management of gastric outlet obstruction**

Cause	Management
Fibrotic stricture from duodenal ulcer (pyloric stenosis)	Balloon dilatation or surgery
Oedema from pyloric channel or duodenal ulcer	Proton pump inhibitor therapy
Carcinoma of antrum	Surgery
Adult hypertrophic pyloric stenosis	Surgery

Later, the patient's condition deteriorates as general peritonitis develops. In at least 50% of cases, an erect chest X-ray shows free air beneath the diaphragm (see Fig. 23.11B). If not, a water-soluble contrast swallow will confirm leakage of gastroduodenal contents. After resuscitation, the acute perforation should be treated surgically, either by simple closure or by conversion of the perforation into a pyloroplasty if it is large. On rare occasions, a 'Polya' partial gastrectomy is required. Following surgery, *H. pylori* should be treated (if present) and NSAIDs avoided. Perforation carries a mortality of around 25%, reflecting the advanced age and significant comorbidity of the population that are affected.

#### **Gastric outlet obstruction**

The causes are shown in Box 23.38. The most common is an ulcer in the region of the pylorus. The presentation is with nausea, vomiting and abdominal distension. Large quantities of gastric content are often vomited and food eaten 24 hours or more previously may be recognised. Physical examination may show evidence of wasting and dehydration. A succussion splash may be elicited 4 hours or more after the last meal or drink. Visible gastric peristalsis is diagnostic of gastric outlet obstruction. Endoscopy should be performed after the stomach has been emptied using a wide-bore nasogastric tube. Intravenous correction of dehydration is undertaken and, in severe cases, at least 4 L of isotonic saline and 80 mmol of potassium may be necessary during the first 24 hours. In some patients, PPIs heal ulcers, relieve pyloric oedema and overcome the need for surgery. Endoscopic balloon dilatation of benign stenoses may be possible in some patients, but in others partial gastrectomy is necessary; this is best done after a 7-day period of nasogastric aspiration, which enables the stomach to return to normal size. A gastroenterostomy is an alternative operation but, unless this is accompanied by vagotomy, patients will require long-term PPI therapy to prevent stomal ulceration.

#### **Bleeding**

See page 797.

### **Zollinger–Ellison syndrome**

This is a rare disorder characterised by gastric acid hypersecretion and severe peptic ulceration, caused by a gastrin-secreting neuro-endocrine tumour ('gastrinoma') (Ch. 21). It probably accounts for about 0.1% of all cases of duodenal ulceration. The syndrome occurs in either sex at any age, although it is most common between 30 and 50 years of age.

#### **Pathophysiology**

Elevated gastrin stimulates acid secretion to its maximal capacity and increases the parietal cell mass three- to sixfold. The acid output may be so great that it reaches the upper small intestine, reducing the luminal pH to 2 or less. Pancreatic lipase is inactivated and bile acids are precipitated. Diarrhoea and steatorrhoea result. Around 90% of tumours occur in the pancreatic head or proximal duodenal wall. Between 20% and 60% of patients have multiple endocrine neoplasia (MEN) type 1 (p. 700). In sporadic disease, the tumours are usually unifocal, but in MEN 1 there are invariably multifocal tumours. Individual tumour size can vary from 1 mm to 20 cm; approximately one-half to two-thirds are malignant, but like many neuro-endocrine tumours they are often slow-growing.

### Clinical features

The presentation is with severe and often multiple peptic ulcers in unusual sites, such as the post-bulbar duodenum, jejunum or oesophagus. There is a poor response to standard ulcer therapy. The history is usually short, and bleeding and perforations are common. Diarrhoea is seen in one-third or more of patients and can be the presenting feature.

### Investigations

Serum gastrin levels are normally grossly elevated (10- to 1000-fold). Injection of the hormone secretin normally causes no change or a slight decrease in circulating gastrin concentrations, but in Zollinger–Ellison syndrome it produces a paradoxical and dramatic increase in gastrin. Tumour localisation (and staging) is best achieved by a combination of CT and EUS; radio-labelled somatostatin receptor scintigraphy and <sup>68</sup>gallium DOTATATE PET scanning may also be used for tumour detection and staging.

### Management

Unifocal tumours may be resected, but surgery may not be appropriate when there are multi-focal tumours or if there is metastatic disease. In this situation, continuous therapy with a PPI in high dose can be successful in healing ulcers and alleviating diarrhoea. Somatostatin analogue therapy may reduce gastrin secretion and have an anti-tumour effect; other treatment options for pancreatic neuro-endocrine tumours are discussed on page 700). Overall 5-year survival is 60%–75% and all patients should undergo genetic screening for MEN 1.

## Tumours of the stomach

### Gastric carcinoma

Around 90% of gastric cancers are adenocarcinomas. Gastric cancer is the fifth most common cancer, with marked geographical variation in incidence. It is most common in China, Japan, South Korea, Eastern Europe and parts of South America. In most countries the incidence is 50% lower in women. In both sexes it rises sharply after 50 years of age. Studies of Japanese migrants to the United States have revealed a much lower incidence in the second generation, confirming the importance of environmental factors. The overall prognosis is poor, with less than 30% surviving 5 years, except in Japan where there are much higher survival rates. The best hope for improved survival lies in more efficient detection of tumours at an earlier stage, with screening for early gastric cancers performed in Japan and South Korea.

### Pathophysiology

Infection with *H. pylori* plays a key pathogenic role and the infection has been classified by the International Agency for Research on Cancer (IARC) as a definite human carcinogen. It is associated with chronic atrophic gastritis, gastric mucosal atrophy and gastric cancer (Fig. 23.40). It has been estimated that *H. pylori* infection may contribute to the occurrence of gastric cancer in 70% of cases. Although the majority of *H. pylori*-infected individuals have normal or increased acid secretion, a few become hypo- or achlorhydric and these people are thought to be at greatest risk. *H. pylori*-induced chronic inflammation with generation of reactive oxygen species and depletion of the normally abundant antioxidant ascorbic acid are also important. There is strong evidence that *H. pylori* eradication, especially if achieved before irreversible pre-neoplastic changes (atrophy and intestinal metaplasia) have developed, reduces the risk of cancer development in high-risk populations and is cost-effective.

Diets rich in salted, smoked or pickled foods and the consumption of nitrites and nitrates may increase cancer risk. Carcinogenic *N*-nitroso-compounds are formed from nitrates by the action of nitrite-reducing bacteria that colonise the achlorhydric stomach. Diets lacking in fresh fruit and vegetables, as well as vitamins C and A, may also contribute. Other risk factors are listed in Box 23.39. Genetic risk factors also play

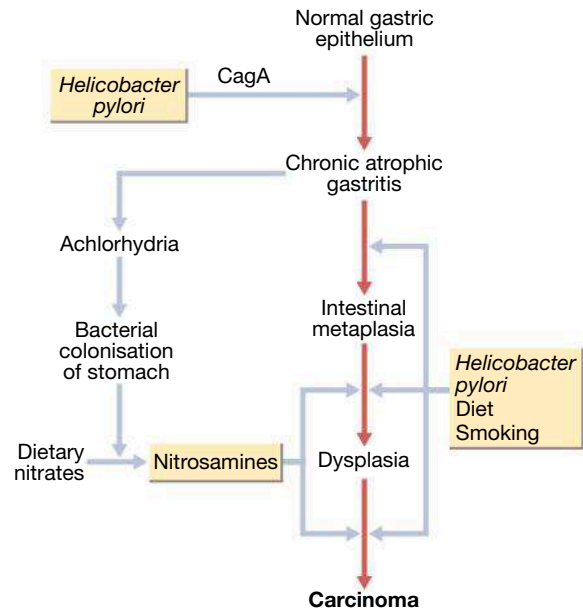

Fig. 23.40 Gastric carcinogenesis: a possible mechanism. (CagA = cytotoxin-associated gene)

### i

#### 23.39 Risk factors for gastric cancer

- *Helicobacter pylori*
- Smoking
- Alcohol
- Dietary associations (see text)
- Autoimmune gastritis (pernicious anaemia)
- Adenomatous gastric polyps
- Previous partial gastrectomy (> 20 years)
- Ménétrier's disease
- Hereditary diffuse gastric cancer families (*CDH1* mutations)
- Familial adenomatous polyposis (p. 831)

a role, with 10%–20% of gastric cancers showing familial history of the disease. Rarely, gastric cancer may be inherited in an autosomal dominant manner in association with mutations of the *E-cadherin* (*CDH1*) gene. There are eight genomic regions associated with an increased risk of gastric cancer.

Virtually all tumours are adenocarcinomas arising from mucus-secreting cells in the base of the gastric crypts. Most develop on a background of chronic atrophic gastritis with intestinal metaplasia and dysplasia. Cancers are either 'intestinal', arising from areas of intestinal metaplasia with histological features reminiscent of intestinal epithelium, or 'diffuse', arising from normal gastric mucosa. Intestinal-type carcinomas are more common and arise against a background of chronic mucosal injury. Diffuse cancers tend to be poorly differentiated and occur in younger patients. In low- and middle-income countries, 50% of gastric cancers develop in the antrum; 20%–30% occur in the gastric body, often on the greater curve; and 20% are found in the cardia. In Western populations, however, proximal gastric tumours are more common than those arising in the body and distal stomach. This change in disease pattern may be a reflection of changes in lifestyle or the decreasing prevalence of *H. pylori* in high-income countries. Diffuse submucosal infiltration by a scirrhous cancer (linitis plastica) is uncommon. Early gastric cancer is defined as cancer confined to the mucosa or submucosa. It is more often recognised in Japan, where widespread screening is practised. Some cases can be cured by endoscopic mucosal or submucosal resection. The majority of patients (> 80%) in the West, however, present with advanced gastric cancer.

### Clinical features

Early gastric cancer is usually asymptomatic, but may be discovered during endoscopy for investigation of dyspepsia. Two-thirds of patients with advanced cancers have weight loss and 50% have ulcer-like pain. Anorexia and nausea occur in one-third, while early satiety, haematemesis, melaena and dyspepsia alone are less common. Dysphagia occurs in tumours of the gastric cardia that obstruct the gastro-oesophageal junction. Anaemia from occult bleeding is also common. Examination may reveal no abnormalities, but signs of weight loss, anaemia and a palpable epigastric mass may be present. Jaundice or ascites signifies metastatic spread. Occasionally, tumour spread occurs to the supraclavicular lymph nodes (Virchow's node), umbilicus (Sister Joseph's nodule) or ovaries (Krukenberg tumour). Paraneoplastic phenomena, such as acanthosis nigricans, thrombophlebitis (Trousseau's sign) and dermatomyositis may rarely occur. Metastases arise most commonly in the liver, lungs, peritoneum and bone marrow.

### Investigations

Upper gastrointestinal endoscopy is the investigation of choice (Fig. 23.41) and should be performed promptly in any dyspeptic patient with 'alarm features' (see Box 23.15). Multiple biopsies from the edge and base of a gastric ulcer are required. Once the diagnosis is made, further imaging is necessary for staging and assessment of resectability. EUS and CT can be used to stage locally advanced gastric cancer; laparoscopy may be required to assess for peritoneal metastatic disease if resection is being contemplated.

### Management

#### Surgery

Resection offers the only hope of cure and this can be achieved in about 90% of patients with early gastric cancer. While surgery is the gold standard, endoscopic mucosal resection or endoscopic submucosal dissection can be considered for very early tumours. For the majority of patients with locally advanced disease, total gastrectomy with lymphadenectomy is the operation of choice, preserving the spleen if possible. Proximal tumours involving the oesophago-gastric junction also require a distal oesophagectomy. Small tumours sited distally can be managed by a partial gastrectomy with lymphadenectomy and either a Billroth I or a Roux-en-Y reconstruction. More extensive lymph node resection may increase survival rates, but carries greater morbidity. Even for those who cannot be cured, palliative resection may be necessary when patients present with bleeding or gastric outflow obstruction. Perioperative chemotherapy is recommended for patients with locally advanced disease (e.g. epirubicin, cisplatin and 5-fluorouracil). For individuals who did not receive

Fig. 23.41 Gastric carcinoma. Endoscopic finding of an early gastric cancer.

pre-operative chemotherapy, post-operative chemoradiotherapy (e.g. 5-fluorouracil and leucovorin with radiotherapy) or adjuvant chemotherapy (e.g. 5-fluorouracil) is recommended.

#### Palliative treatment

Metastatic gastric cancer has a poor outlook, with survival around 4 months with best supportive care. Patients with inoperable locally advanced disease, or metastatic disease should be considered for palliative chemotherapy depending upon fitness, which may extend survival to 12 months. The biologic agent trastuzumab is recommended in conjunction with chemotherapy for patients whose tumours over-express HER2 (p. 137). Endoscopic laser ablation for control of dysphagia or recurrent bleeding benefits some patients. Carcinomas at the cardia or pylorus may require endoscopic dilatation or insertion of expandable metallic stents for relief of dysphagia or vomiting. A nasogastric tube may offer temporary relief of vomiting due to gastric outlet obstruction (Box 23.40).

### Gastric lymphoma

This is a rare tumour, accounting for less than 5% of all gastric malignancies. The stomach is, however, the most common site for extranodal non-Hodgkin lymphoma and 60% of all primary gastrointestinal lymphomas occur at this site. Gastric lymphoma is 2 to 3 times more common in males than females. Lymphoid tissue is not found in the normal stomach, but lymphoid aggregates develop in the presence of *H. pylori* infection. Indeed, *H. pylori* infection is closely associated with the development of a low-grade lymphoma (classified as extranodal marginal-zone lymphomas of MALT type). EUS plays an important role in staging these lesions by accurately defining the depth of invasion into the gastric wall.

The clinical presentation is similar to that of gastric cancer and endoscopically the tumour appears as a polypoid or ulcerating mass. While initial treatment of low-grade lesions confined to the superficial layers

#### 23.40 How to insert a nasogastric tube

##### Equipment

- 8–9F 'fine-bore' tube for feeding or 16–18F 'wide-bore' tube for drainage
- Lubricant jelly
- Cup of water and straw for sipping
- Adhesive tape
- pH (not litmus) paper
- Sickness bowl and tissues
- Catheter drainage bag and clamp (for drainage)

##### Technique

- A clear explanation and a calm patient are essential
- Establish a 'stop signal' for the patient to use, if needed
- Ask the patient to sit semi-upright
- Examine the nose for deformity or blockage to determine which side to use
- Measure the distance from ear to xiphoid process via the nose and mark the position on the tube
- Advance the lubricated tube tip slowly along the floor of the nasal passage to the oropharynx
- Ask the patient to sip water and advance the tube 2–3 cm with each swallow
- Stop, withdraw and retry if the patient is distressed or coughing, as the tube may have entered the larynx
- Advance until the mark on the tube reaches the tip of the nose and secure with tape
- Aspirate the contents and check pH (gastric acid confirmed if pH < 5). If in doubt, perform a chest X-ray to confirm tube position (usually necessary with feeding tubes)
- Attach the catheter drainage bag, if necessary, and clamp

##### Aftercare

- Flush the tube daily after feeding or drug dosing
- Check position regularly and look for signs of displacement
- Check with the pharmacist what drugs, if any, can be safely given via the tube

of the gastric wall consists of *H. pylori* eradication and close observation, 25% contain t(11:18) chromosomal translocations. In these cases, additional radiotherapy or chemotherapy is usually necessary. High-grade B-cell lymphomas should be treated by a combination of rituximab, chemotherapy (p. 971), surgery and radiotherapy. The choice depends on the site and extent of tumour, the presence of comorbid illnesses, and other factors, such as symptoms of bleeding and gastric outflow obstruction. The prognosis depends on the stage at diagnosis. Features predicting a favourable prognosis are stage I or II disease, small resectable tumours, tumours with low-grade histology and age below 60 years.

### Other tumours of the stomach

Gastrointestinal stromal cell tumours (GISTs), arising from the interstitial cells of Cajal, are occasionally found incidentally at endoscopy and account for 1%–2% of gastrointestinal neoplasms. They are differentiated from other mesenchymal tumours by expression of the *c-kit* proto-oncogene, which encodes a tyrosine kinase receptor. These tumours, particularly the smaller lesions of less than 2 cm, are usually benign and asymptomatic, but larger ones may have malignant potential and may occasionally be responsible for dyspepsia, ulceration and gastrointestinal bleeding. Small lesions (< 2 cm) are usually monitored by endoscopy, while larger ones require surgical resection. Very large lesions should be treated pre-operatively with imatinib (a tyrosine kinase inhibitor) to reduce their size and make surgery easier. Imatinib can also provide prolonged control of metastatic GISTs. Sunitinib and regorafenib are used as second-line agents.

A variety of different types of gastric polyps occur. Fundic gland polyps are common and usually not associated with an increased risk of malignancy, other than in the context of familial adenomatous polyposis (FAP) (see p. 834). Hyperplastic polyps are also common, with regression generally occurring after *H. pylori* eradication. Adenomatous polyps are rare but have malignant potential and should be removed endoscopically with subsequent surveillance by periodic endoscopy.

Occasionally, gastric neuro-endocrine (carcinoid) tumours are seen in the fundus and body in patients with long-standing pernicious anaemia. These benign tumours arise from ECL or other endocrine cells, and are often multiple, but rarely invasive. Unlike carcinoid tumours arising elsewhere in the gastrointestinal tract, they usually run a benign and favourable course. Large (> 2 cm) carcinoids may, however, metastasise and should be removed. Rarely, small nodules of ectopic pancreatic exocrine tissue are found. These 'pancreatic rests' may be mistaken for gastric neoplasms and usually cause no symptoms. EUS is the most useful investigation.

## Gastric motility disorders

### Gastroparesis

Defective gastric emptying without mechanical obstruction of the stomach or duodenum can occur as a primary event, due to inherited or acquired disorders of the gastric pacemaker, or can be secondary to disorders of autonomic nerves (particularly diabetic neuropathy) or the gastroduodenal musculature (systemic sclerosis, myotonic dystrophies and amyloidosis). Drugs such as opiates, calcium channel antagonists and those with anticholinergic activity (tricyclics, phenothiazines) can also cause gastroparesis. Early satiety and recurrent vomiting are the major symptoms; abdominal fullness and a succussion splash may be present on examination. Symptoms may overlap with functional dyspepsia (postprandial distress syndrome). Treatment is based on small, frequent, low-fat meals and the use of metoclopramide and domperidone. In severe cases, nutritional failure can occur and long-term jejunostomy feeding or total parenteral nutrition is required. Surgical insertion of a gastric neurostimulator may be considered in refractory cases, especially those complicating diabetic autonomic neuropathy.

## Disorders of the small intestine

### Disorders causing malabsorption

#### Coeliac disease

Coeliac disease is an inflammatory disorder of the small bowel occurring in genetically susceptible individuals, which results from intolerance to wheat gluten and similar proteins found in rye, barley and, to a lesser extent, oats. It can result in malabsorption and responds to a gluten-free diet. The condition occurs worldwide, but is more common in northern Europe. The prevalence in the UK is approximately 1%, although 50% of these people are asymptomatic. These include both undiagnosed 'silent' cases of the disease and cases of 'latent' coeliac disease – genetically susceptible people who may later develop clinical coeliac disease.

#### Pathophysiology

The precise mechanism of mucosal damage is unclear, but immunological responses to gluten play a key role (Fig. 23.42). There is a strong genetic component, with around 8% of first-degree relatives of an index case affected, and there is strong (approximately 80%) concordance in monozygotic twins. There is a strong association with human leukocyte antigen (HLA)-DQ2/DQ8. Dysbiosis of the intestinal microbiota has been identified, but it is unclear if this is pathological or a response to the underlying mucosal changes.

#### Clinical features

Coeliac disease can present at any age. In infancy, it occurs after weaning on to cereals and typically presents with diarrhoea, malabsorption and failure to thrive. In older children, it may present with non-specific features, such as delayed growth. Features of malnutrition are found on examination and mild abdominal distension may be present. Affected children have growth and pubertal delay, leading to short stature in adulthood.

In adults, the disease usually presents during the third or fourth decade and females are affected twice as often as males. The presentation is highly variable, depending on the severity and extent of small bowel involvement. Some have florid malabsorption, while others develop non-specific symptoms, such as tiredness, weight loss, folate deficiency or iron deficiency anaemia. Other symptoms include oral ulceration, dyspepsia and bloating; such non-specific symptomatology is more common in older people (see Box 23.41). Unrecognised coeliac disease is associated with mild under-nutrition and osteoporosis.

Coeliac disease is associated with other HLA-linked autoimmune disorders and with certain other diseases (Box 23.42). In some centres, individuals at higher risk of developing coeliac disease, e.g. people with type 1 diabetes, undergo periodic antibody screening. This may identify people with asymptomatic or minimally symptomatic disease.

#### Investigations

These are performed to confirm the diagnosis and to look for consequences of malabsorption.

#### Duodenal biopsy

Endoscopic small bowel biopsy is the gold standard. Endoscopic appearances should not preclude biopsy, as the mucosa usually looks normal. As the histological changes can be patchy, an adequate number of biopsies (four biopsies from the second part of the duodenum plus one from the duodenal bulb) should be taken. The histological features are usually characteristic, but other causes of villous atrophy should be considered (Box 23.43 and Fig. 23.43).

#### Antibodies

Antibody tests constitute a valuable screening tool in patients with diarrhoea or other suggestive symptoms, but are not a diagnostic substitute for small bowel biopsy at present. Tissue transglutaminase (tTG) is now recognised

**Fig. 23.42 Pathophysiology of coeliac disease.** After being taken up by epithelial cells, gluten peptides are deamidated by the enzyme tissue transglutaminase in the subepithelial layer. They are then able to fit the antigen-binding motif on human leucocyte antigen (HLA)-DQ2-positive antigen-presenting cells. Recognition by CD4<sup>+</sup> T cells triggers a Th<sub>1</sub> immune response with generation of pro-inflammatory cytokines: interleukin-1 (IL-1), interferon gamma (IFN- $\gamma$ ) and tumour necrosis factor alpha (TNF- $\alpha$ ). Lymphocytes infiltrate the lamina propria and an increase in intra-epithelial lymphocytes (IELs), crypt hyperplasia and villous atrophy ensue.

### 23.41 Malabsorption in old age

- **Coeliac disease:** symptoms such as dyspepsia tend to be vague; only 25% present classically with diarrhoea and weight loss. Metabolic bone disease, folate or iron deficiency, coagulopathy and small bowel lymphoma are more common.
- **Small bowel bacterial overgrowth:** more common due to atrophic gastritis, resulting in hypo- or achlorhydria, increased prevalence of jejunal diverticulosis and long-term adverse effects of gastric surgery for ulcer disease.

### 23.42 Disease associations of coeliac disease

- Type 1 diabetes mellitus (2%–8%)
- Thyroid disease (5%)
- Primary biliary cholangitis (3%)
- Sjögren syndrome (3%)
- Immunoglobulin A deficiency (2%)
- Pernicious anaemia
- Sarcoidosis
- Neurological complications:
  - Encephalopathy
  - Cerebellar atrophy
  - Peripheral neuropathy
  - Epilepsy
- Myasthenia gravis
- Dermatitis herpetiformis
- Down syndrome
- Enteropathy-associated T-cell lymphoma
- Small bowel carcinoma
- Squamous carcinoma of oesophagus
- Ulcerative jejunitis
- Pancreatic insufficiency
- Microscopic colitis
- Splenic atrophy

### 23.43 Important causes of subtotal villous atrophy

- Coeliac disease
- Tropical sprue
- Dermatitis herpetiformis
- Lymphoma
- HIV-related enteropathy
- Giardiasis
- Hypogammaglobulinaemia
- Radiation
- Whipple's disease
- Zollinger–Ellison syndrome

(HIV = human immunodeficiency virus)

as the autoantigen for anti-endomysial antibodies. If the antibody screen is positive, adult patients should remain on a gluten-containing diet until duodenal biopsies are taken. High-titre serology in symptomatic children can be considered diagnostic without the need for endoscopy and biopsy. The use of this approach for diagnosis in adults is currently being explored.

Anti-endomysial antibodies of the IgA class are detectable by immunofluorescence in most untreated cases. They are sensitive (85%–95%) and specific (approximately 99%) for the diagnosis, except in very young infants. IgG antibodies, however, must be measured in patients with coexisting IgA deficiency. Measurement of the concentration of tTG antibodies has become the serological test of choice in many countries, as it is easier to perform, is semi-quantitative, has more than 95% sensitivity and specificity, and is more accurate in patients with IgA deficiency.

#### Haematology and biochemistry

A full blood count may show microcytic or macrocytic anaemia from iron or folate deficiency and features of hyposplenism (target cells, spherocytes and Howell–Jolly bodies). Biochemical tests may reveal reduced concentrations of calcium, magnesium, total protein, albumin or vitamin D. Serum IgA measurement is required to ensure an appropriate IgA response and to allow accurate analysis of serological testing.

#### Other investigations

Measurement of bone density should be considered to look for osteopenia or osteoporosis, especially in older patients and post-menopausal women.

#### Management

The aims are to correct existing deficiencies of micronutrients, such as iron, folate, calcium and/or vitamin D, and to achieve mucosal healing through a life-long gluten-free diet. This requires the exclusion of wheat, rye, barley and initially oats, although oats may be re-introduced safely in most patients after 6–12 months. Initially, frequent dietary counselling is required to make sure the diet is being observed, as the most common reason for failure to improve with dietary treatment is accidental or unrecognised gluten ingestion. Mineral and vitamin supplements are also given when indicated, but are seldom necessary when a strict gluten-free diet is adhered to. Booklets

**Fig. 23.43** Jejunal mucosa. **A** Normal. **B** Subtotal villous atrophy in coeliac disease. There is blunting of villi (B), crypt hyperplasia (H) and inflammatory infiltration of the lamina propria (I).

produced by 'coeliac societies' in many countries contain diet sheets and recipes using gluten-free flour, and are of great value. Dietetic follow-up is key to management. Patients should be followed up after initiation of a gluten-free diet, with assessment of symptoms, weight and nutritional status, and blood should be taken for measurement of tTG or anti-endomysial antibodies. There are currently no effective non-invasive tests to assess small bowel mucosal healing. Repeat small bowel biopsies should be considered in patients whose symptoms fail to improve and those in whom antibody levels remain high. In these circumstances, if the diet is satisfactory, then other conditions, such as pancreatic insufficiency or microscopic colitis, should be sought, as should complications of coeliac disease, such as ulcerative jejunitis or enteropathy-associated T-cell lymphoma. Some patients who fail to respond adequately to a gluten-free diet may require therapy with glucocorticoids or immunosuppressive drugs, and may be classified as refractory coeliac disease (RCD). RCD can be classified as type 1, characterised as a normal intraepithelial lymphocyte phenotype, or type 2, characterised by an abnormal expansion of a subset of small intestinal intraepithelial lymphocytes. Type 2 RCD has a 5-year survival of around 50%, compared to 90% in type 1 RCD.

### Complications

A twofold-increased risk of malignancy, particularly of enteropathy-associated T-cell lymphoma, small bowel carcinoma and squamous carcinoma of the oesophagus, has been reported.

A few patients develop ulcerative jejuno-ileitis. This may present with fever, pain, obstruction or perforation. This diagnosis can be made by barium studies or enteroscopy but laparotomy and full-thickness biopsy may be required. Treatment is difficult. Glucocorticoids are used with mixed success and some patients require surgical resection and parenteral nutrition. The course is often progressive.

Osteoporosis and osteomalacia may occur in patients with long-standing, poorly controlled coeliac disease. These complications are less common in those who adhere strictly to a gluten-free diet.

### Dermatitis herpetiformis

This is characterised by crops of intensely itchy blisters over the elbows, knees, back and buttocks (Ch. 27). Immunofluorescence shows granular or linear IgA deposition at the dermo-epidermal junction. Almost all patients have partial villous atrophy on duodenal biopsy, identical to that seen in coeliac disease, even though they usually have no gastrointestinal symptoms. In contrast, fewer than 10% of coeliac patients have evidence of dermatitis herpetiformis, although both disorders are associated with the same histocompatibility antigen groups. The rash usually responds to a gluten-free diet, but some patients require additional treatment with dapsone (100–150 mg daily).

### Tropical sprue

Tropical sprue is defined as chronic, progressive malabsorption in a patient in or from a tropical country, associated with abnormalities of

small intestinal structure and function. The disease occurs mainly in the West Indies and in southern India, Malaysia and Indonesia.

### Pathophysiology

The epidemiological pattern and occasional epidemics suggest that an infective agent may be involved. Although no single bacterium has been isolated, the condition often begins after an acute diarrhoeal illness. Small bowel bacterial overgrowth with *Escherichia coli*, *Enterobacter* and *Klebsiella* is frequently seen. The changes closely resemble those of coeliac disease.

### Clinical features

There is diarrhoea, abdominal distension, anorexia, fatigue and weight loss. In visitors to the tropics, the onset of severe diarrhoea may be sudden and accompanied by fever. When the disorder becomes chronic, the features of megaloblastic anaemia (vitamin B<sub>12</sub> and folic acid malabsorption) and other deficiencies, including ankle oedema, glossitis and stomatitis, are common. Remissions and relapses may occur. The differential diagnosis in the indigenous tropical population is an infective cause of diarrhoea. The important differential diagnosis in visitors to the tropics is giardiasis (Ch. 13).

### Management

Tetracycline (250 mg 4 times daily for 28 days) is the treatment of choice and brings about long-term remission or cure. In most patients, pharmacological doses of folic acid (5 mg daily) improve symptoms and jejunal morphology. In some cases, treatment must be prolonged before improvement occurs and occasionally patients must leave the tropics.

### Small intestinal bacterial overgrowth

The normal duodenum and jejunum contain fewer than 10<sup>4</sup>/mL organisms and these are usually derived from saliva. The count of coliform organisms never exceeds 10<sup>3</sup>/mL. In bacterial overgrowth, there may be 10<sup>8</sup>–10<sup>10</sup>/mL organisms, most of which are normally found only in the colon. Disorders that impair the normal physiological mechanisms controlling bacterial proliferation in the intestine predispose to bacterial overgrowth (Box 23.44). The most important are loss of gastric acidity, impaired intestinal motility and structural abnormalities that allow colonic bacteria to gain access to the small intestine or provide a secluded haven from the peristaltic stream.

### Pathophysiology

Bacterial overgrowth can occur in patients with small bowel diverticuli or following surgery that creates 'blind loops' of bowel, e.g. Billroth II or Roux-en-Y reconstructions. Diabetic autonomic neuropathy reduces small bowel motility and affects enterocyte secretion. In systemic sclerosis, bacterial overgrowth arises because the circular and longitudinal layers of the intestinal muscle are fibrosed and motility is abnormal. In idiopathic hypogammaglobulinaemia, bacterial overgrowth occurs because the IgA and IgM levels in serum and jejunal secretions are reduced. Chronic diarrhoea and malabsorption occur because of

23.44 Causes of small intestinal bacterial overgrowth	
Mechanism	Examples
Hypo- or achlorhydria	Pernicious anaemia Partial gastrectomy Long-term proton pump inhibitor therapy
Impaired intestinal motility	Systemic sclerosis Diabetic autonomic neuropathy
Structural abnormalities	Gastric surgery (e.g. blind loop after Billroth II operation) Jejunal diverticulosis Enterocolic fistulae* Extensive small bowel resection Strictures*
Impaired immune function	Hypogammaglobulinaemia

\*Most commonly caused by Crohn's disease.

bacterial overgrowth and recurrent gastrointestinal infections (particularly giardiasis, Ch. 13).

### Clinical features

Patients commonly present with bloating, abdominal pain, distension and diarrhoea. Nutritional deficiencies can occur in severe cases, e.g. vitamin B<sub>12</sub> deficiency can arise as the bacteria utilise vitamin B<sub>12</sub>. Nutritional deficiencies are more commonly seen in patients with structural abnormalities, such as 'blind loop syndrome' or systemic sclerosis. Symptoms can commonly overlap with other diagnoses such as IBS and functional dyspepsia. There may also be symptoms from any underlying intestinal cause.

### Investigations

Culture of small bowel aspirate, obtained at endoscopy, is the gold standard for diagnosis. However, this is a time-consuming, invasive and expensive technique. Bacterial overgrowth can also be diagnosed non-invasively using hydrogen breath tests, although they lack sensitivity. These simple, non-radioactive tests involve serial measurement of breath samples for hydrogen after oral ingestion of 75 g glucose or 10 g lactulose. If bacteria are present within the small bowel, they rapidly metabolise the glucose/lactulose, causing an early rise in exhaled hydrogen, in advance of that normally resulting from metabolism by colonic flora. Lactulose breath tests have a higher sensitivity than glucose, although may be less specific, as a rise in hydrogen can coincide with the arrival of lactulose in the caecum, leading to a false-positive result.

### Management

The underlying cause of small intestinal bacterial overgrowth should be addressed, where possible. A course of broad-spectrum antibiotic for 2 weeks is the first-line treatment, although there is no consensus on agent or dose. Examples include rifaximin (which is not absorbed from the gut after oral administration), as well as systemic antibiotics such as ciprofloxacin, metronidazole and amoxicillin. Around 30%–40% of patients do not respond adequately and relapse rates are high. Some patients require up to 4 weeks of treatment and, in a few, continuous rotating courses of antibiotics are necessary. Consideration needs to be given to the risk of emerging antimicrobial resistance. Intramuscular vitamin B<sub>12</sub> supplementation may be needed in chronic cases. Patients with motility disorders, such as diabetes and systemic sclerosis, can sometimes benefit from anti-diarrhoeal drugs (diphenoxylate or loperamide orally). Giardiasis should be controlled in patients with hypogammaglobulinaemia, using metronidazole or tinidazole, but if symptoms fail to respond adequately, immunoglobulin infusions may be required.

## Whipple's disease

This rare condition is characterised by infiltration of small intestinal mucosa by 'foamy' macrophages, which stain positive with periodic acid–Schiff (PAS) reagent. The disease is a multisystem one and almost any organ can be affected, sometimes long before gastrointestinal involvement becomes apparent (Box 23.45).

### Pathophysiology

Whipple's disease is caused by infection with the Gram-positive bacillus *Tropheryma whipplei*, which becomes resident within macrophages in the bowel mucosa. Villi are widened and flattened, containing densely packed macrophages in the lamina propria, which obstruct lymphatic drainage and cause fat malabsorption. Between 50% and 70% of the individuals have antibodies against *Tropheryma whipplei* worldwide, indicating prior environmental exposure, and yet Whipple's disease only occurs in a minority. This is presumably because host, bacterial and environmental factors are contributory in its pathogenesis.

### Clinical features

Middle-aged men of European descent are most frequently affected and presentation depends on the pattern of organ involvement. Low-grade fever is common and most patients have joint symptoms to some degree, often as the first manifestation. Occasionally, neurological manifestations may predominate, due to CNS infection. Endocarditis can also occur, but usually only in a late phase.

### Investigations

Diagnosis is made by the characteristic features on small bowel biopsy, with characterisation of the bacillus by polymerase chain reaction (PCR).

### Management

Whipple's disease is often fatal if untreated but responds well, at least initially, to intravenous ceftriaxone (2 g daily for 2 weeks), followed by oral co-trimoxazole for at least 1 year. Symptoms usually resolve quickly and biopsy changes revert to normal in a few weeks. Long-term follow-up is essential, as clinical relapse occurs in up to one-third of patients, often within the CNS; in this case, the same therapy is repeated or else treatment with doxycycline and hydroxychloroquine is necessary.

## Bile acid diarrhoea

Causes of bile acid diarrhoea are shown in [Box 23.46](#). The population prevalence is estimated at around 1% and it is often under-diagnosed. It is now appreciated that up to a third of patients diagnosed with diarrhoea-predominant irritable bowel syndrome have evidence of bile acid diarrhoea. A common scenario is in patients with Crohn's disease who have undergone ileal resection, which can also lead to other malabsorptive manifestations ([Fig. 23.44](#)). Unabsorbed bile salts pass into the colon, stimulating water and electrolyte secretion and causing diarrhoea. If hepatic synthesis of new bile acids cannot keep pace with faecal losses, fat malabsorption occurs. Another consequence is the formation of lithogenic bile, leading to gallstones. Renal calculi, rich in oxalate, develop. Normally, oxalate in the colon is bound to and precipitated by calcium. Unabsorbed bile salts preferentially bind calcium, leaving oxalate to be absorbed, with development of urinary oxalate calculi.

Patients have urgent watery diarrhoea or mild steatorrhoea. Contrast studies and tests of B<sub>12</sub> and bile acid absorption, such as the <sup>75</sup>Se-homocholic acid taurine (SeHCAT) test (see [Box 23.12](#)), are useful investigations but are not available throughout the world due to use of synthetic radio-labelled compound. An elevated serum 7 $\alpha$ -hydroxycholestone is a useful non-invasive marker of bile acid diarrhoea. Diarrhoea usually responds well to bile acid sequestrants, such as colestyramine or colesevelam, which bind bile salts in the intestinal lumen. Bile acid sequestrants can also be used as a diagnostic trial, where investigations are unavailable.

## Short bowel syndrome

This is discussed in detail in [Chapter 22](#).

### 23.46 Classification of bile acid diarrhoea

Type	Cause
Type 1	Terminal ileal disease leading to malabsorption of bile acids from terminal ileum, e.g. Crohn's disease, terminal ileal resection
Type 2	Primary or idiopathic – no anatomical abnormalities or risk factors present
Type 3	Other conditions that affect GI absorption, e.g. chronic pancreatitis, coeliac disease, small intestinal bacterial overgrowth

## Radiation enteropathy

Intestinal damage occurs in 10%–15% of patients undergoing radiotherapy for abdominal or pelvic malignancy. The risk varies with total dose, dosing schedule and the use of concomitant chemotherapy.

### Pathophysiology

The rectum, sigmoid colon and terminal ileum are most frequently involved. Radiation causes acute inflammation, shortening of villi, oedema and crypt abscess formation. These usually resolve completely, but some patients develop an obliterative endarteritis affecting the endothelium of submucosal arterioles over 2–12 months. In the longer term, this can provoke a fibrotic reaction, leading to adhesions, ulceration, strictures, obstruction or fistula to adjacent organs.

### Clinical features

In the acute phase, there is nausea, vomiting, cramping abdominal pain and diarrhoea. When the rectum and colon are involved, rectal mucus, bleeding and tenesmus occur. The chronic phase develops after 3 or more months in some patients and produces one or more of the problems listed in [Box 23.47](#).

### Investigations

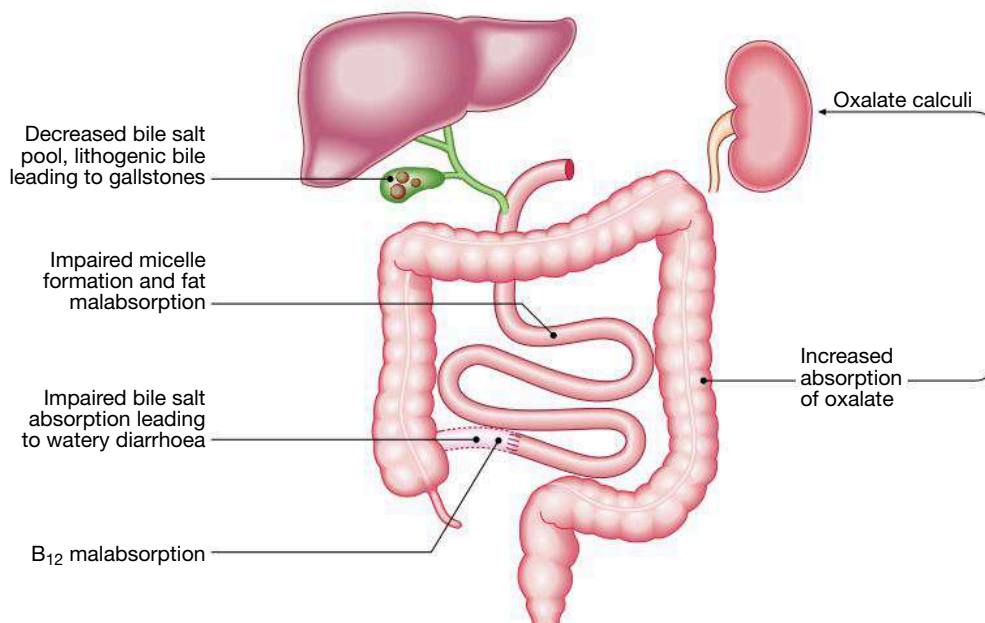

In the acute phase, the rectal changes at sigmoidoscopy resemble ulcerative proctitis (see [Fig. 23.64](#)). The extent of the lesion can be assessed by colonoscopy. Barium follow-through or MRI enterography can be of diagnostic value in showing small bowel strictures, ulcers and fistulae.

### Management

Diarrhoea in the acute phase should be treated with codeine phosphate, diphenoxylate or loperamide. Antibiotics may be required for bacterial

### 23.47 Chronic complications of intestinal irradiation

- Proctocolitis
- Bleeding from telangiectasia
- Small bowel strictures
- Fistulae: rectovaginal, colovesical, enterocolic
- Adhesions
- Malabsorption: bacterial overgrowth, bile acid diarrhoea (ileal damage)

**Fig. 23.44** Consequences of ileal resection.

overgrowth. Nutritional supplements are necessary when malabsorption is present. Colestyramine or colesvelam is useful for associated bile acid diarrhoea. In radiation enteropathy, the underlying pathophysiology is tissue ischaemia rather than inflammation; glucocorticoid enemas are therefore not effective. Treatments include sucralfate enema and hyperbaric oxygen. Different endoscopic techniques may also be used, including argon plasma coagulation, radiofrequency ablation and heater probe thermocoagulation. Surgery should be avoided, if possible, because the injured intestine is difficult to resect and anastomose, but may be necessary if there is obstruction, perforation or fistula.

### Abetalipoproteinaemia

This rare autosomal recessive disorder is caused by deficiency of apolipoprotein B, which results in failure of chylomicron formation. It leads to fat malabsorption and deficiency of fat-soluble vitamins. Jejunal biopsy reveals enterocytes distended with resynthesised triglyceride and normal villous morphology. Serum cholesterol and triglyceride levels are low. A number of other abnormalities occur in this syndrome, including acanthocytosis, retinitis pigmentosa and a progressive neurological disorder with cerebellar and dorsal column signs. Symptoms may be improved by a low-fat diet supplemented with medium-chain triglycerides and vitamins A, D, E and K.

### Miscellaneous disorders of the small intestine

#### Protein-losing enteropathy

This term is used when there is excessive loss of protein into the gut lumen, sufficient to cause hypoproteinaemia. Protein-losing enteropathy occurs in many gut disorders but is most common in those where ulceration occurs (Box 23.48). In other disorders, protein loss can result from increased mucosal permeability or obstruction of intestinal lymphatic vessels. Patients present with peripheral oedema and hypoproteinaemia (reduced serum albumin and immunoglobulins), in the context of normal liver function and absent proteinuria. The diagnosis can be confirmed by measurement of faecal clearance of  $\alpha_1$ -antitrypsin or  $^{51}\text{Cr}$ -labelled albumin after intravenous injection. Other investigations should be performed to determine the underlying cause. Treatment is that of the underlying disorder, with nutritional support and measures to control peripheral oedema.

#### Intestinal lymphangiectasia

This may be primary, resulting from congenital malunion of lymphatics, or secondary to lymphatic obstruction due to lymphoma, filariasis or constrictive pericarditis. Impaired drainage of intestinal lymphatic vessels leads to discharge of protein and fat-rich lymph into the gastrointestinal lumen. The condition presents with peripheral lymphoedema, pleural effusions or chylous ascites, and steatorrhoea. Investigations reveal hypoalbuminaemia, lymphopenia and reduced serum immunoglobulin concentrations. The diagnosis can be made by CT or MRI scanning and by enteroscopy with jejunal biopsy, which shows greatly dilated lacteals. Treatment consists of a low-fat diet with medium-chain triglyceride supplements.

#### Ulceration of the small intestine

Small bowel ulcers are uncommon and are either idiopathic or secondary to underlying intestinal disorders (Box 23.49). Ulcers are more common in the ileum and cause bleeding, perforation, stricture formation or obstruction. Capsule endoscopy and enteroscopy confirm the diagnosis.

#### NSAID-associated small intestinal toxicity

NSAIDs cause a spectrum of small intestinal lesions, ranging from erosions and ulcers to mucosal webs, strictures and, rarely, a condition known as 'diaphragm disease', in which intense submucosal fibrosis results in circumferential stricturing. The condition can present with pain,

### 23.48 Causes of protein-losing enteropathy

#### With mucosal erosions or ulceration

- Crohn's disease
- Ulcerative colitis
- Radiation damage
- Oesophageal, gastric or colonic cancer
- Lymphoma

#### Without mucosal erosions or ulceration

- Ménétrier's disease
- Bacterial overgrowth
- Coeliac disease
- Tropical sprue
- Eosinophilic gastroenteritis
- Systemic lupus erythematosus

#### With lymphatic obstruction

- Intestinal lymphangiectasia
- Constrictive pericarditis
- Lymphoma
- Whipple's disease

### 23.49 Causes of small intestinal ulcers

- Idiopathic
- Inflammatory bowel disease
- Non-steroidal anti-inflammatory drugs
- Ulcerative jejuno-ileitis
- Lymphoma and carcinoma
- Infections (tuberculosis, typhoid, *Yersinia enterocolitica*)
- Others (radiation, vasculitis)

obstruction, bleeding or anaemia, and may mimic Crohn's disease, carcinoma or lymphoma. Enteroscopy or capsule endoscopy can reveal the diagnosis but sometimes this is discovered only at laparotomy.

### Eosinophilic gastroenteritis

This disorder of unknown aetiology can affect any part of the gastrointestinal tract, with the stomach and small intestine being the areas most commonly affected; it is characterised by eosinophil infiltration involving the gut wall, in the absence of parasitic infection or eosinophilia of other tissues. It may be mucosal, muscular or subserosal. Peripheral blood eosinophilia is present in around 70% of cases.

#### Clinical features

There are features of obstruction and inflammation, such as colicky pain, nausea and vomiting, diarrhoea and weight loss. Protein-losing enteropathy occurs and up to 50% of patients have a history of other allergic disorders. Steatorrhoea may be present in around 30% of patients. Serosal involvement may produce eosinophilic ascites.

#### Investigations and management

The diagnosis is made by histological assessment of multiple endoscopic biopsies, although full-thickness biopsies are occasionally required. Other investigations should be performed to exclude parasitic infection and other causes of eosinophilia. Serum IgE concentration is raised in around two-thirds of cases. Dietary manipulations can be considered as an initial strategy, but are rarely effective, although elimination diets (especially of milk) may benefit a few patients. Severe symptoms are treated with prednisolone (20–40 mg daily) and/or sodium cromoglicate, which stabilises mast cell membranes. The prognosis is good in the majority of patients.

### Meckel's diverticulum

This is the most common congenital anomaly of the gastrointestinal tract and occurs in 0.3%–3% of people, but the vast majority of affected individuals are asymptomatic throughout life. The diverticulum results from failure of closure of the vitelline duct, with persistence of a blind-ending sac arising from the anti-mesenteric border of the ileum; it usually occurs within 100 cm of the ileocaecal valve and is up to 5 cm long. Approximately 50% contain ectopic gastric mucosa; rarely, colonic,

pancreatic or endometrial tissue is present. Complications most commonly occur in the first 2 years of life, but are occasionally seen in young adults. Bleeding can result from ulceration of ileal mucosa adjacent to the ectopic parietal cells and presents as recurrent melaena or altered blood per rectum. The diagnosis can be made by scanning the abdomen using a gamma camera following an intravenous injection of  $^{99m}\text{Tc}$ -pertechnetate, which is concentrated by ectopic parietal cells. Other complications include intestinal obstruction, diverticulitis, intussusception and perforation. Intervention is unnecessary unless complications occur.

## Adverse food reactions

Adverse food reactions are common and are subdivided into food intolerance and food allergy, the former being much more common. In food intolerance, there is an adverse reaction to food that is not immune-mediated and results from pharmacological (histamine, tyramine or monosodium glutamate), metabolic (lactase deficiency) or other mechanisms (toxins or chemical contaminants in food). Food allergies (discussed in the section on 'Allergy' in Chapter 4) are immune-mediated disorders, most commonly due to type I hypersensitivity reactions with production of IgE antibodies, although type IV delayed hypersensitivity reactions are also seen.

## Lactose intolerance

Human milk contains around 200mmol/L (68g/L) of lactose, which is normally digested to glucose and galactose by the brush border enzyme lactase prior to absorption. In most populations, enterocyte lactase activity declines throughout childhood. The enzyme is deficient in up to 90% of adult Africans, Asians and South Americans, but only 5% of northern Europeans.

In cases of genetically determined (primary) lactase deficiency, jejunal morphology is normal. 'Secondary' lactase deficiency occurs as a consequence of disorders that damage the jejunal mucosa, such as coeliac disease and viral gastroenteritis. Unhydrolysed lactose enters the colon, where bacterial fermentation produces volatile short-chain fatty acids, hydrogen and carbon dioxide.

### Clinical features

In most people, lactase deficiency is completely asymptomatic. However, some complain of colicky pain, abdominal distension, increased flatus, borborygmi and diarrhoea after ingesting milk or milk products. Irritable bowel syndrome may be suspected, but the correct diagnosis is suggested by clinical improvement on lactose withdrawal. The lactose hydrogen breath test is a useful non-invasive investigation.

Dietary exclusion of lactose is recommended, although most sufferers are able to tolerate small amounts of milk (up to 250mL milk, 12g lactose) without symptoms. Addition of commercial lactase preparations to milk may be effective, but is costly.

## Infections of the small intestine

Infections of the small intestine are discussed in other chapters. For travellers' diarrhoea, giardiasis and amoebiasis, see Chapter 13. Abdominal tuberculosis is discussed on page 520. Cryptosporidiosis and other protozoal infections, including cystoisosporiasis (*Cystoisospora belli*) and microsporidiosis, are covered Chapters 13 and 14.

## Tumours of the small intestine

The small intestine is rarely affected by neoplasia and fewer than 5% of all gastrointestinal tumours occur at this site.

### Benign tumours

The most common are adenomas, GISTs, lipomas and hamartomas. Adenomas are most often found in the periampullary region and are usually asymptomatic, although occult bleeding or obstruction due to intussusception may occur. Transformation to adenocarcinoma is rare.

Multiple adenomas are common in the duodenum of patients with familial adenomatous polyposis (FAP), who require regular endoscopic surveillance. Hamartomatous polyps with almost no malignant potential occur in Peutz–Jeghers syndrome (p. 832).

## Malignant tumours

These are rare and include, in decreasing order of frequency, neuro-endocrine tumours, adenocarcinoma, malignant GIST and lymphoma. The majority occur in middle age or later. Kaposi's sarcoma of the small bowel may arise in patients with HIV/AIDS.

### Adenocarcinomas

Adenocarcinomas occur with increased frequency in patients with FAP, coeliac disease, small bowel Crohn's disease and Peutz–Jeghers syndrome. This rare cancer accounts for fewer than 5% of all gastrointestinal malignancies. The non-specific presentation and rarity of these lesions often lead to a delay in diagnosis. Most are noted during assessment of anaemia or obscure GI bleeding. Capsule endoscopy or device-assisted enteroscopy, and small bowel enterography studies (CT or MRI) can be used to identify lesions. Treatment is by surgical resection.

### Neuro-endocrine tumours

These are discussed in detail on page 691.

### Lymphoma

Non-Hodgkin lymphoma (Ch. 25) may involve the gastrointestinal tract as part of more generalised disease or may rarely arise in the gut, the small intestine being most commonly affected. Lymphomas occur with increased frequency in patients with coeliac disease, HIV/AIDS and other immunodeficiency states. Most are of B-cell origin, although lymphoma associated with coeliac disease is derived from T cells (enteropathy-associated T-cell lymphoma).

Colicky abdominal pain, obstruction and weight loss are the presenting features and perforation is also seen occasionally. Malabsorption is a feature of diffuse bowel involvement and hepatosplenomegaly is rare.

The diagnosis is made by small bowel biopsy, radiological contrast studies and CT. Staging investigations should be performed as for lymphomas occurring elsewhere (p. 133). Surgical resection, where possible, is the treatment of choice, with radiotherapy and combination chemotherapy reserved for those with advanced disease. The prognosis depends largely on the stage at diagnosis, cell type, patient age and the presence of 'B' symptoms (fever, weight loss, night sweats).

### Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (IPSID), also known as alpha heavy chain disease, is a rare condition occurring mainly in Mediterranean countries, the Middle East, India, Pakistan and North America. It is a variant of B-cell lymphoma of MALT type and often associated with *Campylobacter jejuni* infection. The condition varies in severity from relatively benign to frankly malignant.

The small intestinal mucosa is diffusely affected, especially proximally, by a dense lymphoplasmacytic infiltrate. Enlarged mesenteric lymph nodes are also common. Most patients are young adults who present with malabsorption, anorexia and fever. Serum electrophoresis confirms the presence of alpha heavy chains (from the  $F_c$  portion of IgA). Prolonged remissions can be obtained with long-term antibiotic therapy, but chemotherapy is required for those who fail to respond or who have aggressive disease.

## Small intestine motility disorders

### Chronic small intestine pseudo-obstruction

Small intestinal motility is disordered in conditions that affect the smooth muscle or nerves of the intestine. Many cases are 'primary' (idiopathic), while others are 'secondary' to a variety of disorders or drugs (Box 23.50).

### 23.50 Causes of chronic intestinal pseudo-obstruction

#### Primary or idiopathic

- Rare familial visceral myopathies or neuropathies
- Congenital aganglionosis

#### Secondary

- Drugs (opiates, tricyclic antidepressants, phenothiazines)
- Smooth muscle disorders (systemic sclerosis, amyloidosis, mitochondrial myopathies)
- Myenteric plexus disorders, e.g. paraneoplastic syndrome in small-cell lung cancer
- Central nervous system disorders (Parkinson's disease, autonomic neuropathy)
- Endocrine and metabolic disorders (hypothyroidism, diabetic autonomic neuropathy, pheochromocytoma, acute intermittent porphyria)

### Clinical features

There are recurrent episodes of nausea, vomiting, abdominal discomfort and distension, often worse after food. Alternating constipation and diarrhoea occur and weight loss results from malabsorption (due to bacterial overgrowth) and fear of eating. There may also be symptoms of dysmotility affecting other parts of the gastrointestinal tract, such as dysphagia, and features of bladder dysfunction in primary cases. Some patients develop severe abdominal pain for reasons that are poorly understood and this can be difficult to manage.

### Investigations

The diagnosis is often delayed and a high index of suspicion is needed. Plain X-rays show distended loops of bowel and air–fluid levels, with abdominal CT and small bowel MRI used to exclude mechanical obstruction. Laparotomy is sometimes required to exclude obstruction and to obtain full-thickness biopsies of the intestine. Examination of biopsy material using specialised techniques, such as electron microscopy and immunohistochemistry can diagnose the many rare diseases of enteric smooth muscle and nerves that can cause this syndrome.

### Management

This is often difficult. Underlying causes should be addressed and further surgery avoided. Metoclopramide or domperidone may enhance motility and antibiotics are given for bacterial overgrowth. Nutritional and psychological support is also necessary.

## Disorders of the colon and rectum

### Colorectal polyps

#### Types of colorectal polyps

In the colon, polyps usually arise from the mucosal layer. These can vary in number and size, from a few millimetres to several centimetres. They are commonly described based on their appearance as sessile, pedunculated, flat, elevated or depressed (Fig. 23.45). In addition, they are classified histologically, as neoplastic or non-neoplastic polyps (Box 23.51). This is important to help predict their malignant potential.

Non-neoplastic polyps include hamartomas, inflammatory polyps and hyperplastic polyps, which harbour no malignant potential. Hyperplastic polyps are the commonest type of colorectal polyp, and are a subgroup of so-called serrated polyps, often small in size, and frequently found in the distal colon. Hamartomas can occur sporadically, or as part of a polyposis syndrome. Inflammatory polyps are commonly seen in the context of IBD and are due to inflammation within the colon with distorted mucosa.

The most well-known neoplastic polyps are conventional adenomas, which harbour malignant potential and are extremely common in the

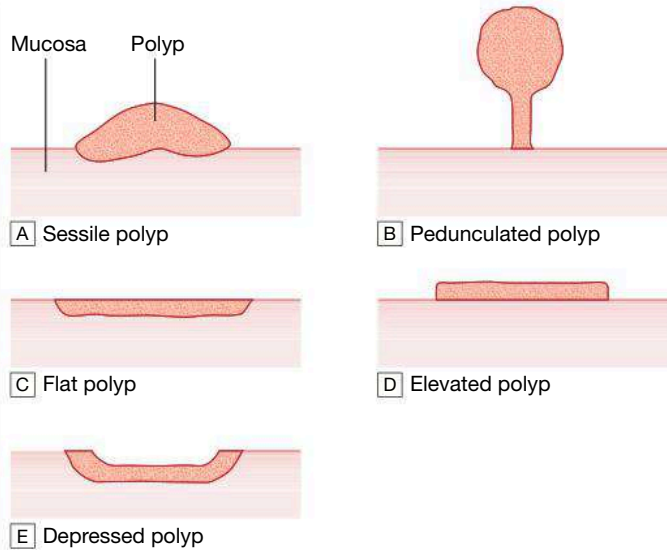

Fig. 23.45 Polyp morphology.

### 23.51 Neoplastic and non-neoplastic polyps

#### Neoplastic polyps

- Conventional adenoma
- Sessile serrated lesion
- Traditional serrated adenoma

#### Non-neoplastic polyps

- Hamartoma
- Inflammatory
- Hyperplastic

Western world. The prevalence of adenomas increases with age; 50% of people over 60 years of age have colorectal adenomas and in half of these the polyps are multiple. Adenomas can be found throughout the colon, although larger polyps, harbouring a higher risk of malignancy, tend to be more common in the rectum and distal colon. They can be further sub-classified histologically, as either tubular, villous or tubulovillous, according to the glandular architecture. Features associated with a higher risk of subsequent malignancy are listed in Box 23.52. Adenomas are usually asymptomatic and discovered incidentally. Larger adenomas can occasionally cause bleeding and anaemia. Rarely, large villous adenomas can secrete significant amounts of mucus, causing diarrhoea and hypokalaemia (McKittrick-Wheelock syndrome).

Traditionally, it was thought that adenomas were the only type of neoplastic polyp. However, it is now known that sessile serrated lesions and traditional serrated adenomas, further subgroups of serrated polyps, bear malignant potential. Sessile serrated lesions are more common in the right colon, tend to be flatter than conventional adenomas and are often covered with a mucus cap, making them hard to detect. They are now thought to account for between 15%–30% of colorectal cancers. Traditional serrated adenomas are relatively rare, accounting for <1% of all polyps, commonly found in the distal colon and can also harbour malignant potential.

### Assessment and treatment of colorectal polyps

Colonic polyps are commonly found incidentally during endoscopy. If a polyp is found during sigmoidoscopy, a colonoscopy should be subsequently performed, as up to 40%–50% of affected individuals have further polyps more proximally in the colon. As neoplastic colonic polyps have malignant potential, these should be removed via colonoscopic polypectomy, as this considerably reduces subsequent colorectal cancer risk (Fig. 23.46). When cancer cells are found within 2 mm of the resection margin of the polyp, when the polyp cancer is poorly differentiated

or when lymphatic invasion is present, segmental colonic resection is recommended because residual tumour or lymphatic spread (in up to 10%) may be present. Malignant polyps without these features can be followed up by surveillance colonoscopy.

Very large sessile polyps can sometimes be removed safely by endoscopic mucosal resection (EMR), but many require surgery. Endoscopic submucosal dissection (ESD) can be used for some lesions with a high suspicion of limited submucosal invasion, although this is a technically challenging procedure that is not routinely performed. Once all polyps have been removed, surveillance colonoscopy should be undertaken in individuals with high-risk findings, as new polyps develop in 50% of patients. Patients over 75 years of age tend not to require repeated colonoscopies, as their subsequent lifetime cancer risk is low.

## Colorectal cancer

Globally, colorectal cancer is the third most commonly diagnosed cancer in males and second in females. High-income countries have the highest incidence of colorectal cancer, while Africa and South Asia have the lowest incidence. Worldwide incidence is continuing to increase, although incidence rates have stabilised in high-income countries. In the UK, the incidence is around 70 per 100 000 of the population. The condition becomes increasingly common over the age of 50 years.

### Pathophysiology

Both environmental and genetic factors are important in colorectal carcinogenesis. The majority (75%) of colorectal cancers are sporadic, with 20% of patients having genetic predisposition and a small minority (5%) being hereditary. [Figure 23.47](#) outlines the key pathophysiological factors.

### Genetics

Colorectal cancer development results from the accumulation of multiple genetic mutations. There are also associated epigenetic influences, such as microRNA expression signature, and potential influences from non-coding genetic variation. Currently, there are three main pathways

of genetic instability and each is associated with histological, clinical and prognostic parameters:

- *Chromosomal instability*. Mutations or deletions of portions of chromosomes arise, with loss of heterozygosity (LOH) and inactivation of specific tumour suppressor genes. In LOH, one allele of a gene is deleted, but gene inactivation occurs only when a subsequent unrelated mutation affects the other allele. Chromosomal instability (CIN) occurs in around 85% of colorectal cancers.
- *Microsatellite instability*. This involves germline mutations in one of six genes encoding enzymes involved in repairing errors that occur normally during DNA replication (DNA mismatch repair); these genes are designated *hMSH2*, *hMSH6*, *hMLH1*, *hMLH3*, *hPMS1* and *hPMS2*. Replication errors accumulate and can be detected in 'microsatellites' of repetitive DNA sequences. They also occur in important regulatory genes, resulting in a genetically unstable phenotype and accumulation of multiple somatic mutations throughout the genome that eventually lead to cancer. Around 15% of sporadic cancers develop this way, as do most cases of hereditary non-polyposis colon cancer (HNPCC).
- *CpG island methylator phenotype (CIMP)*. This phenotype is found in approximately 20%–30% of colorectal cancers and results in widespread gene hypermethylation. The result is functional loss of tumour suppressor genes.

There are two distinct pathways of carcinogenesis: the classical adenoma–carcinoma pathway and the more recently discovered alternate serrated neoplasia pathway. The classical adenoma–carcinoma pathway is characterised by an adenoma as the precursor lesion. Adenomas tend to result in carcinoma through the sequential acquisition of mutations, through chromosomal and microsatellite instability ([Fig. 23.48](#)). The time period for an adenoma to develop into a carcinoma is thought to take between 5 and 10 years. The serrated neoplasia pathway is characterised by a serrated polyp as a precursor lesion. Serrated polyps (hyperplastic, sessile serrated lesions, traditional serrated adenomas) were all thought to be non-neoplastic previously. However, it is now thought that sessile serrated lesions and traditional serrated adenomas are precursor lesions for malignancy. While hyperplastic polyps are generally still viewed as non-neoplastic, some subtypes are thought to be precursors of sessile serrated lesions. There are two pathways of carcinoma formation via the serrated neoplasia pathway, through the traditional serrated and sessile routes, with genetic instability through microsatellite instability and CIMP ([Fig. 23.49](#)), although molecular pathways are still not well understood. The serrated neoplasia pathway is associated with faster carcinoma development in comparison to the classical adenoma–carcinoma pathway.

### 23.52 Risk factors for malignant change in colonic polyps

- Large size (> 2 cm)
- Multiple polyps
- Serrated polyps (excluding small rectal hyperplastic polyps)
- Villous architecture
- High-grade dysplasia

**Fig. 23.46** Large rectal adenomatous polyp. **A** Before colonoscopic polypectomy. **B** After polypectomy.

Fig. 23.47 Risk factors for colorectal cancer. (NSAIDs = non-steroidal anti-inflammatory drugs; UC = ulcerative colitis)

	Normal	Early adenoma	Intermediate adenoma	Late adenoma	Carcinoma
<b>Key gene(s)</b>	<i>APC</i> (adenomatous polyposis coli)	<i>KRAS</i>	<i>DCC</i> (deleted in colon cancer) <i>SMAD4</i>	<i>TP53</i>	
<b>Chromosome</b>	5q	12p	18q	17p	
<b>Normal function</b>	Inhibits translocation of $\beta$ -catenin to nucleus and suppresses cell growth	Transmembrane GTP-binding protein mediating mitogenic signals (p21)	<i>DCC</i> regulates apoptosis and has a tumour suppressor function <i>SMAD4</i> regulates cell growth	Up-regulated during cell damage to arrest cell cycle and allow DNA repair or apoptosis to occur	
<b>Alteration</b>	Truncating mutations	Gain-of-function mutations	Allelic deletion or silencing ( <i>DCC</i> ) Gain-of-function mutations ( <i>SMAD4</i> )	Allelic deletion; gain-of-function mutations	
<b>Effect</b>	Progression to early adenoma development	Cell proliferation	Enhanced tumour growth, invasion and metastasis	Cell proliferation; impaired apoptosis	

**Further mutations**

- Anchorage independence
- Protease synthesis
- Telomerase synthesis
- Multidrug resistance
- Evasion of immune system

Fig. 23.48 The multistep origin of cancer: molecular events implicated in colorectal carcinogenesis. (GTP = guanine triphosphate)

### Environment

The majority of colorectal cancers are sporadic, with the development of carcinoma being dependent upon the penetrance of a genetic predisposition and the severity of environmental insult. It is thought that up to 50% of cases of colorectal cancer may potentially be preventable by lifestyle modifications. Several risk factors increase the risk of colorectal cancer, such as smoking, alcohol and type 2 diabetes. In addition, dietary factors are also key in the pathophysiology of colorectal cancer, such as fruit and vegetable intake (see Fig. 23.47).

### Clinical features

Symptoms vary, depending on the site of the carcinoma. However, the disease is largely asymptomatic until at an advanced stage. In tumours of the left colon, fresh rectal bleeding is common and obstruction occurs early. Tumours of the right colon present with anaemia from occult bleeding or with altered bowel habit, but obstruction is a late feature. Colicky lower abdominal pain is present in two-thirds of patients and rectal bleeding occurs in 50%. A minority present with features of either obstruction or perforation, leading to peritonitis, localised abscess or

Fig. 23.49 The serrated neoplasia pathway.

fistula formation. Carcinoma of the rectum usually causes early bleeding, mucus discharge or a feeling of incomplete emptying. Between 10% and 20% of patients present with iron deficiency anaemia or weight loss. On examination, there may be a palpable mass, signs of anaemia or hepatomegaly from metastases. Low rectal tumours may be palpable on digital examination.

### Investigations

Colonoscopy is the investigation of choice because it is more sensitive and specific than barium enema. Furthermore, lesions can be biopsied and polyps removed. Patients in whom colonoscopy is incomplete and those who are at high risk of complications can be investigated by CT colonography (virtual colonoscopy). This is a sensitive and non-invasive technique for diagnosing tumours and polyps of more than 6 mm diameter. When the diagnosis of colon cancer has been made, CT of the chest, abdomen and pelvis should be performed as a staging investigation, particularly to detect hepatic metastases, with an increasing role of MRI for further characterisation of liver lesions. Pelvic MRI or endoanal ultrasound should be used for local staging of rectal cancer. Measurement of serum carcinoembryonic antigen (CEA) levels is of limited value in diagnosis, since values are normal in many patients, but CEA testing can be helpful during follow-up to monitor for recurrence. FDG PET-CT is being increasingly used, although its exact role is still debated. Tumour stage (TNM) at diagnosis is the most important determinant of prognosis (Fig. 23.50).

### Management

#### Endoscopy

Early colorectal cancers may be amenable to endoscopic treatment, using techniques such as endoscopic mucosal resection, endoscopic submucosal dissection and endoscopic full-thickness resection. Endoscopic submucosal dissection and endoscopic full-thickness resection tend to be used when there is suspicion of superficial submucosal invasion and

needs a highly skilled endoscopist. In addition to such a procedure, surgical mesenteric lymphadenectomy may be required.

#### Surgery

Surgery for colorectal cancer remains the cornerstone of treatment with curative intent. Rectal cancers can be complex to operate on due to the anatomy of the pelvis. Neoadjuvant radiotherapy or chemoradiotherapy should be offered to individuals with high-risk rectal cancers to increase the subsequent chance of a complete (R0) subsequent surgical resection. Colorectal cancer may present as an emergency with obstruction or perforation. Obstruction can be treated by either a decompressing colostomy or endoscopic stenting. Metastatic disease confined to liver or lung should be considered for resection, as this can be potentially curative if there is truly no disease at other sites. Metastatic disease confined to the peritoneum can be considered for cytoreductive surgery and hyperthermic intraperitoneal chemotherapy, which shows benefit in survival in a subset of patients. Post-operatively, patients should undergo colonoscopy after 1 year and then 3 years later to search for local recurrence or development of new lesions.

#### Adjuvant therapy

About 30%–40% of patients have lymph node involvement at presentation and are therefore at risk of recurrence. Most recurrences are within 3 years of diagnosis and affect the liver, lung, distant lymph nodes and peritoneum. Adjuvant chemotherapy with 5-fluorouracil/folinic acid or capecitabine, preferably in combination with oxaliplatin, can reduce the risk of recurrence.

#### Palliation of advanced disease

Surgical resection of the primary tumour is appropriate for some patients with metastases to treat obstruction, bleeding or pain. *RAS* and *BRAF* V600E mutations are tested for in metastatic colorectal cancer in individuals being considered for systemic anti-cancer treatment, with outcomes worse if these mutations are present. Palliative chemotherapy with

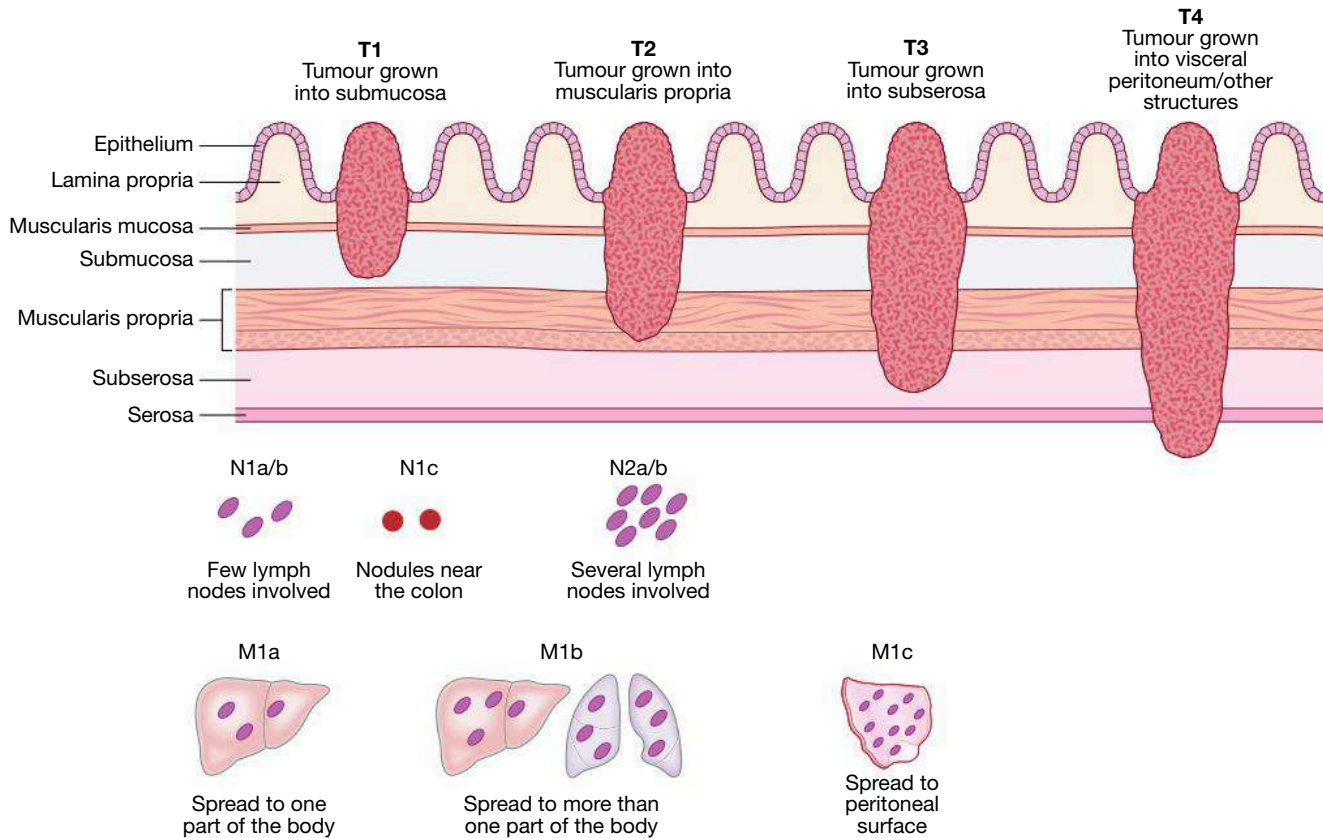

Fig. 23.50 TNM classification in colorectal cancer.

5-fluorouracil/folinic acid, capecitabine, oxaliplatin or irinotecan improves survival. Patients with advanced metastatic disease may be treated with monoclonal antibodies such as panitumumab or cetuximab, which bind to and inhibit the epidermal growth factor receptor. They are often given together with chemotherapy. Pelvic radiotherapy is sometimes useful for distressing rectal symptoms, such as pain, bleeding or severe tenesmus. Endoscopic laser therapy or insertion of an expandable metal stent can be used to relieve obstruction.

### Prevention and screening

Secondary prevention aims to detect and remove lesions at an early or pre-malignant stage by screening the asymptomatic general population. Several potential methods exist:

- Population-based screening of people between the age of 50 to 74 years by regular *faecal immunochemical testing (FIT)* reduces colorectal cancer mortality and increases the proportion of early cancers detected. Serial stool testing with or without subsequent colonoscopy is the screening method of choice in the UK.
- *Colonoscopy* remains the gold standard and allows preventative polypectomy, but is expensive, requires bowel preparation and carries risks (perforation approximately 1:1000). Many countries lack the resources to offer this form of screening.
- *Flexible sigmoidoscopy* is an alternative option and has been shown to reduce overall colorectal cancer mortality by approximately 35% (70% for cases arising in the rectosigmoid). It is recommended in England, where available, as a one-off test in individuals aged 55 years, with subsequent FIT from age 60 years.
- *CT colonography* is fast and low-risk, and offers equivalent sensitivity to colonoscopy. Disadvantages include reduced sensitivity to detect polyps of less than 6 mm, the requirement for bowel preparation, exposure to ionising radiation and its inability to offer therapeutic intent.

### Hereditary syndromes predisposing to colorectal cancer

Whilst hereditary syndromes are rare, collectively accounting for 3%–5% of colorectal carcinomas, they are important to identify, as the risk of colorectal carcinoma is high in these individuals.

#### Non-polyposis syndromes

Hereditary non-polyposis colorectal cancer (HNPCC), also known as Lynch syndrome, has an autosomal dominant mode of inheritance, with a positive family history of colon cancer occurring at a young age. It is the commonest hereditary cancer syndrome, accounting for 1%–3% of all colorectal cancer cases. The lifetime risk in affected individuals is 80%, with a mean age at cancer development of 45 years. In contrast to sporadic colon cancer, two-thirds of tumours occur proximally. The clinical diagnostic criteria are listed in [Box 23.53](#), with diagnosis now shifting from such criteria to testing of tumour material by microsatellite instability polymerase chain reaction and immunohistochemistry for mismatch repair proteins. In a subset of patients, there is also an increased incidence of cancers of the endometrium, ovary, urinary tract, stomach, pancreas, small intestine and CNS, related to inheritance of different mismatch repair gene mutations. Those who fulfil the criteria for HNPCC should be referred for pedigree assessment, genetic testing (see above) and colonoscopy. These should begin at either 25 years or 35 years (dependent upon the specific genetic abnormalities detected). Colonoscopy needs to be repeated every 2 years, but despite this, interval cancers can still occur. Regular daily use of aspirin is thought to reduce colorectal cancer risk.

#### Polyposis syndromes

Polyposis syndromes are classified by histopathology ([Box 23.54](#)). It is important to note that, while the hamartomatous polyps in Peutz-Jeghers syndrome and juvenile polyposis are not themselves neoplastic,

these disorders are associated with an increased risk of malignancy of the breast, colon, ovary and thyroid.

### Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is an uncommon autosomal dominant disorder affecting 1 in 14000 of the population and accounting for 0.07% of colorectal cancers. It results from germline mutation of the tumour suppressor *APC* gene, followed by acquired mutation of the remaining allele (Ch. 3). The *APC* gene is large and over 1400 different mutations have been reported, but most are loss-of-function mutations resulting in a truncated *APC* protein. This protein normally binds to and sequesters  $\beta$ -catenin, but is unable to do so when mutated, allowing  $\beta$ -catenin to translocate to the nucleus, where it up-regulates the expression of many genes. Gene mutations are detected in around 95% of FAP cases. Around 25% of cases arise as new mutations and have no family history.

Hundreds to thousands of adenomatous colonic polyps develop in 80% of patients by age 15 (Fig. 23.51), with symptoms such as rectal bleeding beginning a few years later. In those affected, cancer will develop within 10–15 years of the appearance of adenomas and 90% of patients will develop colorectal cancer by the age of 50 years. Despite surveillance, approximately 1 in 4 patients with FAP have cancer by the time they undergo colectomy. There appears to be phenotypic variability in FAP, with an attenuated form resulting in fewer than 100 adenomatous polyps and later onset of polyposis and cancer.

A second gene involved in base excision repair (*MutY* homolog, *MUTYH*) has been identified and may give rise to colonic polyposis. *MUTYH* displays autosomal recessive inheritance and leads to tens to hundreds of polyps and proximal colon cancer. This variant is referred to as *MUTYH*-associated polyposis (MAP).

In FAP, non-neoplastic cystic fundic gland polyps occur in the stomach, but adenomatous polyps also arise uncommonly. Duodenal adenomas are found in over 90% and are most common around the ampulla of

Vater. Malignant transformation to adenocarcinoma takes place in 10% and is the leading cause of death in those who have had prophylactic colectomy. Many extra-intestinal features are also seen (Box 23.55).

Desmoid tumours occur in up to one-third of patients and usually arise in the mesentery or abdominal wall. Although benign, they may become very large, causing compression of adjacent organs, intestinal obstruction or vascular compromise and are difficult to remove. They sometimes respond to hormonal therapy with tamoxifen, and the NSAID sulindac may bring about regression in some, by unknown mechanisms. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in some cases and is seen as dark, round, pigmented retinal lesions. When present in an at-risk individual, these are 100% predictive of the presence of FAP. A variant, Turcot syndrome, is characterised by FAP with primary CNS tumours (astrocytoma or medulloblastoma).

**Fig. 23.51 Familial adenomatous polyposis.** There are hundreds of adenomatous polyps throughout the colon.

#### 23.53 Modified Amsterdam criteria\* for hereditary non-polyposis colon cancer

- Three or more relatives with colon cancer (at least one first-degree)
- Colorectal cancer in two or more generations
- At least one member affected under 50 years of age
- Familial adenomatous polyposis excluded

\*These criteria are strict and may miss some families with mutations. Hereditary non-polyposis colon cancer should also be considered in individuals with colorectal or endometrial cancer under 45 years of age.

#### 23.55 Extra-intestinal features of familial adenomatous polyposis

- Congenital hypertrophy of the retinal pigment epithelium (CHRPE, 70%–80%)
- Epidermoid cysts (extremities, face, scalp)\* (50%)
- Benign osteomas, especially skull and angle of mandible\* (50%–90%)
- Dental abnormalities (15%–25%)\*
- Desmoid tumours (10%–15%)
- Other malignancies (brain, thyroid, liver, adrenal, 1%–3%)

\*Gardner syndrome.

#### 23.54 Gastrointestinal polyposis syndromes

	Neoplastic		Non-neoplastic <sup>1</sup>		
	Familial adenomatous polyposis	Peutz–Jeghers syndrome	Juvenile polyposis	Cronkhite–Canada syndrome	Cowden disease
<b>Inheritance</b>	Autosomal dominant <sup>2</sup>	Autosomal dominant	Autosomal dominant in one-third	None	Autosomal dominant
<b>Oesophageal polyps</b>	–	–	–	+	+
<b>Gastric polyps</b>	+	+	+	+++	+++
<b>Small bowel polyps</b>	++	+++	++	++	++
<b>Colonic polyps</b>	+++	++	++	+++	+
<b>Other features</b>	Colorectal cancer, bleeding, extra-intestinal features (see Box 23.55)	Pigmentation, bleeding, intussusception, bowel and other cancers	Colorectal cancer	Hair loss, pigmentation, nail dystrophy, malabsorption	Many congenital anomalies, oral and cutaneous hamartomas, thyroid and breast tumours

<sup>1</sup>The polyps themselves are not neoplastic but cancer risk is increased in several syndromes. <sup>2</sup>Rare autosomal recessive variant *MUTYH* (see text). (– = absent; + = may occur; ++ = common; +++ = very common)

Early identification of affected individuals before symptoms develop is essential. The diagnosis can be excluded if sigmoidoscopy is normal. In newly diagnosed cases, genetic testing should be carried out to confirm the diagnosis and identify the causal mutation. Subsequently, all first-degree relatives should undergo genetic testing (Ch. 3). In families with known FAP, adolescents should undergo mutation testing at 13–14 years of age and patients who are found to have the mutation should be offered colectomy after school or college education has been completed. The operation of choice is total proctocolectomy with ileal pouch–anal anastomosis. Ileoanal pouch construction may be associated with reduced fertility in women, which may be due to fallopian tube scarring post surgery. Therefore, colectomy with ileorectal anastomosis can be used, but is associated with a risk of cancer in the retained rectum. Periodic upper gastrointestinal endoscopy every 1–3 years is recommended to detect and monitor duodenal and periampullary adenomas. If large, these may be amenable to endoscopic resection.

### Peutz–Jeghers syndrome

Peutz–Jeghers syndrome occurs in around 1 in 120 000 of the population, accounting for less than 0.01% of colorectal cancer cases. Multiple hamartomatous polyps occur in the small intestine and colon, as well as melanin pigmentation of the lips, mouth and digits (Fig. 23.52). Most cases are asymptomatic, although chronic bleeding, anaemia or intussusception can occur. There is a significant risk of small bowel or colonic adenocarcinoma and of cancer of the pancreas, lung, testis, ovary, breast and endometrium. Peutz–Jeghers syndrome is an autosomal dominant disorder with high penetrance, most commonly resulting from truncating mutations in a serine–threonine kinase gene on chromosome 19p (*STK11*). Diagnosis requires two of the three following features:

- small bowel polyposis
- mucocutaneous pigmentation
- a family history suggesting autosomal dominant inheritance.

The diagnosis can be made by genetic testing, but this may be inconclusive, since mutations in genes other than *STK11* can cause the disorder. Affected people should undergo regular upper endoscopy, colonoscopy and small bowel and pancreatic imaging. Polyps greater than 1 cm in size should be removed. Testicular examination is essential for men, while women should undergo pelvic examination, cervical smears and regular mammography (lifetime risk of breast cancer of 50%). Asymptomatic relatives of affected patients should also undergo screening.

### Juvenile polyposis

In juvenile polyposis, tens to hundreds of mucus-filled hamartomatous polyps are found in the colorectum. One-third of cases are inherited in an autosomal dominant manner and up to one-fifth develop colorectal cancer before the age of 40. The criteria for diagnosis are:

- ten or more colonic juvenile polyps
- juvenile polyps elsewhere in the gut, *or*
- any polyps in those with a family history.

Germline mutations in the *SMAD4* gene are often found, as well as mutations in the *BMPR1A* gene. *SMAD4* mutations may have a more aggressive clinical phenotype, while *BMPR1A* is particularly implicated in European populations. Colonoscopy with polypectomy should be performed every 1–2 years and colectomy considered for extensive involvement. Periodic upper gastrointestinal endoscopy should be performed every 1–2 years, in view of the risk of gastric and duodenal cancer.

## Diverticulosis

Diverticula are acquired and are most common in the sigmoid and descending colon of middle-aged people. Asymptomatic diverticula (diverticulosis) are present in over 50% of people above the age of

Fig. 23.52 Peutz–Jeghers syndrome. Typical lip pigmentation.

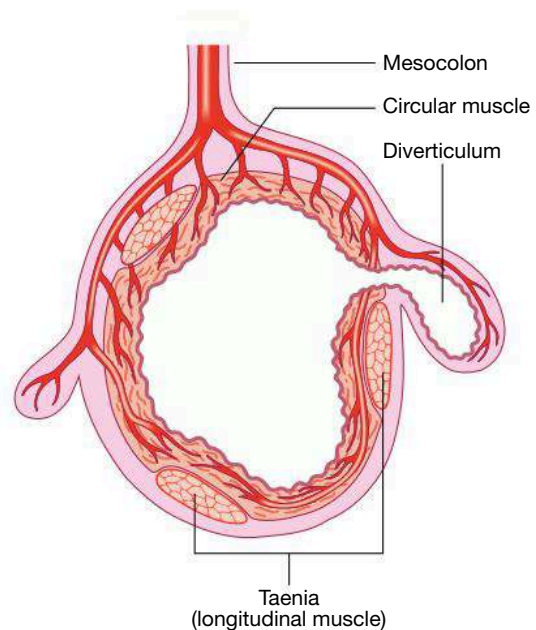

Fig. 23.53 The human colon in diverticulosis. The colonic wall is weak between the taeniae. The blood vessels that supply the colon pierce the circular muscle and weaken it further by forming tunnels. Diverticula usually emerge through these points of least resistance.

70 years. Symptomatic diverticular disease supervenes in 10%–25% of cases, while complicated diverticulosis (acute diverticulitis, pericolic abscess, bleeding, perforation or stricture) is uncommon.

### Pathophysiology

A life-long refined diet with a relative deficiency of fibre is thought to be responsible and the condition is rare in populations with a high dietary fibre intake, such as in Asia, where it more often affects the right side of the colon. It is postulated that small-volume stools require high intracolonic pressures for propulsion and this leads to herniation of mucosa between the taeniae coli (Fig. 23.53). Whilst the pathophysiology of diverticular disease is thought to be mainly due to environmental risk factors, recent evidence suggests the involvement of predisposing genetic factors. Diverticula consist of protrusions of mucosa covered by peritoneum. There is commonly hypertrophy of the circular muscle coat. Inflammation is thought to result from impaction of diverticula with faecoliths. This may resolve spontaneously or progress to cause haemorrhage, perforation, local abscess formation, fistula and peritonitis. Repeated attacks of inflammation lead to thickening of the bowel wall, narrowing of the lumen and eventual obstruction.

### Clinical features

Symptoms are usually the result of associated constipation or spasm. Colicky pain is suprapubic or felt in the left iliac fossa. The sigmoid colon may be palpable and, in attacks of diverticulitis, there is local tenderness, guarding, rigidity ('left-sided appendicitis') and sometimes a palpable mass. During these episodes, there may be diarrhoea, rectal bleeding or fever. The differential diagnosis includes colorectal cancer, ischaemic colitis, IBD and infection. Diverticular disease may be complicated by perforation, pericolic abscess, fistula formation (usually colovesical), acute lower gastrointestinal bleeding and obstruction. These complications are more common in patients who take NSAIDs or aspirin. After one attack of diverticulitis, the recurrence rate is around 3% per year. Over 10–30 years, perforation, obstruction or bleeding may occur, each affecting 5% of patients.

### Investigations

Investigations are usually performed to exclude colorectal neoplasia. Diverticula can be seen during colonoscopy or on imaging modalities such as CT scan, CT colonography or barium enema (see Fig. 23.12C). In severe diverticulosis, colonoscopy requires expertise and carries a risk of perforation. CT is used to assess complications, such as perforation or pericolic abscess.

### Management

Diverticular disease that is asymptomatic and discovered coincidentally requires no treatment. Constipation can be relieved by a high-fibre diet, with or without a bulking laxative (ispaghula husk, 1–2 sachets daily), taken with plenty of fluids. Stimulant laxatives (see Box 23.56) should be avoided. Antispasmodics may sometimes help. Acute attacks of diverticulitis can be treated with antibiotics active against Gram-negative and anaerobic organisms. Severe cases require intravenous fluids, intravenous antibiotics, analgesia and nasogastric suction, but randomised trials show no benefit from acute resection compared to conservative management. Emergency surgery is reserved for severe haemorrhage or perforation. Percutaneous drainage of acute paracolic abscesses can be effective and avoids the need for emergency surgery. Patients who have repeated attacks of obstruction should undergo elective surgery once the acute episode has settled, in order to resect the affected segment of bowel with restoration of continuity by primary anastomosis.

## Colonic motility disorders

The clinical approach to patients with constipation and its aetiology have been described on page 803.

### Simple constipation

Simple constipation is extremely common and does not signify underlying organic disease. It usually responds to increased dietary

fibre or the use of bulking agents; an adequate fluid intake is also essential. Many types of laxative are available, and these are listed in Box 23.56.

### Severe idiopathic constipation

This occurs almost exclusively in young women and often begins in childhood or adolescence. The cause is unknown, but some have 'slow transit' with reduced motor activity in the colon. Others have 'dyssynergic defecation', resulting from inappropriate contraction of the external anal sphincter and puborectalis muscle (anismus). The condition is often resistant to treatment. Bulking agents may exacerbate symptoms, but prokinetic agents or balanced solutions of polyethylene glycol '3350' benefit some patients with slow transit. Glycerol suppositories and bio-feedback techniques are used for those with dyssynergic defecation. Others benefit from agents such as prucalopride or linaclotide. Rarely, subtotal colectomy may be necessary as a last resort.

### Faecal impaction

In faecal impaction, a large, hard mass of stool fills the rectum. This tends to occur in disabled, immobile or institutionalised patients, especially frail older adults or those with dementia (see Box 23.57). Constipating drugs, autonomic neuropathy and painful anal conditions also contribute. Megacolon, intestinal obstruction and urinary tract infections may supervene. Perforation and bleeding from pressure-induced ulceration are occasionally seen. Overflow diarrhoea may also be a presenting feature, sometimes leading to worsening of symptoms with the incorrect use of antidiarrhoeal medication. Treatment should involve adequate hydration and careful digital disimpaction after softening the impacted stool with arachis oil enemas. Stimulants should be avoided.

### Melanos coli and laxative misuse syndromes

Long-term consumption of stimulant laxatives leads to accumulation of lipofuscin pigment in macrophages in the lamina propria. This imparts a brown discoloration to the colonic mucosa, often described as resembling 'tiger skin'. The condition is benign and resolves when the laxatives are stopped. Prolonged laxative use may rarely result in megacolon or 'cathartic colon', in which barium enema demonstrates a featureless mucosa, loss of haustra and shortening of the bowel. Surreptitious laxative misuse is a psychiatric condition seen in young women, some of whom have a history of bulimia or anorexia nervosa (Ch. 31). They complain of refractory watery diarrhoea. Laxative use is usually denied and may continue, even when patients are undergoing investigation. Screening of urine for laxatives may reveal the diagnosis.

### Hirschsprung's disease

This disease is characterised by constipation and colonic dilatation (megacolon) due to congenital absence of ganglion cells in the large intestine. Incidence is approximately 1:5000. About one-third of patients have a positive family history and, in these families, the disease is inherited in

i 23.56 Laxatives	
Class	Examples
Bulk-forming laxatives	Ispaghula husk, methylcellulose
Stimulants	Bisacodyl, dantron (only for terminally ill patients), docusate, senna
Faecal softeners	Docusate, arachis oil enema
Osmotic laxatives	Lactulose, lactitol, magnesium salts
Serotonergic agents	Prucalopride
Prosecretory agents	Linaclotide, lubiprostone, plecanatide
Others	Polyethylene glycol (PEG)*, phosphate enema*

\*Also used for bowel preparation prior to investigation or surgery.

### 23.57 Constipation in old age

- **Evaluation:** particular attention should be paid to immobility, dietary fluid and fibre intake, drugs and depression.
- **Immobility:** predisposes to constipation by increasing the colonic transit time; the longer this is, the greater the fluid absorption and the harder the stool.
- **Bulking agents:** can make matters worse in patients with slow transit times and should be avoided.
- **Overflow diarrhoea:** if faecal impaction develops, paradoxical overflow diarrhoea may occur. If antidiarrhoeal agents are given, the underlying impaction may worsen and result in serious complications, such as stercoral ulceration and bleeding.

an autosomal dominant manner with incomplete penetrance. About 50% of familial cases and 15% of sporadic cases have mutations affecting the *RET* proto-oncogene, which is also implicated in multiple endocrine neoplasia (MEN) types 2a and 2b (p. 700). Unlike MEN 2a and 2b, which are caused by activating *RET* mutations, Hirschsprung's disease is caused by loss-of-function mutations. In some kindreds, Hirschsprung's disease and MEN can actually co-segregate and this presumably represents both 'switch off' and 'switch on' of *RET* in different tissues. Although *RET* is the most important susceptibility gene, some patients with *RET* mutations do not develop clinical Hirschsprung's disease and mutations in other genes have been identified that interact to cause the disease. All of the genes implicated in Hirschsprung's disease are involved in the regulation of enteric neurogenesis and the mutations cause failure of migration of neuroblasts into the gut wall during embryogenesis. Ganglion cells are absent from nerve plexuses, most commonly in a short segment of the rectum and/or sigmoid colon. As a result, the internal anal sphincter fails to relax. Constipation, abdominal distension and vomiting usually develop immediately after birth but a few cases do not present until childhood or adolescence. The rectum is empty on digital examination.

A plain abdominal X-ray or barium enema shows a small rectum and colonic dilatation above the narrowed segment. Full-thickness biopsies are required to demonstrate nerve plexuses and confirm the absence of ganglion cells. Histochemical stains for acetylcholinesterase are also used. Anorectal manometry demonstrates failure of the internal sphincter to relax with balloon distension. Treatment involves resection of the affected segment.

### Acquired megacolon

This may develop in childhood as a result of voluntary withholding of stool during toilet training and can present with faecal impaction and soiling. In such cases, it presents after the first year of life and is distinguished from Hirschsprung's disease by the urge to defecate and the presence of stool in the rectum. It usually responds to osmotic laxatives.

In adults, acquired megacolon has several causes. It is seen in patients with depression or dementia, either as part of the condition or as a side-effect of antidepressant drugs. Prolonged misuse of stimulant laxatives may cause degeneration of the myenteric plexus, while interruption of sensory or motor innervation may be responsible in a number of neurological disorders. Patients taking large doses of opioid analgesics can develop a megacolon: so-called 'narcotic bowel syndrome'. Systemic sclerosis and hypothyroidism are other recognised causes.

Most patients can be managed conservatively by treatment of the underlying cause, high-residue diets, laxatives and the judicious use of enemas. Prokinetics are helpful in a minority of patients. Opioid-induced constipation can be treated with the specific peripheral opioid receptor antagonists, such as naloxegol, methylnaltrexone and naldemedine. Subtotal colectomy is a last resort for the most severely affected patients.

### Acute colonic pseudo-obstruction

Acute colonic pseudo-obstruction (Ogilvie syndrome) has many causes (Box 23.58) and is characterised by sudden onset of painless, massive enlargement of the proximal colon; there are no features of mechanical obstruction. Bowel sounds are normal or high-pitched, rather than absent. Left untreated, it may progress to perforation, peritonitis and death.

#### 23.58 Causes of acute colonic pseudo-obstruction

- Trauma, burns
- Recent surgery
- Drugs (opiates, phenothiazines)
- Respiratory failure
- Electrolyte and acid–base disorders (e.g. hypokalaemia, hypomagnesaemia)
- Diabetes mellitus – autonomic dysfunction
- Uraemia

Abdominal X-rays show colonic dilatation with air extending to the rectum. Caecal diameter greater than 10 cm is associated with a high risk of perforation. CT with contrast demonstrates the absence of mechanical obstruction.

Management consists of treating the underlying disorder and correcting any biochemical abnormalities. The anticholinesterase neostigmine is effective in enhancing parasympathetic activity and gut motility. Decompression, with either a rectal tube or colonoscope, may be effective but needs to be repeated until the condition resolves. In severe cases, surgical or fluoroscopic defunctioning caecostomy is necessary.

## Anorectal disorders

### Haemorrhoids

Haemorrhoids (commonly known as piles) arise from congestion of the internal and/or external venous plexuses around the anal canal. They are extremely common in adults. The aetiology is unknown, although they are associated with constipation and straining, and may develop for the first time during pregnancy. First-degree piles bleed, while second-degree piles prolapse but retract spontaneously. Third-degree piles are those that require manual replacement after prolapsing. Bright red rectal bleeding occurs after defecation. Other symptoms include pain, pruritus ani and mucus discharge; thrombosis can occur in prolapsed piles, which can be very painful (Fig. 23.54). Treatment involves measures to prevent constipation and straining. Band ligation is effective for many, but a minority of patients require haemorrhoidectomy, which is usually curative. Haemorrhoidal artery ligation operation (HALO) procedures have been developed and may replace surgery. HALO involves using Doppler ultrasound to identify all the arteries feeding the haemorrhoids and subsequent ligation.

### Pruritus ani

This is common and can stem from many causes (Box 23.59), most of which result in contamination of the perianal skin with faecal contents.

Itching may be severe and results in an itch–scratch–itch cycle that exacerbates the problem. When no underlying cause is found, all local barrier ointments and creams must be stopped. Good personal hygiene is essential, with careful washing after defecation. The perineal area must be kept dry and clean. Bulk-forming laxatives may reduce faecal soiling.

### Solitary rectal ulcer syndrome

This is most common in young adults and occurs on the anterior rectal wall. It is thought to result from localised chronic trauma and/or ischaemia

Fig. 23.54 Thrombosed prolapsed haemorrhoids.

### 23.59 Causes of pruritus ani

#### Local anorectal conditions

- Haemorrhoids
- Fistula, fissures
- Poor hygiene

#### Infections

- Threadworms
- Candidiasis

#### Skin disorders

- Contact dermatitis
- Psoriasis
- Lichen planus

#### Other

- Diarrhoea or incontinence of any cause
- Irritable bowel syndrome
- Anxiety

associated with disordered puborectalis function and mucosal prolapse. The ulcer is seen at sigmoidoscopy and biopsies show a characteristic accumulation of collagen.

Symptoms include minor bleeding and mucus per rectum, tenesmus and perineal pain. Treatment is often difficult, but avoidance of straining at defecation is important and treatment of constipation may help. Marked mucosal prolapse is treated surgically.

### Anal fissure

In this common problem, traumatic or ischaemic damage to the anal mucosa results in a superficial mucosal tear, most commonly in the midline posteriorly. Spasm of the internal anal sphincter exacerbates the condition. Severe pain occurs on defecation and there may be minor bleeding, mucus discharge and pruritus. The skin may be indurated and an oedematous skin tag, or 'sentinel pile', adjacent to the fissure is common.

Avoidance of constipation with bulk-forming laxatives and increased fluid intake is important. Relaxation of the internal sphincter is normally mediated by nitric oxide and 0.2% glyceryl trinitrate, which donates nitric oxide and improves mucosal blood flow, is effective in 60%–80% of patients. Diltiazem cream (2%) can be used as an alternative. Resistant cases may respond to injection of botulinum toxin into the internal anal sphincter to induce relaxation. Manual dilatation under anaesthesia leads to long-term incontinence and should not be considered. The majority of cases can be treated without surgery, but where these measures fail, healing can be achieved surgically by lateral internal anal sphincterotomy or advancement anoplasty.

### Anorectal abscesses and fistulae

Perianal abscesses develop between the internal and external anal sphincters and may point at the perianal skin. Ischiorectal abscesses occur lateral to the sphincters in the ischiorectal fossa. They usually result from infection of anal glands by normal intestinal bacteria. Crohn's disease (see below) is sometimes responsible.

Patients complain of extreme perianal pain, fever and/or discharge of pus. Spontaneous rupture may lead to the development of fistulae. These may be superficial or track through the anal sphincters to reach the rectum. Abscesses are drained surgically and superficial fistulae are laid open with care to avoid sphincter damage.

### Faecal incontinence

The normal control of anal continence is described on page 788. Common causes of incontinence are listed in [Box 23.60](#). High-risk patients include frail older people, women after childbirth and those with severe neurological/spinal disorders, learning disabilities or cognitive impairment.

Patients are often embarrassed to admit to incontinence and may complain only of 'diarrhoea'. A careful history and examination, especially

### 23.60 Causes of faecal incontinence

- Obstetric trauma: childbirth, hysterectomy
- Severe diarrhoea
- Faecal impaction
- Congenital anorectal anomalies
- Anorectal disease: haemorrhoids, rectal prolapse, Crohn's disease
- Neurological disorders: spinal cord or cauda equina lesions, dementia

of the anorectum and perineum, may help to establish the underlying cause. Endoanal ultrasound is valuable for defining the integrity of the anal sphincters, while anorectal physiology and MR proctography are also useful investigations.

### Management

This is often very difficult. Underlying disorders should be treated and diarrhoea managed with loperamide, diphenoxylate or codeine phosphate. Attention must be paid to a proper diet and adequate fluid intake. Pelvic floor exercises, biofeedback and bowel retraining techniques help some patients, and those with confirmed anal sphincter defects may benefit from sphincter repair operations. Where sphincter repair is not appropriate, a trial of sacral nerve stimulation is undertaken with a view to insertion of a permanent stimulator but, if unsuccessful, creation of a neo-sphincter may be possible, by graciloplasty or by an artificial anal sphincter.

## Inflammatory bowel disease

Ulcerative colitis and Crohn's disease are chronic inflammatory bowel diseases that pursue a protracted relapsing and remitting course, usually extending over years. The diseases have many similarities and it is sometimes impossible to differentiate between them. One crucial distinction is that ulcerative colitis involves only the colonic mucosa, while Crohn's disease can involve any part of the gastrointestinal tract from mouth to anus. A summary of the main features of ulcerative colitis and Crohn's disease is provided in [Box 23.61](#).

The incidence of inflammatory bowel disease (IBD) varies widely between populations. The highest incidence is in North America, Europe and Oceania. A rapid increase in incidence in the 21st century has been seen in newly industrialised countries in Asia, Africa and South America, with the adoption of an increasingly Westernised lifestyle.

Both diseases most commonly start in the second and third decades of life, with a second smaller incidence peak in the seventh decade. The number of people with IBD over the age of 65 years, however, is increasing, and it is becoming more common in younger children. Approximately 620 000 people are affected by IBD in the UK, with a prevalence of 0.5%–1%. Life expectancy in patients with IBD is similar to that of the general population. Although many patients require surgery and admission to hospital for other reasons, with substantial associated morbidity, the majority have an excellent work record and pursue a normal life.

### Pathophysiology

IBD has both environmental and genetic components, and evidence from genome-wide association studies suggests that genetic variants that predispose to Crohn's disease may have undergone positive selection by protecting against infectious diseases, including tuberculosis ([Box 23.62](#)). It is thought that IBD develops because these genetically susceptible individuals mount an abnormal inflammatory response to environmental triggers, such as intestinal bacteria. This leads to inflammation of the intestine with involvement of a wide array of innate and adaptive immune cell responses, with release of inflammatory mediators, including tumour necrosis factor alpha (TNF- $\alpha$ ), interleukin (IL)-12 and IL-23, which cause tissue damage ([Fig. 23.55](#)). There appears to be an association between microbial dysbiosis and IBD. For example, there is a reduced diversity, primarily of *Firmicutes* and *Bacteroides*,

### 23.61 Comparison of ulcerative colitis and Crohn's disease

	Ulcerative colitis	Crohn's disease
<b>Age group</b>	Any	Any
<b>Gender</b>	M = F	Slight female preponderance
<b>Incidence</b>	Stable	Increasing
<b>Ethnic group</b>	Any	Any; more common in Ashkenazi Jews
<b>Genetic factors</b>	<i>HLA-DR*103</i> ; colonic epithelial barrier function ( <i>HNF4α</i> , <i>LAMB1</i> , <i>CDH1</i> )	Defective innate immunity and autophagy ( <i>NOD2</i> , <i>ATG16L1</i> , <i>IRGM</i> )
<b>Risk factors</b>	More common in non-/ex-smokers Appendectomy protects	More common in smokers
<b>Anatomical distribution</b>	Colon only; begins at anorectal margin with variable proximal extension	Any part of gastrointestinal tract; perianal disease common; patchy distribution, skip lesions
<b>Extra-intestinal manifestations</b>	Common	Common
<b>Presentation</b>	Bloody diarrhoea	Variable; pain, diarrhoea, weight loss all common
<b>Histology</b>	Inflammation limited to mucosa; crypt distortion, cryptitis, crypt abscesses, loss of goblet cells	Submucosal or transmural inflammation common; deep fissuring ulcers, fistulae; patchy changes; granulomas
<b>Management</b>	5-ASA; glucocorticoids; azathioprine; biologic therapy (anti-TNF, anti- $\alpha 4\beta 7$ integrin, anti-p40, Janus kinase inhibitor); colectomy is curative	Glucocorticoids; azathioprine; methotrexate; biologic therapy (anti-TNF, anti- $\alpha 4\beta 7$ integrin, anti-p40); nutritional therapy; smoking cessation; surgery for complications is not curative; 5-ASA is not effective

(5-ASA = 5-aminosalicylic acid; TNF = tumour necrosis factor)

### 23.62 Factors associated with the development of inflammatory bowel disease

#### Genetic

- Both CD and UC are common in Ashkenazi Jews
- 10% have first-degree relative/one or more close relative with IBD
- High concordance in identical twins (40%–50% CD; 20%–25% UC)
- 163 susceptibility loci identified at genome-wide levels of significance; most confer susceptibility to both CD and UC; many are also susceptibility loci for other inflammatory conditions (especially ankylosing spondylitis and psoriasis)
- UC and CD are both associated with genetic variants at HLA locus, and with multiple genes involved with immune signalling (especially IL-23 and IL-10 pathways)
- CD is associated with genetic defects in innate immunity and autophagy (*NOD2*, *ATG16L1* and *IRGM* genes)
- UC is associated with genetic defects in barrier function
- *NOD2* is associated with ileal and stricturing disease, and hence a need for resectional surgery
- *HLA-DR\*103* is associated with severe UC

#### Environmental

- UC is more common in non-smokers and ex-smokers
- CD is more common in smokers (relative risk = 3)
- CD is associated with a low-residue, high-refined-sugar diet
- Commensal gut microbiota are altered (dysbiosis) in CD and UC
- Appendectomy protects against UC

(CD = Crohn's disease; HLA = human leucocyte antigen; IBD = inflammatory bowel disease; IL = interleukin; UC = ulcerative colitis)

and a relative increase in Enterobacteriaceae. Functional changes in the bacteria are important and include a reduction of anti-inflammatory metabolites, such as butyrate and other short-chain fatty acids. While microbial dysbiosis has been recognised in IBD, a causal role has yet to be established. There is emerging evidence that the virome and mycobiome (fungal species) may be important in the development of IBD. In both diseases, the intestinal wall is infiltrated with acute and chronic inflammatory cells, but there are important differences between the conditions in the distribution of lesions and in histological features (Fig. 23.56).

**Fig. 23.55 Pathogenesis of inflammatory bowel disease.** (1) Bacterial antigens are taken up by specialised M cells, pass between leaky epithelial cells or enter the lamina propria through ulcerated mucosa. (2) After processing, they are presented to type 1 T-helper cells by antigen-presenting cells (APCs) in the lamina propria. (3) T-cell activation and differentiation results in a Th<sub>1</sub> cell-mediated cytokine response (4) with secretion of cytokines, including interferon gamma (IFN- $\gamma$ ). Further amplification of T cells perpetuates the inflammatory process with activation of non-immune cells and release of other important cytokines, including interleukin (IL)-12, IL-23, IL-1, IL-6 and tumour necrosis factor alpha (TNF- $\alpha$ ). These pathways occur in all normal individuals exposed to an inflammatory insult and this is self-limiting in healthy subjects. In genetically predisposed persons, dysregulation of innate immunity may trigger inflammatory bowel disease.

#### Ulcerative colitis

Inflammation invariably involves the rectum (proctitis) and spreads proximally in a continuous manner to involve the entire colon in some cases (pancolitis). In long-standing pancolitis, the bowel can become

**Fig. 23.56** Common patterns of disease distribution in inflammatory bowel disease.

shortened and post-inflammatory 'pseudopolyps' develop; these are normal or hypertrophied residual mucosa within areas of atrophy (Fig. 23.57). The inflammatory process is limited to the mucosa and spares the deeper layers of the bowel wall (Fig. 23.58). Both acute and chronic inflammatory cells infiltrate the lamina propria and the crypts ('cryptitis'). Crypt abscesses are typical. Goblet cells lose their mucus and, in long-standing cases, glands become distorted. Dysplasia, characterised by heaping of cells within crypts, nuclear atypia and increased mitotic rate, may herald the development of colon cancer.

#### Crohn's disease

The sites most commonly involved, in order of frequency, are the terminal ileum and right side of the colon, the small intestine, the colon alone, and the perianal region (Fig. 23.56). The entire wall of the bowel is oedematous and thickened, and there are deep ulcers that often appear as linear fissures; thus the mucosa between them is described as 'cobblestone'. These may penetrate through the bowel wall to initiate abscesses or fistulae involving the bowel, bladder, uterus, vagina and skin of the perineum. The mesenteric lymph nodes are enlarged and the mesentery is thickened. Crohn's disease has a patchy distribution and the inflammatory process is interrupted by islands of normal mucosa, resulting in 'skip lesions'. On histological examination, the bowel wall is thickened with a chronic inflammatory infiltrate throughout all layers (Fig. 23.59).

### Clinical features

#### Ulcerative colitis

The cardinal symptoms are rectal bleeding with passage of mucus and bloody diarrhoea. The presentation varies, depending on the site and severity of the disease (see Fig. 23.56), as well as the presence of extra-intestinal manifestations. The first attack is usually the most severe and is followed by relapses and remissions. Emotional stress, intercurrent infection, gastroenteritis, antibiotics or NSAID therapy may all provoke a relapse. Proctitis causes rectal bleeding and mucus discharge, accompanied by tenesmus. Some patients pass frequent, small-volume fluid stools, while others pass pelleted stools due to constipation upstream of the inflamed rectum. Constitutional symptoms rarely occur. Left-sided and extensive colitis causes bloody diarrhoea with mucus, often with abdominal cramps. In severe cases, anorexia, malaise, weight loss and abdominal pain occur and the patient is toxic, with fever, tachycardia and signs of peritoneal inflammation (Box 23.63).

**Fig. 23.57** Pseudopolypsis in ulcerative colitis.

**Fig. 23.58** Histology of ulcerative colitis. There is surface ulceration and inflammation is confined to the mucosa with excess inflammatory cells in the lamina propria, loss of goblet cells and crypt abscesses (arrows). (SM = submucosa)

### Crohn's disease

The major symptoms are abdominal pain, diarrhoea and weight loss. Ileal Crohn's disease (Figs. 23.60 and 23.61) may cause subacute or even acute intestinal obstruction. Patients can occasionally present with a perforated abscess. Abdominal pain is often associated with diarrhoea, which is usually watery and does not contain blood or mucus. Patients may lose weight because they avoid food, since eating provokes pain. Weight loss may also be due to malabsorption and some patients present with features of fat, protein or vitamin deficiencies. Crohn's colitis presents in an identical manner to ulcerative colitis, but rectal sparing and the presence of perianal disease are features that favour a diagnosis

**Fig. 23.59** Histology of Crohn's disease. **A** Inflammation is 'transmural'; there is fissuring ulceration (arrow), with inflammation extending into the submucosa (SM). **B** At higher power, a characteristic non-caseating granuloma is seen.

of Crohn's disease. Many patients present with symptoms of both small bowel and colonic disease. A few patients present with isolated perianal disease, vomiting from jejunal strictures or severe oral ulceration.

Physical examination often reveals evidence of weight loss, anaemia with glossitis and angular stomatitis. There is abdominal tenderness, most marked over the inflamed area. An abdominal mass may be palpable and is due to matted loops of thickened bowel or an intra-abdominal abscess. Perianal skin tags, fissures or fistulae are found in at least 50% of patients.

### Differential diagnosis

The differential diagnosis is summarised in Box 23.64. The most important issue is to distinguish the first attack of acute colitis from infection. In general, diarrhoea lasting longer than 10 days in Western countries is unlikely to be the result of infection, whereas a history of foreign travel, antibiotic exposure (*Clostridioides difficile*/pseudomembranous colitis) or homosexual contact increases the possibility of infection, which should be excluded by the appropriate investigations (see below). The

**Fig. 23.60** Ileal Crohn's disease. Small bowel magnetic resonance image showing a terminal ileum that is thickened, narrowed and enhancing (arrow), with dilatation immediately proximal to this.

23.63 Assessment of disease severity in ulcerative colitis			
	Mild	Moderate	Severe
Daily bowel frequency	< 4	4–6	≥ 6*
Blood in stools	+/-	+/++	+++
Stool volume	< 200 g/24 hrs	200–400 g/24 hrs	> 400 g/24 hrs
Pulse	< 90 beats/min	< 90 beats/min	≥ 90 beats/min*
Temperature	Normal	Normal	≥ 37.8°C*
Haemoglobin	Normal	Normal	< 100 g/L (< 10 g/dL)*
Erythrocyte sedimentation rate	Normal	Normal	> 30 mm/hr* (or equivalent C-reactive protein)
Serum albumin	> 35 g/L (> 3.5 g/dL)		< 30 g/L (< 3 g/dL)
Abdominal X-ray	Normal	Normal	Dilated bowel, mucosal islands, thumb-printing of mucosa, or absence of features
Sigmoidoscopy	Normal or erythema/granular mucosa		Severe mucosal inflammatory changes; ulceration; blood in lumen

\*The Truelove–Witts criteria for acute severe ulcerative colitis are ≥ 6 bloody stools/24 hrs plus one or more of: anaemia, fever, tachycardia and high inflammatory markers.

**Fig. 23.61** Barium follow-through showing terminal ileal Crohn's disease. A long stricture is present (arrow A), and more proximally there is ulceration with characteristic 'rose thorn' ulcers (arrow B).

23.64 Conditions that can mimic ulcerative or Crohn's colitis	
<b>Infective</b>	
<b>Bacterial</b>	
<ul style="list-style-type: none"> <li>• <i>Salmonella</i></li> <li>• <i>Shigella</i></li> <li>• <i>Campylobacter jejuni</i></li> <li>• <i>Escherichia coli</i> O157</li> </ul>	<ul style="list-style-type: none"> <li>• Gonococcal proctitis</li> <li>• Pseudomembranous colitis</li> <li>• Chlamydia proctitis</li> </ul>
<b>Viral</b>	
<ul style="list-style-type: none"> <li>• Herpes simplex proctitis</li> </ul>	<ul style="list-style-type: none"> <li>• Cytomegalovirus</li> </ul>
<b>Protozoal</b>	
<ul style="list-style-type: none"> <li>• Amoebiasis</li> </ul>	
<b>Non-infective</b>	
<ul style="list-style-type: none"> <li>• Ischaemic colitis</li> <li>• Collagenous colitis</li> <li>• Non-steroidal anti-inflammatory drugs</li> </ul>	<ul style="list-style-type: none"> <li>• Diverticulitis</li> <li>• Radiation proctitis</li> <li>• Behçet's disease</li> <li>• Colonic carcinoma</li> </ul>

diagnosis of Crohn's disease is usually more straightforward and is made on the basis of imaging and clinical presentation, but in atypical cases biopsy or surgical resection is necessary to exclude other diseases (Box 23.65).

### Complications

#### Life-threatening colonic inflammation

This can occur in both ulcerative colitis and Crohn's colitis. In the most extreme cases, the colon dilates (toxic megacolon) and bacterial toxins pass freely across the diseased mucosa into the portal and then systemic circulation. This complication arises most commonly during the first attack of colitis and is recognised by the features described in Box 23.63. An abdominal X-ray should be taken daily because, when the transverse colon is dilated to more than 6 cm (Fig. 23.62), there is a high risk of colonic perforation, although this complication can also occur in the absence of toxic megacolon. Severe colonic inflammation with toxic dilatation is a surgical emergency and often requires colectomy.

#### Haemorrhage

Haemorrhage due to erosion of a major artery is rare, but can occur in both conditions. This is more common in Crohn's disease, where deep ulceration erodes larger vessels.

### 23.65 Differential diagnosis of small bowel Crohn's disease

- Other causes of right iliac fossa mass:
  - Caecal carcinoma
  - Appendix abscess\*
- Infection (tuberculosis, *Yersinia*, actinomycosis)
- Mesenteric adenitis
- Pelvic inflammatory disease
- Lymphoma

\*Common; other causes are rare.

**Fig. 23.62** Plain abdominal X-ray showing a grossly dilated colon due to severe ulcerative colitis. There is also marked mucosal oedema and 'thumb-printing' (arrows).

#### Fistulae

These are specific to Crohn's disease. Enteroenteric fistulae can cause diarrhoea and malabsorption due to blind loop syndrome. Enterovesical fistulation causes recurrent urinary infections and pneumaturia. An enterovaginal fistula causes a faeculent vaginal discharge. Fistulation from the bowel may also cause perianal or ischiorectal abscesses, fissures and fistulae.

#### Cancer

Colorectal cancer accounts for one in six deaths in ulcerative colitis. The risk of dysplasia and cancer increases with the duration and extent of uncontrolled colonic inflammation. Thus patients who have long-standing, extensive colitis are at highest risk. 5-ASA therapy may reduce the risk of dysplasia and neoplasia in ulcerative colitis. Thiopurines also seem to reduce the risk of colorectal cancer in ulcerative colitis, but not Crohn's disease. However, these benefits must be weighed against the very small increase in lymphoma, especially in older patients. The cumulative incidence for IBD-associated colorectal cancer has been reported at 1% at 10 years after diagnosis, which increases to 7% after 30 years. For unknown reasons, the risk is particularly high in patients who have concomitant primary sclerosing cholangitis. Tumours develop in areas of dysplasia and may be multiple. Patients with long-standing colitis are therefore entered into surveillance programmes beginning 8 years after diagnosis, with patients with primary sclerosing cholangitis having annual surveillance colonoscopy from diagnosis. Targeted biopsies of areas that show abnormalities on

staining with indigo carmine or methylene blue increase the chance of detecting dysplasia and this technique (termed pancolonoscopic chromo-endoscopy) has replaced colonoscopy with random biopsies taken every 10 cm in screening for malignancy. The procedure allows patients to be stratified into high-, medium- or low-risk groups to determine the interval between surveillance procedures. Family history of colon cancer is also an important factor to consider. If high-grade dysplasia is found, panproctocolectomy is usually recommended because of the high risk of colon cancer.

#### Extra-intestinal complications

Extra-intestinal complications are common in IBD and may dominate the clinical picture. Some of these occur during relapse of intestinal disease; others appear to be unrelated to intestinal disease activity (Fig. 23.63).

#### Investigations

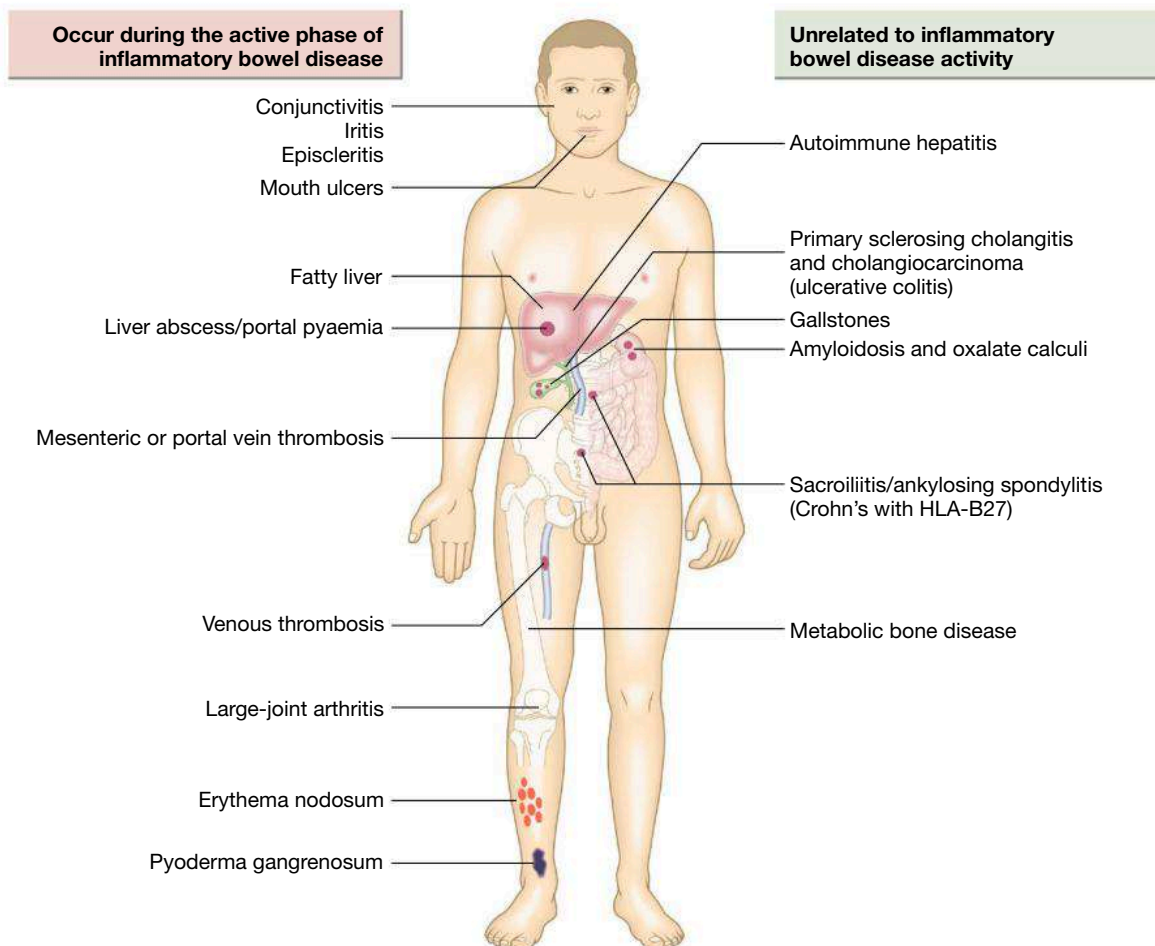

Investigations are necessary to confirm the diagnosis, define disease distribution and activity, and identify complications. Full blood count may show anaemia resulting from bleeding or malabsorption of iron, folic acid or vitamin B<sub>12</sub>. Platelet count can also be high as a marker of chronic inflammation. Serum albumin concentration falls as a consequence of protein-losing enteropathy, inflammatory disease or poor nutrition. ESR and CRP are elevated in exacerbations and in response to abscess formation. Faecal calprotectin has a high sensitivity for detecting gastrointestinal inflammation and may be elevated, even when the CRP is normal. It is particularly useful for distinguishing inflammatory bowel disease from irritable bowel syndrome at diagnosis, and for subsequent monitoring of disease activity.

#### Bacteriology

At initial presentation, stool microscopy, culture and examination for *Clostridioides difficile* toxin or for ova and cysts, blood cultures and serological tests should be performed. These investigations should be repeated in established disease to exclude superimposed enteric infection in patients who present with exacerbations of IBD. During acute flares necessitating hospital admission, three separate stool samples should be sent for bacteriology to maximise sensitivity.

#### Endoscopy

Patients who present with diarrhoea plus raised inflammatory markers or alarm features, such as weight loss, rectal bleeding and anaemia, should undergo ileocolonoscopy. Flexible sigmoidoscopy is occasionally performed to make a diagnosis, especially during acute severe presentations when ileocolonoscopy may confer an unacceptable risk; ileocolonoscopy should still be performed at a later date, however, in order to evaluate disease extent. In ulcerative colitis, there is loss of vascular pattern, granularity, friability and contact bleeding, with or without ulceration (Fig. 23.64). In Crohn's disease, patchy inflammation, with discrete, deep ulcers, strictures and perianal disease (fissures, fistulae and skin tags), is typically observed, often with rectal sparing. In established disease, colonoscopy may show active inflammation with pseudo-polyps or a complicating carcinoma. Biopsies should be taken from each anatomical segment (terminal ileum, right colon, transverse colon, left colon and rectum) to confirm the diagnosis and define disease extent, and also to seek dysplasia in patients with long-standing colitis guided by pancolonoscopic chromo-endoscopy. In Crohn's disease, wireless capsule

**Fig. 23.63** Systemic complications of inflammatory bowel disease. See also Chapters 24 and 26. (HLA = human leucocyte antigen)

**Fig. 23.64** Sigmoidoscopic view of moderately active ulcerative colitis. Mucosa is erythematous and friable with contact bleeding. Submucosal blood vessels are no longer visible.

endoscopy has a greater sensitivity for detecting small bowel disease in comparison to radiological techniques and is useful when there is a high suspicion of Crohn's despite normal imaging. Enteroscopy may be required to make a histological diagnosis of small bowel Crohn's disease, when the inflamed segment is out of reach of standard endoscopes, or for a therapeutic indication, such as dilatation of strictures. In individuals with upper gastrointestinal symptoms, an upper gastrointestinal endoscopy may be useful. However, this is not routinely used in adults with suspected or proven Crohn's disease.

### Radiology

Where colonoscopy is incomplete, a CT colonogram is preferred. Small bowel imaging is essential to complete staging of Crohn's disease. Traditional contrast imaging by barium follow-through demonstrates affected areas of the bowel as narrowed and ulcerated, often with multiple strictures (see Fig. 23.61). This has largely been replaced by MRI enterography, which does not involve exposure to radiation and is a sensitive way of detecting extra-intestinal manifestations and of assessing pelvic and perineal involvement. These studies use an orally administered small bowel-distending agent and intravenous contrast to provide transmural imaging that can usefully distinguish between predominantly inflammatory strictures (that should respond to anti-inflammatory medical strategies) and fibrotic strictures (that require a mechanical solution, such as surgical resection, stricturoplasty or endoscopic balloon dilatation). A plain abdominal X-ray is essential in the management of patients who present with severe active disease. Dilatation of the colon (see Fig. 23.62), mucosal oedema (thumb-printing) or evidence of perforation may be found. Patients with proctitis may have features of proximal faecal loading. In small bowel Crohn's disease, there may be evidence of intestinal obstruction or displacement of bowel loops by a mass. Ultrasound is a very powerful tool to detect small bowel inflammation and stricture formation, but it is operator-dependent. The role of CT is limited to screening for complications, such as perforation or abscess formation, in the acutely unwell.

### Management

Medical therapy plays an important role in the management of IBD. However, optimal management depends on establishing a multidisciplinary team-based approach involving physicians, surgeons, radiologists, nurse specialists and dietitians. Both ulcerative colitis and Crohn's disease are life-long conditions and have important psychosocial implications; specialist nurses, counsellors and patient support groups have key

23.66 Non-biologic agents used in the treatment of inflammatory bowel disease		
Class	Drug	Indication
Aminosalicylates	Mesalazine	Induce remission or maintenance in mild/moderate ulcerative colitis
	Olsalazine	
	Sulfasalazine	
	Balsalazide	
Glucocorticoids	Prednisolone	Induce remission in acute ulcerative colitis or Crohn's disease
	Hydrocortisone	
	Budesonide	
	Beclomethasone	
	Methylprednisolone	
Anti-metabolites	Azathioprine	Maintenance therapy in ulcerative colitis or Crohn's disease
	Mercaptopurine	
	Methotrexate	Maintenance therapy in Crohn's disease
Calcineurin inhibitors	Ciclosporin	Severe ulcerative colitis refractory to glucocorticoids
Antibiotics	Ciprofloxacin	Peri-anal Crohn's disease and pouchitis
	Metronidazole	

roles in education, reassurance and coping. The key aims of medical therapy are to:

- treat acute attacks (induce remission)
- prevent relapses (maintain remission)
- prevent bowel damage
- detect dysplasia and prevent carcinoma
- select appropriate patients for surgery.

### Medical therapy

Several medical treatment options exist in the management for IBD. Whilst traditional management for IBD has been through the use of non-biologic treatments, there has been a rapid expansion in the use of biologics, with common treatments described below.

#### Non-biologic therapies

Non-biologics used in IBD are summarised in Box 23.66.

#### Aminosalicylates (5-ASA)

5-ASAs are more commonly used in ulcerative colitis than in Crohn's disease. 5-ASAs are thought to have multiple anti-inflammatory effects, including inhibition of mediators of lipoyxygenase and cyclooxygenase, modulating cytokine release from the mucosa. Several types are available, with different means of delivery to the colon; pH-dependent (Asacol, Salofalk), time-dependent (Pentasa) or bacterial breakdown by colonic bacteria from a carrier molecule (sulfasalazine, balsalazide). While sulfasalazine was the first 5-ASA to be used in IBD, side-effects are common, such as headache, nausea, diarrhoea and blood dyscrasias. Other 5-ASAs are better tolerated. 5-ASAs can be administered orally or topically (suppositories or enema). Patients commencing a 5-ASA should have their urea and electrolytes checked at baseline, after 2–3 months and then annually, as nephrotoxicity can occur rarely (1 in 4000 patient years).

#### Glucocorticoids

Glucocorticoids such as prednisolone, hydrocortisone, budesonide and beclomethasone can be used to induce clinical remission in both ulcerative colitis and Crohn's disease, but have no role in preventing relapse. They can be administered orally, topically (suppositories or enema) or intravenously and have powerful anti-inflammatory effects. When administered, it is important to have high vigilance for complications, such as

osteoporosis, diabetes and weight gain. Simultaneous calcium and vitamin D supplementation should be given for bone protection. Budesonide is a potent glucocorticoid, which is efficiently cleared from circulation by the liver, thereby minimising adrenocortical suppression and side-effects. It is commonly considered for active ileitis and ileocolitis.

### Thiopurines

Thiopurines used in IBD are azathioprine and mercaptopurine. They are immunomodulators that induce T-cell apoptosis. Azathioprine and mercaptopurine are administered orally and metabolised to thioguanine nucleotides (TGNs). Thiopurine methyltransferase (TPMT) methylates thiopurine metabolites away from TGNs and affects drug levels. Leucopenia can occur in 3%, particularly in inherited TPMT deficiency. TPMT levels are checked prior to starting treatment and thiopurines are avoided if deficient/very low due to risk of toxicity. Thiopurines take around 6 weeks after starting treatment to be effective. Around 20% of patients will have complications leading to drug withdrawal. Complications include influenza-like syndrome with myalgia, nausea and vomiting. Genetic variation of NUDT15 has been described in association with myelosuppression and testing is performed if available. Other adverse effects include hepatotoxicity and pancreatitis. Patients are counselled on the increase lymphoma (approximately 2–3-fold) and non-melanoma skin cancer (life-long sun protection advised) risk. Caution is taken in prescribing thiopurines in patients presenting over the age of 60 years due to risk of malignancy.

### Methotrexate

Methotrexate can be used for maintenance therapy in Crohn's disease, with no role in ulcerative colitis. It is commonly used in individuals who have failed to respond with thiopurines. It is a folic acid antagonist, which inhibits dihydrofolate reductase, preventing DNA synthesis. The bio-availability of oral methotrexate is variable when compared to parental administration, with the subcutaneous injection being generally preferred to intramuscular due to ease of administration. Nausea, stomatitis, diarrhoea, hepatotoxicity and pneumonitis can occur with methotrexate. Folic acid should be given concurrently to reduce gastrointestinal and liver toxicity. Women of child-bearing potential must use a robust contraceptive method and should be counselled to plan pregnancy with a 6-month methotrexate-free period prior to conception as it is teratogenic.

### Ciclosporin

Ciclosporin is a calcineurin inhibitor, inhibiting in particular the transcription of interleukin-2. It is used in ulcerative colitis that has responded poorly to glucocorticoids and has no role in Crohn's disease. Major side-effects include nephrotoxicity, infections and neurotoxicity (including fits). Minor complications include tremor, paraesthesiae, abnormal liver function tests and hirsutism. Acutely, ciclosporin is usually administered intravenously, with responders to treatment converted to oral administration, which is continued for several months as a bridging therapy. Thiopurine maintenance therapy is commonly given as maintenance subsequently, as ciclosporin has no benefit as maintenance therapy.

### Antibiotics

Antibiotics are useful in perianal Crohn's disease and pouchitis. There is little evidence comparing different antibiotics for acute pouchitis, although ciprofloxacin is better tolerated with fewer adverse effects than metronidazole. The major concern is peripheral neuropathy with long-term metronidazole, with tendon inflammation and damage potentially occurring with ciprofloxacin. Combination antibiotics may be needed for chronic pouchitis. Antibiotics tend to be used in combination with thiopurines and anti-TNF therapy in perianal disease.

### Biologic agents

Several classes of biologic agents are used in the management of IBD, with their indication shown in [Box 23.67](#) and site of action shown in [Fig. 23.65](#). The majority of biologics are administered either intravenously or subcutaneously, with the exception of tofacitinib, which is administered orally.

### Anti-TNF antibodies

These include infliximab, adalimumab, golimumab and certolizumab. They are monoclonal antibodies that bind to TNF- $\alpha$ , preventing pro-inflammatory and pathological cytokine release by TNF- $\alpha$ . Acute (anaphylactic) and delayed (serum sickness) infusion reactions can occur after multiple infusions. Anti-drug antibody titres and drug levels can be also measured to assess efficacy. Anti-TNF antibodies are contraindicated in infection; reactivation of latent tuberculosis and moderate to severe cardiac failure can occur. In view of this, assessment for latent tuberculosis and hepatitis B and C prior to commencement is required. There is a possible increased risk of malignancy and, rarely, neurological adverse events. Treatment should occur until treatment failure, or should be reassessed after 12 months.

### Anti- $\alpha 4\beta 7$ integrin

Vedolizumab is a monoclonal antibody that blocks  $\alpha 4\beta 7$  integrin expressed on leukocytes and inhibits leukocyte interaction with a gut-specific receptor on endothelium, reducing leukocyte migration into gut mucosa. It is a gut-selective biologic used in both ulcerative colitis and Crohn's disease. Side-effects include nasopharyngitis, arthralgia and headache. Treatment is discontinued if there is no improvement after 14 weeks. Treatment should occur until treatment failure, or should be reassessed after 12 months.

### Janus kinase inhibitor

Tofacitinib is a Janus kinase inhibitor that selectively inhibits the Janus-associated tyrosine kinases JAK1 and JAK3, blocking pro-inflammatory cytokine signalling via the STAT pathway. It has the advantage of oral administration in comparison to other biologics being used in ulcerative colitis. High doses should be avoided in patients at risk of pulmonary embolism and it is contraindicated in pregnancy. Herpes zoster has been noted to occur more often on active treatment; zoster vaccination is therefore recommended in those over age of 70 years or high-risk individuals (recurrent shingles) over 50 years.

### Anti-p40 antibodies

Ustekinumab is a monoclonal antibody that binds to p-40 subunit of both IL-12 and IL-23 to prevent T-cell activation; it is used in both ulcerative colitis and Crohn's disease. Side-effects include nasopharyngitis, headache and arthralgia. Treatment should occur until treatment failure or should be reassessed after 12 months.

### Therapeutic drug monitoring

Up to one-third of patients do not respond to biologic therapy (primary non-response), with up to a half discontinuing biologic therapy after initial response due to secondary loss of response or adverse effects. This can be due to pharmacokinetic or pharmacodynamic issues of the drug. Favourable outcomes have been associated with good drug concentrations, with low levels leading to immunogenicity and drug failure. Therapeutic drug monitoring can be performed with biologic therapy, ensuring patients have adequate drug levels, pre-emptively preventing flares due to low drug levels. Combination treatment of biologics with thiopurines or methotrexate can be used to prevent and reduce anti-drug antibodies. Drug monitoring can also be performed with thiopurines, with thiopurine metabolites measured to tailor therapy.

### Ulcerative colitis

#### Active ulcerative colitis

Patients with active ulcerative colitis are initially treated with topical or oral 5-aminosalicylate (5-ASA) therapy. Patients with left-sided or extensive ulcerative colitis should continue oral 5-ASA in the long term to prevent relapse and minimise the risk of dysplasia. Individuals with an incomplete response to 5-ASA treatment may require treatment with systemic glucocorticoids, immunomodulator or biologic therapy. Glucocorticoids

Fig. 23.65 Site of action of biologics. (TNF = tumour necrosis factor; IL = interleukin; RBC = red blood cell)

23.67 Biologic agents used in the treatment of inflammatory bowel disease		
Class	Drug	Indication
Anti-TNF antibodies	Infliximab	Moderate to severe Crohn's disease and ulcerative colitis Acute severe ulcerative colitis as rescue therapy
	Adalimumab	Moderate to severe Crohn's disease and ulcerative colitis
	Golimumab	Moderate to severe ulcerative colitis
	Certolizumab	Moderate to severe Crohn's disease
Anti-α4β7 integrin	Vedolizumab	Moderate to severe Crohn's disease and ulcerative colitis
Janus kinase inhibitor	Tofacitinib	Moderate to severe ulcerative colitis
Anti-p40 antibodies	Ustekinumab	Moderate to severe Crohn's disease and ulcerative colitis

should never be used for maintenance therapy. An algorithm for the management of active ulcerative colitis is shown in Fig. 23.66.

**Severe ulcerative colitis**

Patients who fail to respond to maximal oral therapy and those who present with acute severe colitis (meeting the Truelove–Witts criteria; see Box 23.63) are best managed in hospital and should be monitored jointly by a physician and surgeon:

- *clinically*: for the presence of abdominal pain, temperature, pulse rate, stool blood and frequency

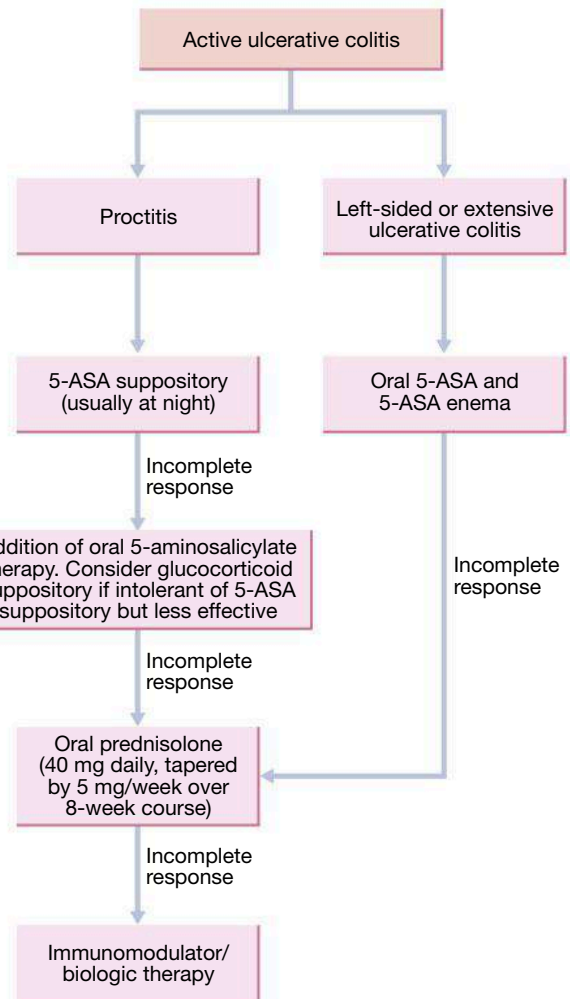

Fig. 23.66 Medical management of active ulcerative colitis.

### 23.68 Medical management of fulminant ulcerative colitis

- Admit to hospital for intensive therapy and monitoring
- Give IV fluids and correct electrolyte imbalance
- Consider transfusion if haemoglobin is  $< 100 \text{ g/L}$  ( $< 10 \text{ g/dL}$ )
- Give IV methylprednisolone (60 mg daily) or hydrocortisone (100 mg four times daily)
- Give antibiotics until enteric infection is excluded
- Arrange nutritional support
- Give subcutaneous low-molecular-weight heparin for prophylaxis of venous thromboembolism
- Avoid opiates and antidiarrhoeal agents
- Consider infliximab (5 mg/kg) or ciclosporin (2 mg/kg) in stable patients not responding to 3–5 days of glucocorticoids

(IV = intravenous)

- *by laboratory testing*: haemoglobin, white cell count, albumin, electrolytes, ESR and CRP, stool culture, including *Clostridioides difficile* toxin assay
- *radiologically*: for colonic dilatation on plain abdominal X-rays.

All patients should be given supportive treatment with intravenous fluids to correct dehydration and enteral nutritional support should be provided for malnourished patients (Box 23.68). Intravenous glucocorticoids (methylprednisolone 60 mg every 24 hours or hydrocortisone 100 mg four times daily) should be given by infusion or bolus injection. Patients should receive prophylactic low-molecular weight heparin, as the risk of venous thromboembolism is 2–3-fold higher compared to inpatients without IBD. Topical and oral aminosalicylates have no role to play in the acute severe attack. Response to therapy is judged over the first 3 days. Patients who do not respond promptly to glucocorticoids should be considered for medical rescue therapy with ciclosporin (2 mg/kg daily by intravenous infusion followed by 5 mg/kg daily, then orally after 7 days) or infliximab (5 mg/kg), which can avoid the need for urgent colectomy in approximately 60% of cases.

Patients who develop colonic dilatation ( $> 6 \text{ cm}$ ), those whose clinical and laboratory measurements deteriorate and those who do not respond after 7–10 days' maximal medical treatment usually require urgent surgery. Subtotal colectomy with end ileostomy is the operation of choice and can be performed open or laparoscopically, dependent upon local expertise. The surgical and medical teams should liaise early in the disease course and, if possible, the patient should have the opportunity to speak with the stoma nurse prior to colectomy.

#### Maintenance of remission

Life-long maintenance therapy is recommended for all patients with left-sided or extensive disease, but is not necessary in those with proctitis (although 20% of these patients will develop proximal 'extension' over the lifetime of their disease). Once-daily oral 5-aminosalicylates are the preferred first-line agents. Sulfasalazine has a higher incidence of side-effects, but is equally effective and can be considered in patients with coexistent arthropathy. Patients who frequently relapse despite aminosalicylate drugs have in the past always been offered thiopurines (azathioprine or 6-mercaptopurine). While thiopurines still have an important role for treatment, other immunosuppressive drugs may also be used. Biologic therapy with anti-TNF antibodies (infliximab, adalimumab or golimumab) can be considered for maintenance treatment in patients with moderate to severe ulcerative colitis. Combination therapy of infliximab with a thiopurine should be used, as it is more effective than monotherapy with infliximab. In patients where anti-TNF treatment has failed, anti- $\alpha 4\beta 7$  integrin antibodies (vedolizumab), Janus kinase inhibitors (tofacitinib) and anti-p40 antibodies (ustekinumab), can be considered to maintain remission.

### 23.69 Monitoring of inflammatory bowel disease (IBD)

- Assess symptoms, including extra-intestinal manifestations
- Examine for abdominal mass or perianal disease
- Perform full blood count, urea and electrolytes, liver function tests, albumin, C-reactive protein (CRP)
- Check haematinics (vitamin B<sub>12</sub>, folate, iron studies) at least annually
- Check faecal calprotectin (to monitor each disease flare/change in therapy and assess response)
- Perform stool cultures (at each flare to exclude infection)
- Assess mucosal healing: surrogate markers (CRP/calprotectin), small bowel capsule, ileocolonoscopy and/or small bowel magnetic resonance imaging
- Enrol patient in a dedicated IBD clinic (monitoring of stable, uncomplicated patients may be carried out by a nurse or phone clinic)
- Arrange IBD multidisciplinary meeting for acutely ill or complex patients
- Check vaccinations are up to date; live vaccinations may be given at least 4 weeks before starting immunosuppressive therapy and at least 3 months after stopping immunosuppressive therapy. Patients on immunosuppressive therapy should receive influenza and pneumococcal vaccination
- Ensure surveillance colonoscopy is scheduled where appropriate

#### Crohn's disease

##### Principles of management

Crohn's disease is a progressive condition that may result in stricture or fistula formation if suboptimally treated. It is therefore important to agree long-term treatment goals with the patient; these are to induce remission and then maintain glucocorticoid-free remission with a normal quality of life. Treatment should focus on monitoring the patient carefully for evidence of disease activity and complications (Box 23.69), and ensuring that mucosal healing is achieved.

##### Induction of remission in mild to moderate disease

Glucocorticoids remain the mainstay of treatment for active Crohn's disease. The drug of first choice in patients with ileal disease is budesonide, since it undergoes 90% first-pass metabolism in the liver and has very little systemic toxicity. A typical regimen is 9 mg once daily for 4 weeks, with a step-wise reduction of 3 mg every 4 weeks until therapy is stopped. If there is no response to budesonide within 2 weeks, the patient should be switched to prednisolone, which has greater potency. This is typically given in a dose of 40 mg daily, reducing by 5 mg/week over 8 weeks, at which point treatment is stopped. Oral prednisolone in the dose regimen described above is the treatment of choice for inducing remission in colonic Crohn's disease.

As an alternative to glucocorticoid therapy, enteral nutrition with either an elemental (constituent amino acids) or polymeric (liquid protein) diet may induce remission. Both types of diet are equally effective, but the polymeric one is more palatable when taken by mouth, and this improves adherence. It is particularly effective in children, in whom equal efficacy to glucocorticoids has been demonstrated, and in extensive ileal disease in adults. As well as resting the gut and providing excellent nutritional support, it also has a direct anti-inflammatory effect. It is an effective bridge to urgent staging investigations at first presentation and can be given by mouth or by nasogastric tube. With sufficient explanation, encouragement and motivation, most patients will tolerate it well.

##### Induction of remission in severe disease

Patients with severe disease can be treated with systemic glucocorticoids. The early introduction of biologics can also be considered, providing that acute perforating complications, such as abscess, have not arisen. Anti-TNF (infliximab or adalimumab), anti- $\alpha 4\beta 7$  integrin (vedolizumab) and anti-p40 (ustekinumab) therapy can be considered as first-line biologics. Patients with evidence of persistently active disease require further maintenance treatment (see below).

##### Maintenance therapy

Glucocorticoids are not effective at maintaining remission in Crohn's disease. Immunosuppressive treatment with thiopurines (azathioprine and

### 23.70 How to give anti-tumour necrosis factor (TNF) therapy in inflammatory bowel disease

- Infliximab (5 mg/kg IV infusion) is given as three loading doses (at 0, 2 and 6 weeks), with 8-weekly maintenance thereafter. Some patients may require dose escalation to 10 mg/kg up to 4 weekly
- Adalimumab is given as SC injections, which patients can be trained to give themselves. Loading dose is 160 mg, followed by 80 mg 2 weeks later and 40 mg every second week thereafter; some patients require dose escalation to 40 mg once weekly
- Concomitant immunosuppression with a thiopurine or methotrexate may be more efficacious than monotherapy but has more side-effects
- Anti-TNF therapy is contraindicated in the presence of active infection and latent tuberculosis without appropriate prophylaxis; it carries an increased risk of opportunistic infections and a possible increased risk of malignancy; rarely, multiple sclerosis may be unmasked in susceptible individuals. Counselling about the balance of risk and benefit for each patient is important
- Prior to therapy, latent tuberculosis must be excluded, as well as checking immunisation status, as well as hepatitis B, hepatitis C, HIV and VZV status
- Live vaccines should not be given
- Golimumab is effective for ulcerative colitis
- Certolizumab is effective for luminal Crohn's disease, but is not licensed in Europe

(HIV = human immunodeficiency virus; IV = intravenous; SC = subcutaneous; TNF = tumour necrosis factor; VZV = varicella zoster virus)

mercaptopyrine) may be used as maintenance therapy, but methotrexate is also effective and can be given once weekly, either orally or by subcutaneous injection; subcutaneous administration has better bioavailability. Patients refractory to immunomodulator therapy should be considered for biologic therapy with anti-TNF (infliximab or adalimumab) (Box 23.70), anti- $\alpha 4\beta 7$  integrin (vedolizumab) or anti-p40 (ustekinumab) therapies. Combination therapy of infliximab with a thiopurine should be used, as it is more effective than monotherapy with infliximab. Combination therapy of infliximab with methotrexate may also be used to reduce immunogenicity. In patients who still require glucocorticoids despite optimal treatment with biologics, other options must be considered including surgery.

Cigarette smokers with Crohn's disease should be strongly counselled to stop smoking at every possible opportunity. Those that do not manage to stop smoking fare much worse, with increased rates of relapse and surgical intervention, with adverse effects of smoking being more pronounced in women than in men. Careful monitoring of disease activity (see Box 23.69) is the key to maintaining sustained remission and preventing the accumulation of bowel damage in Crohn's disease.

#### Fistulae and perianal disease

Fistulae may develop in relation to active Crohn's disease and are often associated with sepsis. The first step is to define the site by imaging (usually MRI of the pelvis). Endoanal ultrasound is another option for assessment, but is limited in patients with luminal stenoses, as well as by local expertise. Surgical exploration by examination under anaesthetic is usually then required, to delineate the anatomy and drain abscesses. Seton sutures can be inserted through fistula tracts to ensure adequate drainage and to prevent future sepsis. Glucocorticoids are ineffective. Use of antibiotics, such as metronidazole and/or ciprofloxacin, can aid healing as an adjunctive treatment. Thiopurines can be used in chronic disease, but do not usually result in fistula healing. Anti TNF therapy can heal fistulae and perianal disease in many patients and are indicated when the measures described above have been ineffective. Higher trough infliximab drug levels are aimed for in perianal Crohn's disease. The evidence of benefit in perianal fistulating disease for the newer biologics is presently unclear. Other options for refractory perianal disease are proctectomy or faecal diversion with an upstream stoma.

### 23.71 Indications for surgery in ulcerative colitis

#### Impaired quality of life

- Loss of occupation or education
- Disruption of family life

#### Failure of medical therapy

- Dependence on oral glucocorticoids
- Resistant to drug therapy
- Intolerable side-effects of drug therapy

#### Fulminant colitis

- Life-threatening bleeding

#### Toxic megacolon

- Perforation

#### Colon cancer or severe dysplasia

## Surgical management

### Ulcerative colitis

Up to 60% of patients with extensive ulcerative colitis eventually require surgery. The indications are listed in Box 23.71. Impaired quality of life, with its impact on occupation and social and family life, is the most important of these. Surgery involves removal of the entire colon and rectum, and cures the patient. One-third of those with pancolitis undergo colectomy within 5 years of diagnosis. Before surgery, patients should be counselled by doctors, stoma nurses and patients who have undergone similar surgery. The procedure of choice is usually an initial subtotal colectomy with ileostomy and a subsequent ileorectal anastomosis, or a proctocolectomy and ileal pouch–anal anastomosis. The companion text to this book, *Principles and Practice of Surgery*, should be consulted for further details.

### Crohn's disease

Operations are often necessary to deal with fistulae, abscesses and perianal disease, and may also be required to relieve small or large bowel obstruction. In contrast to ulcerative colitis, surgery is not curative and disease recurrence is the rule. The only method that has consistently been shown to reduce post-operative recurrence is smoking cessation. Antibiotics are effective in the short term only. Use of thiopurines post surgery is suggested if there are indicators of a high chance of recurrence, i.e. more than one resection or evidence of penetrating disease, such as fistulae or abscess. Otherwise, it is common to undertake colonoscopy 6 months after surgery to inspect and biopsy the anastomosis and neo-terminal ileum. Patients with endoscopic recurrence are then prescribed immunomodulators or biologics to prevent further complications.

Surgery should be as conservative as possible in order to minimise the loss of viable intestine and to avoid the creation of a short bowel syndrome (p. 771). Obstructing or fistulating small bowel disease may require resection of affected tissue. Patients who have localised segments of Crohn's colitis may be managed by segmental resection and/or multiple stricturoplasties, in which the stricture is not resected but instead incised in its longitudinal axis and sutured transversely. Others who have extensive colitis require total colectomy but ileal pouch formation should be avoided because of the high risk of recurrence within the pouch and subsequent fistulae, abscess formation and pouch failure.

Historical datasets show that around 80% of Crohn's patients undergo surgery at some stage and 70% of these require more than one operation during their lifetime. Clinical recurrence following resectional surgery is present in 50% of all cases at 10 years. Emerging data demonstrate that aggressive medical therapy, coupled with intense monitoring, probably reduces the requirement for surgery substantially.

## IBD in special circumstances

### Childhood

Children developing IBD tend to have more extensive disease than adults. Chronic ill health in childhood or adolescence may result in impaired growth, metabolic bone disease and delayed puberty. Loss of schooling and social contact, as well as frequent hospitalisation, can have important psychosocial consequences. Treatment is similar to that described for adults and may involve glucocorticoids, immunosuppressive drugs, biologic agents and surgery. However, exclusive enteral nutrition can also be used to induce disease remission in Crohn's disease, as well as aiding with growth and nutritional status. Monitoring of height, weight and sexual development is crucial. Children with IBD should be managed by specialised paediatric gastroenterologists and transitioned to adult care in dedicated clinics (Box 23.72).

### Pregnancy

Pregnant women with IBD are best managed in an MDT approach involving an IBD physician and an obstetrician. A woman's ability to become pregnant is adversely affected by active IBD. Pre-conceptual counselling should focus on optimising disease control. During pregnancy, roughly one-third of women improve, one-third get worse and one-third remain stable with active disease. In the post-partum period, these changes sometimes reverse spontaneously, e.g. improvement during pregnancy is followed by post-partum relapse. Drug therapy, including aminosalicylates, glucocorticoids, thiopurines and biologics can be safely continued throughout pregnancy, but methotrexate and tofacitinib must be avoided, both during pregnancy and pre-conception (Box 23.73). Biologics such as infliximab, adalimumab, vedolizumab and ustekinumab may pass across the placenta and concentrate in the fetus, especially in the last trimester. Some women who are in deep remission may therefore choose to omit their biologics in the last trimester. However, biologics can be safely continued throughout the pregnancy, especially in women with ongoing active disease, at high risk of relapse or when limited treatment options. Breast feeding is recommended in all women and the use of thiopurines and biologics does not preclude women from breastfeeding. Thiopurine drug levels in breast milk are very low, with negligible levels measured in breast-fed infants of mothers on thiopurines. Levels of biologics are also very low in breastmilk and lead to negligible levels in the breast-fed infant due to normal gut digestion. Mode of delivery should be discussed with pregnant women and in the absence of active rectal or perianal fistulating disease, where a caesarean section is recommended, a vaginal delivery is safe.

### Metabolic bone disease

Patients with IBD are prone to developing osteoporosis due to the effects of chronic inflammation, glucocorticoids, weight loss, malnutrition and malabsorption. Osteomalacia can also occur in Crohn's disease that is complicated by malabsorption, but is less common than osteoporosis. The risk of osteoporosis increases with age and with the dose and duration of glucocorticoid therapy. Patients should have their fracture risk assessed prior to glucocorticoid therapy. Individuals who receive prolonged (> 3 months) or repeated courses of oral glucocorticoid therapy should have bone densitometry assessed. Oral bisphosphonates, in the form of alendronate and risedronate, are commonly used for treatment if required. Denosumab and high dose intravenous bisphosphonates should be avoided in women of childbearing age, due to their unknown effects on the fetus.

## Microscopic colitis

Microscopic colitis, which comprises two related conditions called lymphocytic colitis and collagenous colitis, has no known cause. Both forms are commoner in women with a mean age of presentation of around 60 years. The presentation is with chronic non-bloody watery diarrhoea. The colonoscopic appearances are normal, but histological examination of

### 23.72 Inflammatory bowel disease in adolescence

- **Delayed growth and pubertal development:** chronic active inflammation, malabsorption, malnutrition and long-term glucocorticoids contribute to short stature and delayed development, with physical and psychological consequences.
- **Metabolic bone disease:** more common with chronic disease beginning in childhood, resulting from chronic inflammation, dietary deficiency and malabsorption of calcium and vitamin D.
- **Drug side-effects and adherence issues:** young people are more likely to require azathioprine or biologic therapy than adults. Poor adherence to therapy is more common than with adults, as younger patients may feel well, lack self-motivation to adhere and believe that drugs are ineffective or cause side-effects.
- **Loss of time from education:** physical illness, surgery, fatigue in chronic inflammatory bowel disease, privacy and dignity issues, and social isolation may all contribute.
- **Emotional difficulties:** may result from challenges in coping with illness, problems with forming interpersonal relationships, and issues relating to body image or sexual function.

### 23.73 Pregnancy and inflammatory bowel disease (IBD)

#### Pre-conception

- Outcomes are best when pregnancy is carefully planned and disease is in remission
- Methotrexate must be stopped 6 months prior to conception; other IBD drugs should be continued until discussed with a specialist
- Aminosalicylates and azathioprine are safe in pregnancy
- Glucocorticoids are probably safe
- Biologic therapy (infliximab, adalimumab, vedolizumab, ustekinumab) in pregnancy can continue if established pre-pregnancy
- Tofacitinib should be avoided in pregnancy
- Folic acid (5 mg/day) is recommended pre-conception. Consider high-dose supplements in small bowel Crohn's disease with low levels despite 5 mg dose

#### Pregnancy

- Two-thirds of patients in remission will remain so in pregnancy
- Active disease is likely to remain active
- Severe active disease carries an increased risk of premature delivery and low birth weight
- Perform endoscopy only when absolutely essential for clinical decision-making (ideally in second trimester)
- X-rays can be performed if clinically indicated, but discuss with the radiologist first. Ultrasound is preferable but is operator-dependent. MRI small bowel can be performed without intravenous gadolinium and oral contrast

#### Labour

- This needs careful discussion between patient, gastroenterologist and obstetrician
- Normal labour and vaginal delivery are possible for most
- Caesarean section may be preferred for patients with perianal Crohn's or an ileo-anal pouch to reduce risks of pelvic floor damage, fistulation and late incontinence
- Venous thromboembolism prophylaxis is important if in hospital

#### Breastfeeding

- This is safe and does not exacerbate IBD
- Data on the risk to babies from drugs excreted in breast milk are limited; most of these drugs are probably safe
- Patients should discuss breastfeeding and drug therapy with their doctor

biopsies shows a range of abnormalities. It is therefore recommended that biopsies of the right and left colon plus the terminal ileum should be undertaken in all patients undergoing colonoscopy for diarrhoea. An increased number of intraepithelial and lamina propria lymphocytes is noted in both forms of microscopic colitis, with a thickened subepithelial collagen band also noted in collagenous colitis. Microscopic colitis may be associated with autoimmune diseases such as coeliac disease,

rheumatoid arthritis and thyroid disease, and some drug therapies, such as NSAIDs and PPIs. Bile acid diarrhoea has also been reported to be more prevalent in this group. Treatment with budesonide is usually effective for inducing remission. Up to 70% of individuals can relapse and require further treatment, but others can remain symptom free.

## Functional bowel disorders

Functional gastrointestinal disorders are a common diagnosis in gastroenterology, accounting for around 40% of all referrals to gastroenterology. They are thought to be disorders of brain–gut interaction, with alterations in motility, visceral hypersensitivity, gut microbiota, immune and mucosal function, as well as alterations in central nervous system processing.

### Functional dyspepsia

Functional dyspepsia can be diagnosed in patients presenting with dyspepsia where organic disease has been excluded. Patients are usually young (< 40 years) and women are affected twice as commonly as men. There are subtypes of this condition, with individuals being classified as having postprandial distress syndrome, epigastric pain syndrome or a mixture of both.

#### Pathophysiology

The cause is poorly understood, but probably covers a spectrum of mucosal, motility and psychological factors.

#### Clinical features

Symptoms such as bloating, early satiety, loss of appetite, nausea, vomiting or retching may suggest a diagnosis of postprandial distress syndrome, whereas symptoms of epigastric pain or epigastric burning may suggest a diagnosis of epigastric pain syndrome. Symptoms seen in functional dyspepsia can significantly overlap with symptoms of an organic disease, and alarm features should be sought (see Box 23.15). While patients with functional dyspepsia can experience vomiting, persistent vomiting may suggest an underlying organic disorder. Peptic ulcer disease must be considered, while in older people intra-abdominal malignancy is a prime concern. There are no diagnostic signs, although there may be inappropriate tenderness on abdominal palpation. A drug history should be taken and the possibility of a depressive illness should be considered. Pregnancy should be ruled out in young women before radiological studies are undertaken. Alcohol misuse should be suspected when early-morning nausea and retching are prominent.

#### Investigations

The history will often suggest the diagnosis. All patients should be checked for *H. pylori* infection and patients with alarm features should undergo endoscopy to exclude mucosal disease. While an ultrasound scan may detect gallstones, these are rarely responsible for dyspeptic symptoms, unless the patient has features to suggest biliary pathology.

#### Management

Up to 10% of patients benefit from *H. pylori* eradication therapy and this should be offered to infected individuals. Eradication also removes a major risk factor for peptic ulcers and gastric cancer, but at the cost of a small risk of side-effects and worsening symptoms of underlying gastro-oesophageal reflux disease. Idiosyncratic and restrictive diets are of little benefit but smaller portions and fat restriction may help.

Drug treatment is targeted on the subtype of functional dyspepsia. Prokinetic drugs (e.g. metoclopramide), fundus-relaxing drugs (e.g. buspirone) or centrally acting neuromodulators (e.g. mirtazapine) can be used in postprandial distress syndrome. Acid suppression medication (e.g. PPI) and tricyclic antidepressants (e.g. amitriptyline) may be used in epigastric pain syndrome. Patients with major psychological disorders

that result in persistent or recurrent symptoms may require behavioural or other formal psychotherapy (Ch. 31).

### Functional causes of vomiting

Cyclical vomiting syndrome (CVS) is an increasingly recognised cause of functional vomiting. It is characterised by distinct phases. There tends to be a prodrome phase, where symptoms of nausea, pallor and sweating are noted. This is then followed by an intense vomiting phase, with other associated symptoms such as abdominal pain, which can last up to a week. After this, patients enter a recovery phase, with improvement and resolution of symptoms. There will then be a period of time without symptoms. Triggers can include stress, fatigue and menstruation. The cause of CVS is unknown, although an association with migraine headaches is recognised. A subset of adults with CVS have symptoms triggered by chronic cannabis use, known as cannabinoid hyperemesis syndrome. Patients with CVS are managed with general lifestyle advice, with avoidance of triggers such as cannabis. Acute episodes can be managed with medications, such as anxiolytics (e.g. lorazepam) and antiemetics (e.g. ondansetron). Prophylactic treatment includes the use of tricyclic antidepressants (e.g. amitriptyline) and antiepileptic medication (e.g. levetiracetam).

In all patients it is essential to exclude other common causes of vomiting (see; Fig. 23.18). Patients who do not have characteristic symptoms seen in CVS, with nausea or vomiting occurring weekly, in the absence of organic disease may be diagnosed as having chronic nausea and vomiting syndrome (CNVS). These patients may respond to treatments including antiemetics (e.g. ondansetron) and tricyclic antidepressants (e.g. amitriptyline).

### Irritable bowel syndrome

Irritable bowel syndrome (IBS) has an estimated worldwide prevalence of around 5%. It is characterised by recurrent abdominal pain in association with abnormal defecation in the absence of a structural abnormality of the gut. IBS accounts for frequent absenteeism from work and impaired quality of life. Young women are affected more often than men.

#### Pathophysiology

The cause of IBS is incompletely understood but biopsychosocial factors are thought to play an important role, along with luminal factors, such as diet and the gut microbiota, as discussed below.

#### Behavioural and psychosocial factors

Early learning difficulties or emotionally challenging interactions during childhood may contribute to IBS in later life. Most patients seen in general practice do not have psychological problems but about 50% of patients referred to hospital have a psychiatric illness, such as anxiety, depression, somatisation and neurosis. Panic attacks are also common. Acute psychological stress and overt psychiatric disease are known to alter visceral perception and gastrointestinal motility. There is an increased prevalence of abnormal illness behaviour, with frequent consultations for minor symptoms and reduced coping ability (Ch. 31). These factors contribute to but do not cause IBS.

#### Physiological factors

The pathophysiology of IBS is still not fully understood. IBS is thought to be a disorder of the brain–gut axis, with alterations in visceral hypersensitivity. There is some evidence that IBS may be a serotonergic (5-HT) disorder, as evidenced by relatively excessive release of 5-HT in diarrhoea-predominant IBS (IBS-D) and relative deficiency with constipation-predominant IBS (IBS-C). Accordingly, 5-HT<sub>3</sub> receptor antagonists are effective in IBS-D, while 5-HT<sub>4</sub> agonists improve bowel function in IBS-C. There is some evidence that IBS may represent a state of low-grade gut inflammation or immune activation, not detectable by tests, with raised numbers of mucosal mast cells that sensitise enteric neurons by releasing histamine and tryptase. Some patients respond positively to mast cell stabilisers,

such as ketotifen, which supports a pathogenic role of mast cells in at least some patients. Immune activation may be associated with altered CNS processing of visceral pain signals. This is more common in women and in IBS-D, and may be triggered by a prior episode of gastroenteritis with *Salmonella* or *Campylobacter* species.

### Luminal factors

Both quantitative and qualitative alterations in intestinal bacterial microbiota have been reported. Small intestinal bacterial overgrowth (SIBO) may be present in some patients and lead to symptoms. This 'gut dysbiosis' may explain the response to probiotics or the non-absorbable antibiotic rifaximin.

Dietary factors are also important. Some patients have chemical food intolerances (not allergy) to poorly absorbed, short-chain carbohydrates (lactose, fructose and sorbitol, among others), collectively known as FODMAPs (fermentable oligo-, di- and monosaccharides, and polyols). Whilst their fermentation in the colon is normal physiology, this leads to bloating, pain, wind and altered bowel habit in patients with IBS, thought to be due to visceral hypersensitivity. Gluten exposure seems to cause symptoms in some IBS patients and there is an overlap with the diagnosis of non-coeliac gluten sensitivity (negative coeliac serology and normal duodenal biopsies).

### Clinical features

The key symptoms of IBS include recurrent abdominal pain and altered bowel habit (Box 23.74). Abdominal pain is usually colicky or cramping in nature, felt in the lower abdomen and related to defecation. The bowel habit is variable, with IBS stratified by predominant bowel habit; those with mainly constipation (IBS-C), mainly diarrhoea (IBS-D), mixed bowel habit (IBS-M) or unsubtyped (IBS-U). Those with constipation tend to pass infrequent pellety stools, usually in association with abdominal pain or proctalgia. Those with diarrhoea have frequent defecation but produce low-volume stools and rarely have nocturnal symptoms. Passage of mucus is common but rectal bleeding does not occur. Patients do not lose weight and are constitutionally well. Diagnosis is made through a careful history, exploring diet, medical, surgical and psychological history. The presence of other functional gastrointestinal disorders may also support the diagnosis, in addition to non-gastrointestinal symptoms such as migraine headaches, dyspareunia and interstitial cystitis. Onset after gastroenteritis may point towards a diagnosis of post-infectious IBS. Physical examination is generally unremarkable, with the exception of variable tenderness to palpation.

### Investigations

The diagnosis is clinical in nature and can be made confidently in most patients using the Rome IV criteria, combined with the absence of alarm symptoms and without resorting to complicated tests (Box 23.75). Limited laboratory tests are normally performed prior to making a diagnosis of IBS, including full blood count, faecal calprotectin and C-reactive protein, which are all normal. Colonoscopy should be undertaken when patients present with alarm features, to exclude other diagnoses such as colorectal cancer and inflammatory bowel disease. Those who present atypically require investigations to exclude other gastrointestinal diseases. Diarrhoea-predominant patients justify investigations to exclude coeliac disease, microscopic, lactose intolerance, bile acid diarrhoea (see earlier in this chapter), thyrotoxicosis (Ch. 20) and, in relevant countries, parasitic infection.

### Management

The most important steps are to make a positive diagnosis, as well as educating and reassuring the patient. Communicating diagnostic certainty is crucial, to prevent further unwarranted testing. Many people are concerned that they have developed cancer. A cycle of anxiety leading to colonic symptoms, which further heighten anxiety, can be broken by explaining that symptoms are not due to a serious underlying disease, but instead are the result of behavioural, psychosocial, physiological and luminal factors. In individuals who fail to respond to reassurance, treatment is traditionally tailored to the predominant symptoms (Fig. 23.67).

#### 23.74 Rome IV criteria for diagnosis of irritable bowel syndrome

Recurrent abdominal pain at least 1 day per week on average in the last 3 months (onset at least 6 months before diagnosis), associated with *two or more* of the following:

- Related to defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool

#### 23.75 Alarm features in suspected irritable bowel syndrome

- Age >50 years
- Unintentional weight loss
- Nocturnal symptoms
- Recent change in bowel habit
- Palpable abdominal mass or lymphadenopathy
- Family history of colon cancer or inflammatory bowel disease
- Anaemia
- Evidence of overt gastrointestinal bleeding (i.e. melaena or fresh blood in stools (haematochezia))

A large proportion of IBS patients report symptoms triggered by food, with diet being shown to be an effective management option for many patients (Box 23.76). Dietary advice should be implemented under the expert guidance of a dietitian, to prevent potential nutritional deficiencies of restrictive diets. General dietary advice is the first-line option recommended in the UK, with advice on regular meals, adjustment of fibre intake, adequate fluid intake, assessment of alcohol and caffeine intake, decreasing fat intake and assessing components of spicy meals which may be contributing to symptoms. If these measures fail, a low FODMAP diet may help some patients, as may a trial of a gluten-free diet. Up to 30% may benefit from a wheat-free diet, some may respond to lactose exclusion and excess intake of artificial sweeteners, such as sorbitol, should be addressed. Probiotics, in capsule form, may be effective if taken for several months, although the optimum combination of bacterial strains and dose have yet to be clarified.

Patients with intractable symptoms sometimes benefit from several months of therapy with a tricyclic antidepressant, such as amitriptyline or imipramine. Side-effects include dry mouth and drowsiness, but these are usually mild and the drug is generally well tolerated, although patients with features of somatisation tolerate the drug poorly and lower doses should be used. It may act by reducing visceral sensation and by altering gastrointestinal motility. Anxiety and affective disorders may also require specific treatment (Ch. 31). The 5-HT<sub>4</sub> agonist prucalopride, the guanylate cyclase-C receptor agonist linaclotide and chloride channel activators, such as lubiprostone, can be effective in IBS-C.

Systemic and nonabsorbable antibiotics, such as rifaximin, that act strictly on the gut lumen are sometimes used to manage symptoms, although the mechanism of action remains uncertain.

Psychological interventions, such as cognitive behavioural therapy, relaxation and gut-directed hypnotherapy, should be reserved for the most difficult cases. Cognitive behavioural therapy is the most widely studied psychotherapy treatment for IBS and may improve bowel symptoms, quality of life and psychological distress. A range of complementary and alternative therapies exist; most lack a good evidence base but are popular and help some patients (Box 23.77).

Most patients have a relapsing and remitting course. Exacerbations often follow stressful life events, occupational dissatisfaction and difficulties with interpersonal relationships.

## Ischaemic gut injury

Ischaemic gut injury is usually the result of arterial occlusion. Severe hypotension and venous insufficiency are less frequent causes. The presentation is variable, depending on the different vessels involved and the acuteness of the event. Diagnosis is often difficult.

Fig. 23.67 Management of irritable bowel syndrome. (FODMAP = fermentable oligo-, di- and monosaccharides, and polyols)

### 23.76 Dietary management of irritable bowel syndrome

- Eat regularly and avoid missing meals
- Take time to eat
- Ensure adequate hydration and avoid carbonated and caffeinated drinks
- Reduce alcohol intake
- Reduce intake of 'resistant' starch and insoluble fibre
- Avoid foods with artificial sweeteners
- Consider a low FODMAP diet
- Consider a gluten-free diet
- Consider a lactose exclusion diet

(FODMAPs = fermentable oligo-, di- and monosaccharides, and polyols)

### Acute small bowel ischaemia

An embolus from the heart or aorta to the superior mesenteric artery is responsible for 40%–50% of cases, thrombosis of underlying atherosclerotic disease for approximately 25% and non-occlusive ischaemia due to hypotension complicating myocardial infarction, heart failure, arrhythmias or sudden blood loss for approximately 25%. Vasculitis and venous occlusion are rare causes. The clinical spectrum ranges from transient alteration of bowel function to transmural haemorrhagic necrosis and gangrene. Patients usually have evidence of cardiac disease and arrhythmia. Almost all develop abdominal pain that is more impressive than the physical findings. In the early stages, the only physical signs may be a

### 23.77 Complementary and alternative therapies for irritable bowel syndrome

#### Manipulative and body-based

#### Biologically based

- Herbal products\*, dietary additives, probiotics\*

#### Alternative medical systems

- Ayurveda, homeopathy, traditional Chinese medicine

\*Some evidence for benefit exists.

silent, distended abdomen or diminished bowel sounds, with peritonitis developing only later.

Leucocytosis, lactic acidosis, hyperphosphataemia and hyperamylasaemia are typical. Plain abdominal X-rays show 'thumb-printing' due to mucosal oedema. CT with contrast has replaced percutaneous angiography as the gold standard for diagnosis and may demonstrate features such as occlusion of the mesenteric vessels and bowel wall thickening. Laparoscopy may also be used for diagnosis. Resuscitation, management of cardiac disease and intravenous broad-spectrum antibiotic therapy, followed by laparotomy, are key steps. If treatment is instituted

early, embolectomy and vascular reconstruction may salvage some small bowel. In these rare cases, a 'second look' laparotomy should be undertaken 24 hours later and further necrotic bowel resected. While laparotomy is the established approach, endovascular techniques may be considered, such as thrombolysis or percutaneous transluminal angioplasty. The results of therapy depend on early intervention; patients treated late have a 75% mortality rate. Survivors often have nutritional failure from short bowel syndrome (Ch. 22) and require intensive nutritional support, including home parenteral nutrition and anticoagulation. Small bowel transplantation can be considered in selected patients. Patients with mesenteric venous thrombosis also require surgery if there are signs of peritonitis, but are otherwise treated with anticoagulation. Investigations for underlying prothrombotic disorders should be performed (p. 988).

## Acute colonic ischaemia

The splenic flexure and descending colon have little collateral circulation and lie in 'watershed' areas of arterial supply. The spectrum of injury ranges from reversible colopathy to transient colitis, colonic stricture, gangrene and fulminant pancolitis. Arterial thromboembolism is usually responsible, but colonic ischaemia can also follow severe hypotension, colonic volvulus, strangulated hernia, systemic vasculitis or hypercoagulable states. Ischaemia of the descending and sigmoid colon is also a complication of abdominal aortic aneurysm surgery (where the inferior mesenteric artery is ligated). The patient is usually an older adult who presents with sudden onset of cramping, left-sided, lower abdominal pain and rectal bleeding. Symptoms usually resolve spontaneously over 24–48 hours and healing occurs in 2 weeks. Some may develop a fibrous stricture or segment of colitis. A minority develop gangrene and peritonitis. CT with contrast is the imaging of choice for diagnosis, with early colonoscopy within 48 hours of presentation recommended; otherwise, mucosal ulceration may have resolved. Resection is required for peritonitis; colonoscopy should not be performed in this circumstance.

## Chronic mesenteric ischaemia

This results from atherosclerotic stenosis of the coeliac axis, superior mesenteric artery and inferior mesenteric artery. At least two of the three vessels must be affected for symptoms to develop. The typical presentation is with dull but severe mid- or upper abdominal pain developing about 30 minutes after eating. Weight loss is common because patients are reluctant to eat and some experience diarrhoea. Physical examination shows evidence of generalised arterial disease. An abdominal bruit is sometimes audible but is non-specific. The diagnosis is made by mesenteric angiography. Treatment is by vascular reconstruction or percutaneous angioplasty and stenting, if the patient's clinical condition permits. The condition is frequently complicated by intestinal infarction, if left untreated.

## Diseases of the pancreas

### Acute pancreatitis

Acute pancreatitis accounts for 3% of all cases of abdominal pain admitted to hospital. It affects 2–28 per 100 000 of the population and is increasing in incidence. It is a potentially serious condition with an overall mortality of 10%. About 80% of all cases are mild and have a favourable outcome. Approximately 98% of deaths from pancreatitis occur in the 20% of patients with severe disease and about one-third of these arise within the first week, usually from multi-organ failure. After this time, the majority of deaths result from sepsis, especially that complicating infected necrosis. At admission, it is possible to predict patients at risk of these complications (Box 23.78). Individuals who are predicted to have severe pancreatitis (Box 23.79) and those with necrosis or other complications should be managed in a specialist centre with an intensive care unit and multidisciplinary hepatobiliary specialists.

### 23.78 Glasgow criteria for prognosis in acute pancreatitis\*

- Age > 55 years
- $P O_2 < 8$  kPa (60 mmHg)
- White blood cell count >  $15 \times 10^9/L$
- Albumin < 32 g/L (3.2 g/dL)
- Serum calcium < 2 mmol/L (8 mg/dL) (corrected)
- Glucose > 10 mmol/L (180 mg/dL)
- Urea > 16 mmol/L (45 mg/dL) (after rehydration)
- Alanine aminotransferase > 200 U/L
- Lactate dehydrogenase > 600 U/L

\*Severity and prognosis worsen as the number of these factors increases. More than three implies severe disease.

### 23.79 Features that predict severe pancreatitis

- Initial assessment
- Clinical impression of severity
  - Body mass index > 30 kg/m<sup>2</sup>
  - Pleural effusion on chest X-ray
  - APACHE II score > 8 (see Box 9.55)
- 24 hours after admission
- Clinical impression of severity
  - APACHE II score > 8
  - Glasgow score > 3 (see Box 23.78)
  - Persisting organ failure, especially if multiple
  - CRP > 150 mg/L
- 48 hours after admission
- Clinical impression of severity
  - Glasgow score > 3
  - CRP > 150 mg/L
  - Persisting organ failure for 48 hours
  - Multiple or progressive organ failure

(CRP = C-reactive protein)

### Pathophysiology

Acute pancreatitis occurs as a consequence of premature intracellular trypsinogen activation, releasing proteases that digest the pancreas and surrounding tissue. Triggers for this are many, including alcohol, gallstones and pancreatic duct obstruction (Fig. 23.68). There is simultaneous activation of nuclear factor kappa B (NFκB), leading to mitochondrial dysfunction, autophagy and a vigorous inflammatory response. The normal pancreas has only a poorly developed capsule, and adjacent structures, including the common bile duct, duodenum, splenic vein and transverse colon, are commonly involved in the inflammatory process. The severity of acute pancreatitis is dependent on the balance between the activity of released proteolytic enzymes and antiproteolytic factors. The latter comprise an intracellular pancreatic trypsin inhibitor protein and circulating  $\beta_2$ -macroglobulin,  $\alpha_1$ -antitrypsin and C1-esterase inhibitors. The causes of acute pancreatitis are listed in Box 23.80. Acute pancreatitis is often self-limiting, but in some patients with severe disease, local complications, such as necrosis, pseudocyst or abscess, occur, as well as systemic complications that lead to multi-organ failure.

### Clinical features

The typical presentation is with severe, constant upper abdominal pain, of increasing intensity over 15–60 minutes, which radiates to the back. Nausea and vomiting are common. There is marked epigastric tenderness, but in the early stages (and in contrast to a perforated peptic ulcer), guarding and rebound tenderness are absent because the inflammation is principally retroperitoneal. Bowel sounds become quiet or absent as paralytic ileus develops. In severe cases, the patient becomes hypoxic and develops hypovolaemic shock with oliguria. Discoloration of the flanks (Grey Turner's sign) or the periumbilical region

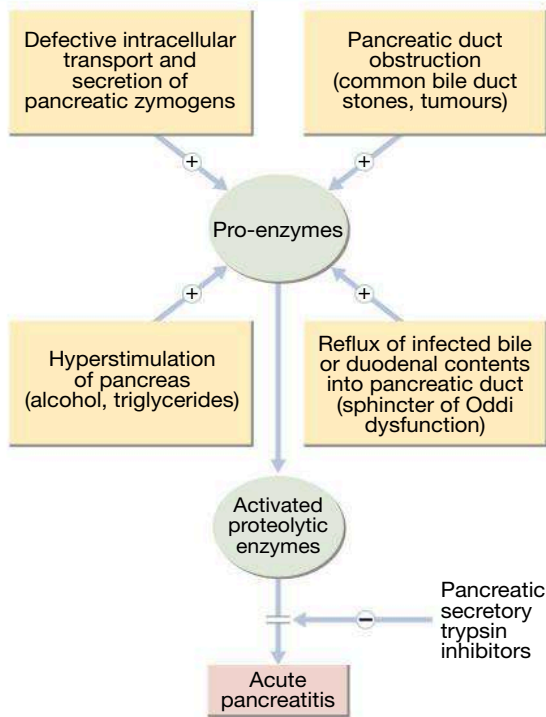

Fig. 23.68 Pathophysiology of acute pancreatitis.

23.80 Causes of acute pancreatitis	
<b>Common (90% of cases)</b>	
<ul style="list-style-type: none"> <li>• Gallstones</li> <li>• Alcohol</li> <li>• Idiopathic causes</li> <li>• Post-ERCP</li> </ul>	
<b>Rare</b>	
<ul style="list-style-type: none"> <li>• Post-surgical (abdominal, cardiopulmonary bypass)</li> <li>• Trauma</li> <li>• Drugs (azathioprine/mercaptopurine, thiazide diuretics, sodium valproate)</li> <li>• Metabolic (hypercalcaemia, hypertriglyceridaemia)</li> <li>• Pancreas divisum (p. 854)</li> <li>• Sphincter of Oddi dysfunction</li> <li>• Infection (mumps, Coxsackie virus)</li> <li>• Hereditary factors</li> <li>• Renal failure</li> <li>• Organ transplantation (kidney, liver)</li> <li>• Severe hypothermia</li> <li>• Petrochemical exposure</li> <li>• Scorpion sting</li> </ul>	
(ERCP = endoscopic retrograde cholangiopancreatography)	

(Cullen's sign) is a feature of severe pancreatitis with haemorrhage. The differential diagnosis includes a perforated viscus, acute cholecystitis and myocardial infarction. Various complications may occur and these are listed in Box 23.81.

A collection of fluid and debris may develop in the lesser sac, following inflammatory rupture of the pancreatic duct; this is known as a pancreatic fluid collection. It is initially contained within a poorly defined, fragile wall of granulation tissue, which matures over a 6-week period to form a fibrous capsule (Fig. 23.69). Such 'pseudocysts' are common and usually asymptomatic, resolving as the pancreatitis recovers. Pseudocysts greater than 6 cm in diameter seldom disappear spontaneously and can cause constant abdominal pain and compress or erode surrounding

23.81 Complications of acute pancreatitis	
Complication	Cause
<b>Systemic</b>	
Systemic inflammatory response syndrome (SIRS)	Increased vascular permeability from cytokine, platelet-aggregating factor and kinin release
Hypoxia	Acute respiratory distress syndrome (ARDS) due to microthrombi in pulmonary vessels
Hyperglycaemia	Disruption of islets of Langerhans with altered insulin/glucagon release
Hypocalcaemia	Sequestration of calcium in fat necrosis, fall in ionised calcium
Reduced serum albumin concentration	Increased capillary permeability
<b>Pancreatic</b>	
Necrosis	Non-viable pancreatic tissue and peripancreatic tissue death; frequently infected
Abscess	Circumscribed collection of pus close to the pancreas and containing little or no pancreatic necrotic tissue
Pseudocyst	Disruption of pancreatic ducts
Pancreatic ascites or pleural effusion	Disruption of pancreatic ducts
<b>Gastrointestinal</b>	
Upper gastrointestinal bleeding	Gastric or duodenal erosions
Variceal haemorrhage	Splenic or portal vein thrombosis
Erosion into colon	Erosion by pancreatic pseudocyst
Duodenal obstruction	Compression by pancreatic mass
Obstructive jaundice	Compression of common bile duct

Fig. 23.69 Computed tomogram showing large pancreatic pseudocyst (C) compressing the stomach (S). The pancreas is atrophic and calcified (arrows).

structures, including blood vessels, to form pseudoaneurysms. Large pseudocysts can be detected clinically as a palpable abdominal mass.

Pancreatic ascites occurs when fluid leaks from a disrupted pancreatic duct into the peritoneal cavity. Leakage into the thoracic cavity can result in a pleural effusion or a pleuro-pancreatic fistula.

### Investigations

The diagnosis is based on raised serum amylase or lipase concentrations and ultrasound or CT evidence of pancreatic swelling. Plain X-rays should be taken to exclude other diagnoses, such as perforation or

obstruction and to identify pulmonary complications. Amylase is efficiently excreted by the kidneys and concentrations may have returned to normal if measured 24–48 hours after the onset of pancreatitis. A persistently elevated serum amylase concentration suggests pseudocyst formation. Peritoneal amylase concentrations are massively elevated in pancreatic ascites. Serum amylase concentrations are also elevated (but less so) in intestinal ischaemia, perforated peptic ulcer and ruptured ovarian cyst, while the salivary isoenzyme of amylase is elevated in parotitis. If available, serum lipase measurements are preferable to amylase, as they have greater diagnostic accuracy for acute pancreatitis.

Ultrasound scanning can confirm the diagnosis, although in the earlier stages the gland may not be grossly swollen. An ultrasound scan is also useful because it may show gallstones, biliary obstruction or pseudocyst formation.

Contrast-enhanced pancreatic CT performed at least 3 days after admission can be useful in assessing viability of the pancreas if persisting organ failure, sepsis or clinical deterioration is present, since these features may indicate that pancreatic necrosis has occurred. Necrotising pancreatitis is associated with decreased pancreatic enhancement on CT, following intravenous injection of contrast material. The presence of gas within necrotic material (Fig. 23.70) suggests infection and impending abscess formation, in which case percutaneous aspiration of material for bacterial culture should be carried out and appropriate antibiotics prescribed. Involvement of the colon, blood vessels and other adjacent structures by the inflammatory process is best seen on CT.

Certain investigations stratify the severity of acute pancreatitis and have important prognostic value at the time of presentation (see Boxes 23.78 and 23.79). In addition, serial assessment of CRP is a useful indicator of progress. A peak CRP of > 210 mg/L in the first 4 days predicts severe acute pancreatitis with 80% accuracy. It is worth noting that the serum amylase concentration has no prognostic value.

### Management

Management comprises several related steps:

- establishing the diagnosis and disease severity
- early resuscitation, according to whether the disease is mild or severe
- detection and treatment of complications
- treatment of the underlying cause.

Opiate analgesics should be given to treat pain and hypovolaemia should be corrected using normal saline or other crystalloids. All severe cases should be managed in a high-dependency or intensive care unit. A urinary catheter should be inserted in patients with shock, with a central venous line inserted if required. Oxygen should be given to hypoxic patients and those who develop systemic inflammatory response syndrome (SIRS) may require ventilatory support. Hyperglycaemia should be corrected using insulin and hypocalcaemia by intravenous calcium injection.

Nasogastric aspiration is required only if paralytic ileus is present. Enteral feeding, if tolerated, should be started at an early stage in patients with severe pancreatitis because they are in a severely catabolic state and need nutritional support. Enteral feeding decreases endotoxaemia and so may reduce systemic complications. Nasogastric feeding is just as effective as feeding by the nasojejunal route. Prophylaxis of thromboembolism with subcutaneous low-molecular-weight heparin is also advisable. The use of prophylactic, broad-spectrum intravenous antibiotics to prevent infection of pancreatic necrosis is not indicated, but infected necrosis is treated with antibiotics that penetrate necrotic tissue, e.g. carbapenems or quinolones, and metronidazole.

Patients who present with cholangitis in association with severe acute pancreatitis should undergo urgent ERCP to diagnose and treat choledocholithiasis. In less severe cases of gallstone pancreatitis, biliary imaging (using MRCP or EUS) can be carried out after the acute phase has resolved. If the liver function tests return to normal and ultrasound has not demonstrated a dilated biliary tree, laparoscopic cholecystectomy with an on-table cholangiogram is appropriate because any common bile

**Fig. 23.70 Pancreatic necrosis.** Lack of vascular enhancement of the pancreas during contrast-enhanced computed tomography indicates necrosis (arrow). The presence of gas suggests that infection has occurred.

duct stones have probably passed. When the operative cholangiogram detects residual common bile duct stones, these should be removed by laparoscopic exploration of the duct or by post-operative ERCP. Cholecystectomy should be undertaken within 2 weeks of resolution of pancreatitis – and preferably during the same admission – to prevent further potentially fatal attacks of pancreatitis. Patients with infected pancreatic necrosis or pancreatic abscess require urgent endoscopic drainage or minimally invasive retroperitoneal pancreatic (MIRP) necrosectomy to debride all cavities of necrotic material. Pancreatic pseudocysts can be treated by drainage into the stomach or duodenum. This is usually performed after an interval of at least 6 weeks, once a pseudocapsule has matured, by surgical or endoscopic cystogastrostomy.

### Chronic pancreatitis

Chronic pancreatitis is a chronic inflammatory disease characterised by fibrosis and destruction of exocrine pancreatic tissue. Diabetes mellitus occurs in advanced cases because the islets of Langerhans are involved (Ch. 21).

#### Pathophysiology

Around 80% of cases in Western countries result from alcohol misuse, with idiopathic chronic pancreatitis being the second most common cause. In southern India, severe chronic fibrocalcific pancreatitis occurs in non-alcoholics, possibly as a result of malnutrition, deficiency of trace elements and micronutrients, and cassava consumption. Other causes are listed in Box 23.82. The pathophysiology of chronic pancreatitis is shown in Figure 23.71.

#### Clinical features

Chronic pancreatitis predominantly affects middle-aged men with alcohol dependence. More than 80% present with abdominal pain. In 50%, this occurs as episodes of 'acute pancreatitis', although each attack results in a degree of permanent pancreatic damage. Relentless, slowly progressive chronic pain without acute exacerbations affects 35% of patients, while the remainder have no pain but present with diarrhoea. Pain is due to a combination of increased pressure within the pancreatic ducts and direct involvement of peripancreatic nerves by the inflammatory process. Pain may be relieved by leaning forwards or by drinking alcohol. Approximately one-fifth of patients chronically consume opiate analgesics. Weight loss is common and results from a combination of anorexia, avoidance of food because of post-prandial pain, malabsorption and/or diabetes. Steatorrhoea occurs when more than 90% of the exocrine tissue has been destroyed; protein malabsorption develops only in the most advanced cases. Overall, 30% of patients have (secondary) diabetes, but this figure rises to 70% in those with chronic fibrocalcific

pancreatitis. Physical examination reveals a thin, malnourished patient with epigastric tenderness. Skin pigmentation over the abdomen and back is common and results from chronic use of a hot water bottle (erythema ab igne). Many patients have features of other alcohol- and smoking-related diseases. Complications are listed in [Box 23.83](#).

### Investigations

Investigations ([Box 23.84](#) and [Fig. 23.72](#)) are carried out to:

- make a diagnosis of chronic pancreatitis
- define pancreatic function
- demonstrate anatomical abnormalities prior to surgical intervention.

23.82 Causes of chronic pancreatitis*	
<b>Toxic–metabolic</b>	
• Alcohol	• Hypercalcaemia
• Tobacco	• Chronic kidney disease
<b>Idiopathic</b>	
• Tropical	• Early-/late-onset types
<b>Genetic</b>	
• Hereditary pancreatitis (cationic trypsinogen mutation)	• <i>SPINK-1</i> mutation
	• Cystic fibrosis
<b>Autoimmune</b>	
• In isolation or as part of multi-organ problem	
<b>Recurrent and severe acute pancreatitis</b>	
• Recurrent acute pancreatitis	• Post-necrotic
<b>Obstructive</b>	
• Ductal adenocarcinoma	• Pancreas divisum
• Intraductal papillary mucinous neoplasia	• Sphincter of Oddi stenosis

\*These can be memorised by the mnemonic 'TIGARO'. Gallstones do not cause chronic pancreatitis but may be observed as an incidental finding.

## Management

### Alcohol misuse

Alcohol avoidance is crucial in halting progression of the disease and reducing pain.

### 23.83 Complications of chronic pancreatitis

- Pseudocysts and pancreatic ascites, which occur in both acute and chronic pancreatitis
- Obstructive jaundice due to benign stricture of the common bile duct as it passes through the diseased pancreas
- Duodenal stenosis
- Portal or splenic vein thrombosis leading to segmental portal hypertension and gastric varices
- Peptic ulcer
- Secondary diabetes mellitus
- Pancreatic cancer
- Pancreatic exocrine insufficiency
- Osteopenia or osteoporosis

### 23.84 Investigations in chronic pancreatitis

#### Tests to establish the diagnosis

- Ultrasound
- Computed tomography (may show atrophy, calcification or ductal dilatation)
- Abdominal X-ray (may show calcification)
- Magnetic resonance cholangiopancreatography
- Endoscopic ultrasound

#### Tests to define pancreatic function

- Collection of pure pancreatic juice after secretin injection (gold standard but invasive and seldom used)
- Faecal pancreatic elastase (see [Box 23.12](#))

#### Tests to demonstrate anatomy prior to surgery

- Magnetic resonance cholangiopancreatography

**Fig. 23.71 Pathophysiology of chronic pancreatitis.** Alcohol and other risk factors may trigger acute pancreatitis through multiple mechanisms. The first (or 'sentinel') episode of acute pancreatitis initiates an inflammatory response involving T-helper (Th) cells. Ongoing exposure to alcohol drives further inflammation but this is modified by regulatory T cells (Treg) with subsequent fibrosis, via activation of pancreatic stellate cells. A cycle of inflammation and fibrosis ensues, with development of chronic pancreatitis. Alcohol is the most relevant risk factor, as it is involved at multiple steps.

**Fig. 23.72** Imaging in chronic pancreatitis. **A** Computed tomogram showing a grossly dilated and irregular duct with a calcified stone (arrow A). Note the calcification in the head of the gland (arrow B). **B** Magnetic resonance cholangiopancreatogram of the same patient showing marked ductal dilatation with abnormal dilated side branches (arrows A). A small cyst is also present (arrow B).

## i

### 23.85 Intervention in chronic pancreatitis

#### Endoscopic therapy

- Dilatation or stenting of pancreatic duct strictures
- Removal of calculi (mechanical or shock-wave lithotripsy)
- Drainage of pseudocysts

#### Surgical methods

- Partial pancreatic resection, preserving the duodenum
- Pancreatico-jejunostomy

#### Pain relief

A range of analgesic drugs, particularly NSAIDs, are valuable but the severe and unremitting nature of the pain often leads to opiate use with the risk of addiction. Analgesics, such as pregabalin and tricyclic antidepressants at a low dose, may be effective. Oral pancreatic enzyme supplements suppress pancreatic secretion and their regular use reduces analgesic consumption in some patients. Patients who are abstinent from alcohol and who have severe chronic pain that is resistant to conservative measures should be considered for surgical or endoscopic pancreatic therapy (Box 23.85). Coeliac plexus neurolysis sometimes produces long-lasting pain relief, although relapse occurs in the majority of cases. In some patients, MRCP does not show a surgically or endoscopically correctable abnormality and, in these individuals, the only surgical approach is total pancreatectomy. Unfortunately, even after this operation, some continue to experience pain. Moreover, the procedure causes diabetes, which may be difficult to control, with a high risk of

hypoglycaemia (since both insulin and glucagon are absent) and significant morbidity and mortality.

#### Malabsorption

This is treated by dietary fat restriction (with supplementary medium-chain triglyceride therapy in malnourished patients) and oral pancreatic enzyme supplements. A PPI is added to optimise duodenal pH for pancreatic enzyme activity.

#### Management of complications

Surgical or endoscopic therapy may be necessary for the management of pseudocysts, pancreatic ascites, common bile duct or duodenal stricture and the consequences of portal hypertension. Many patients with chronic pancreatitis also require treatment for other alcohol- and smoking-related diseases and for the consequences of self-neglect and malnutrition.

### Autoimmune pancreatitis

Autoimmune pancreatitis (AIP) is a chronic fibroinflammatory disease of the pancreas that can mimic cancer, but which responds to glucocorticoids. There are two different subtypes, type 1 and type 2 AIP. Type 1 AIP belongs to IgG4-related disorders, which can include various organs such as bile ducts, salivary glands, kidneys, lungs and thyroid glands. Type 2 AIP affects the pancreas only, but is strongly associated with inflammatory bowel disease, particularly ulcerative colitis. AIP can present with obstructive jaundice, weight loss and abdominal pain. Blood tests may reveal increased serum IgG4 in type 1 AIP, with no reliable serological markers for type 2 AIP. Imaging in type 1 AIP may show a diffusely enlarged pancreas, narrowing of the pancreatic duct and stricture of the lower bile duct. Focal mass-like pancreatic lesions may be seen in type 2 AIP. The symptom response to glucocorticoids is usually good in AIP, but recurrence can occur after initial response, particularly in type 1 AIP, with some patients requiring immunomodulators (e.g. azathioprine) or rituximab.

### Congenital abnormalities affecting the pancreas

#### Pancreas divisum

This is due to failure of the primitive dorsal and ventral ducts to fuse during embryonic development of the pancreas. As a consequence, most of the pancreatic drainage occurs through the smaller accessory ampulla rather than through the major ampulla. The condition occurs in 7%–10% of the normal population and is usually asymptomatic, but some patients develop acute pancreatitis, chronic pancreatitis or atypical abdominal pain.

#### Annular pancreas

In this congenital anomaly, the pancreas encircles the second/third part of the duodenum, leading to gastric outlet obstruction. Annular pancreas is associated with malrotation of the intestine, atresias and cardiac anomalies.

#### Cystic fibrosis

This disease is considered in detail on page 510. The major gastrointestinal manifestations are pancreatic insufficiency and meconium ileus. Peptic ulcer and hepatobiliary disease may also occur. In cystic fibrosis, pancreatic secretions are protein- and mucus-rich. The resultant viscous juice forms plugs that obstruct the pancreatic ductules, leading to progressive destruction of acinar cells. Steatorrhea is universal and the large-volume bulky stools predispose to rectal prolapse. Malnutrition is compounded by the metabolic demands of respiratory failure and by diabetes, which develops in 40% of patients by adolescence.

Nutritional counselling and supervision are important to ensure intake of high-energy foods, providing 120%–150% of the recommended intake for normal subjects. Fats are an important calorie source and, despite the presence of steatorrhoea, fat intake should not be restricted. Supplementary fat-soluble vitamins are also necessary. High-dose oral pancreatic enzymes are required, in doses sufficient to control steatorrhoea and stool frequency. A PPI aids fat digestion by producing an optimal duodenal pH.

### Meconium ileus

Mucus-rich plugs within intestinal contents can obstruct the small or large intestine of a newborn child. Meconium ileus is treated by the mucolytic agent *N*-acetylcysteine, given orally, by Gastrografin enema or by gut lavage using polyethylene glycol. In resistant cases of meconium ileus, surgical resection may be necessary.

## Tumours of the pancreas

### Adenocarcinoma of the pancreas

Some 90% of pancreatic neoplasms are adenocarcinomas that arise from the pancreatic ducts. These tumours involve local structures and metastasise to regional lymph nodes at an early stage. Most patients have advanced disease at the time of presentation. Neuro-endocrine tumours also arise in the pancreas, but tend to grow more slowly and have a better prognosis; these are discussed in detail on page 691. The incidence of pancreatic adenocarcinoma is higher in high-income

countries, affecting 10–15 per 100 000 in Western populations, rising to 100 per 100 000 in those over the age of 70. Men are affected more often than women. The disease is associated with increasing age, smoking, diabetes and chronic pancreatitis. Between 5% and 10% of patients have a genetic predisposition: hereditary pancreatitis, HNPCC and familial atypical mole multiple melanoma syndrome (FAMMM). Overall survival is only 3%–5%, with a median survival of 6–10 months for those with locally advanced disease and 3–5 months if metastases are present.

### Clinical features

Many patients are asymptomatic until an advanced stage, when they present with central abdominal pain, weight loss and obstructive jaundice (Fig. 23.73). The pain results from invasion of the coeliac plexus and is characteristically incessant and gnawing. It often radiates from the upper abdomen through to the back and may be eased a little by bending forwards. Almost all patients lose weight and many are cachectic. Around 60%–70% of tumours arise from the head of the pancreas, and involvement of the common bile duct results in the development of obstructive jaundice, often with severe pruritus. Some patients present with diarrhoea, vomiting from duodenal obstruction, diabetes mellitus, recurrent venous thrombosis, acute pancreatitis or depression. Physical examination reveals clear evidence of weight loss. An abdominal mass due to the tumour, a palpable gallbladder or hepatic metastases is commonly found. A palpable gallbladder in a jaundiced patient is usually the consequence of distal biliary obstruction by a pancreatic cancer (Courvoisier's sign).

Fig. 23.73 Features of pancreatic cancer.

**Fig. 23.74** Carcinoma of the pancreas. **A** A computed tomogram showing a large, necrotic mass encasing the coeliac axis (arrows). **B** Endoscopic ultrasound was subsequently performed to enhance staging and to obtain a fine needle aspiration biopsy, which confirmed pancreatic ductal adenocarcinoma.

### Investigations

The diagnosis is usually made by ultrasound and contrast-enhanced CT (Fig. 23.74). Diagnosis in non-jaundiced patients is often delayed because presenting symptoms are relatively non-specific. Fit patients with small, localised tumours should undergo staging to define operability. EUS or laparoscopy with laparoscopic ultrasound will define tumour size, involvement of blood vessels and metastatic spread. In patients unsuitable for surgery because of advanced disease, frailty or comorbidity, EUS- or CT-guided cytology or biopsy can be used to confirm the diagnosis (see Fig. 23.74). MRCP and ERCP are sensitive methods of diagnosing pancreatic cancer and are valuable when the diagnosis is in doubt, although differentiation between cancer and localised chronic pancreatitis can be difficult. The main role of ERCP is to insert a stent into the common bile duct to relieve obstructive jaundice in inoperable patients. Serum cancer antigen 19-9 (CA 19-9) can be used to monitor response to treatment and as a marker of recurrent disease. It has a poor predictive value for diagnosis.

### Management

Surgical resection is the only method of effecting cure and 5-year survival in patients undergoing a complete resection is around 12%. Adjuvant chemotherapy can also be used in these patients, using gemcitabine and capecitabine. Only 10%–15% of tumours are resectable with potential curative intent, since most are locally advanced at the time of diagnosis. For the great majority of patients, treatment is palliative. Chemotherapy with FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan and oxaliplatin) improves median survival to 11 months. Pain relief can be achieved using analgesics, but in some patients coeliac plexus neurolysis may be required. Jaundice can be relieved by choledochojejunostomy in fit patients, whereas percutaneous or endoscopic stenting is preferable in older patients and those with very advanced disease. Ampullary or periampullary adenocarcinomas are rare neoplasms that arise from the ampulla of Vater or adjacent duodenum. They are often polypoid and may ulcerate; they frequently infiltrate the duodenum, but behave less aggressively than pancreatic adenocarcinoma. Around 25% of patients undergoing resection of ampullary or periampullary tumours survive for 5 years, in contrast to patients with pancreatic ductal cancer.

### Incidental pancreatic mass

Cystic neoplasms of the pancreas are increasingly being seen with widespread use of CT. These are a heterogeneous group; serous cystadenomas rarely, if ever, become malignant and do not require surgery. Mucinous cysts occur more often in women, are usually in the pancreatic tail and display a spectrum of behaviour from benign to frankly malignant. Aspiration of the cyst contents for cytology and measurement of CEA and amylase concentrations in fluid obtained at EUS can help determine

whether a lesion is mucinous or not. In fit patients, all mucinous lesions should be resected. A variant, called intraductal papillary mucinous neoplasia (IPMN), is often discovered coincidentally on CT, frequently in men in old age. This may affect the main pancreatic duct with marked dilatation and plugs of mucus, or may involve a side branch. The histology varies from villous adenomatous change to dysplasia or carcinoma. Since IPMN is a pre-malignant, but indolent, condition, the decision to resect or to monitor depends on age and fitness of the patient and location, size and evolution of lesions.

## Diseases of the peritoneal cavity

### Peritonitis

Surgical peritonitis occurs as the result of a ruptured viscus (for details see this book's companion text, *Principles and Practice of Surgery*). Peritonitis may also complicate ascites in chronic liver disease (spontaneous bacterial peritonitis, p. 877) or may occur in children in the absence of ascites, due to infection with *Streptococcus pneumoniae* or  $\beta$ -haemolytic streptococci (p. 301).

Chlamydial peritonitis is a complication of pelvic inflammatory disease (p. 375). The patient presents with right upper quadrant pain, pyrexia and a hepatic rub (the Fitz-Hugh–Curtis syndrome). Tuberculosis may cause peritonitis and ascites (p. 518).

### Tumours

The most common is secondary adenocarcinoma from the ovary or gastrointestinal tract. Mesothelioma is a rare tumour complicating asbestos exposure. It presents as a diffuse abdominal mass, due to omental infiltration, and with ascites. The prognosis is extremely poor. Pseudomyxoma peritonei is a rare tumour of the appendix that spreads into the peritoneal cavity and is often found incidentally. Diagnosis can be confirmed by abdominal CT or MRI, with cytoreductive surgery and hyperthermic intraperitoneal chemotherapy being used for curative treatment.

## Other disorders

### Endometriosis

Ectopic endometrial tissue can become embedded on the serosal aspect of the intestine, most frequently in the sigmoid and rectum. The overlying mucosa is usually intact. Cyclical engorgement and inflammation result in pain, bleeding, diarrhoea, constipation and adhesions or

obstruction. Low backache is frequent. The onset is usually between 20 and 45 years and the condition is more common in nulliparous women. Bimanual examination may reveal tender nodules in the pouch of Douglas. Endoscopic studies reveal the diagnosis only if carried out during menstruation, when a bluish mass with intact overlying mucosa is apparent. In some patients, laparoscopy is required. Treatment options include laparoscopic diathermy and hormonal therapy with progestogens (e.g. norethisterone), gonadotrophin-releasing hormone analogues or danazol.

### Pneumatosis cystoides intestinalis

In this rare condition, multiple gas-filled submucosal cysts line the colonic and small bowel walls. The cause is unknown but the condition may be seen in patients with chronic cardiac or pulmonary disease, pyloric obstruction, systemic sclerosis or dermatomyositis. Most patients are asymptomatic, although there may be abdominal cramp, diarrhoea, tenesmus, rectal bleeding and mucus discharge. The cysts are recognised on sigmoidoscopy, plain abdominal X-rays, CT or MRI. Therapies reported to be effective include prolonged high-flow oxygen, elemental diets and antibiotics.

### HIV/AIDS and the gastrointestinal tract

Patients with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) may develop several symptoms referable to the gastrointestinal tract, as discussed in detail on page 359. HIV testing

should be considered in all patients with atypical or unexplained gastrointestinal symptoms and in those resident in areas of high prevalence.

## Multiple Choice Questions

23.1. A 27-year-old woman with coeliac disease presents with ongoing symptoms of chronic diarrhoea despite being on a gluten-free diet. Bloods tests for tTG are taken, which are elevated. Which would be the next appropriate test?

- A. Capsule endoscopy
- B. Colonoscopy
- C. Endoscopy with duodenal biopsies
- D. CT abdomen
- E. Lactose hydrogen breath test

Answer: C.

The most likely cause of symptoms in this patient is ongoing disease activity from coeliac disease. The gold standard of assessment of adherence in coeliac disease is an endoscopy with duodenal biopsies. Other causes of diarrhoea are also possible, and investigations such as a colonoscopy may be later considered, provided that there is no ongoing villous atrophy on biopsy.

23.2. A 72-year-old man presents with a 24-hour history of haematemesis. He receives resuscitation prior to a planned endoscopy. Which of the medications below should he continue to take if possible?

- A. Rivaroxaban
- B. Warfarin
- C. Clopidogrel
- D. Aspirin
- E. Prasugrel

Answer: D.

Low-dose aspirin (75 mg) can be continued during an upper gastrointestinal bleed. Caution should be taken with discontinuation, in view of an increased association of cardiovascular and cerebrovascular events noted within one week of discontinuation. Whilst bleeding risk may be increased during an upper GI bleed with aspirin, all-cause mortality is reduced with continuation. Direct oral anticoagulants, P2Y<sub>12</sub>-receptor antagonists and warfarin should be discontinued in most cases, although balance and risks may need to be evaluated, such as the continuation of dual antiplatelets (aspirin and clopidogrel) being considered for patients with drug-eluting coronary artery stents.

23.3. A 28-year-old pregnant woman with known pan-ulcerative colitis presents to clinic. Her most recent colonoscopy prior to pregnancy showed severe active colonic disease both macroscopically and histologically. She is 30 weeks pregnant and currently is taking infliximab for management of her ulcerative colitis, opening her bowels 4 times per day. What is the most appropriate ongoing management?

- A. Commence methotrexate in addition to infliximab
- B. Switch to vedolizumab
- C. Discontinue infliximab and restart post-partum
- D. Discontinue infliximab with restart in future if has symptoms
- E. Continue with infliximab during remainder of pregnancy

Answer: E.

The best course of action in this circumstance would be to continue with infliximab during her third trimester. Women with moderate to active disease can experience disease activity during pregnancy, which can be associated with low birth weight and preterm birth. Despite significant exposure of the fetus to anti-TNF drugs during the third trimester, no negative impact on neonatal outcomes or pregnancy has been shown. In individuals with inactive disease, it may be reasonable to discontinue TNF therapy during the third trimester. Patients must be counselled on the risks and benefits during pregnancy. There is no indication for changing class of drug at this point, with methotrexate being shown to be teratogenic.

23.4. A 28-year-old man with a background of asthma presents with a history of intermittent dysphagia to solids and liquids, in addition to chest pain. An endoscopy is performed which shows longitudinal furrows and exudate in the oesophagus. Oesophageal biopsies demonstrate 25 eosinophils/HPF. What is the most appropriate initial pharmacological management?

- A. Amitriptyline
- B. 8-week empirical trial of PPI
- C. Swallowed fluticasone
- D. Oral budesonide
- E. Inhaled salbutamol

Answer: B.

The most likely diagnosis in this man is eosinophilic oesophagitis. An empirical 8-week trial of PPIs should be used in the first instance, with around one-third of patients responding, known as PPI-responsive oesophageal eosinophilia. In individuals who fail to respond to this, 8–12 weeks of topical therapy with glucocorticoids can be used, such as fluticasone or budesonide. In addition, dietary modifications are an effective management strategy, including elemental and elimination diets.

23.5. A 55-year-old female with a history of chronic constipation presents having failed to respond to fibre supplements, lactulose and bisacodyl. In view of this, anorectal manometry is performed, suggesting dyssynergic defecation. What is the next appropriate management step?

- A. Low FODMAP diet
- B. Reassurance
- C. Biofeedback
- D. Lincalotide
- E. Prucalopride

Answer: C.

Biofeedback therapy has been shown to be an effective management option in individuals with dyssynergic defecation, with up to 70% of individuals responding to this therapy. Agents such as lincalotide and prucalopride may be considered in individuals with functional or slow transit constipation. It is worth noting that patients with dyssynergic defecation may have secondary slow transit constipation, which may respond to pharmacological management. However, biofeedback would be the first-line management for dyssynergic defecation.

## History and significance of abdominal signs

### Interpretation of physical signs in cirrhosis

#### Signs of cirrhosis

- Spider naevi
- Palmar erythema
- Leuconychia
- Bruising (low platelets)
- Loss of body hair (increased oestrogens)
- Gynaecomastia (increased oestrogens)

#### Signs of portal hypertension

- Splenomegaly
- Dilated abdominal wall veins

#### Signs of decompensation

- Jaundice
- Ascites/peripheral oedema
- Flapping tremor (encephalopathy)

#### Signs related to specific aetiologies

- Dupuytren's contracture (alcohol)
- Parotid swelling (alcohol)
- Intoxication/withdrawal (alcohol)
- Xanthelasma (PBC, NAFLD)
- Scratch marks (cholestatic liver disease)
- Clubbing (hepatopulmonary syndrome)

(NAFLD = non-alcoholic fatty liver disease; PBC = primary biliary cholangitis)

### Silent presentation of liver disease

It is important to note that patients with liver disease can present silently following detection of abnormality on screening investigation. This occurs frequently in practice in three settings:

#### Biochemical abnormality

- Liver enzyme abnormality detected during health screening or drug monitoring

#### Radiological abnormality

- Observation of an unexpected structural abnormality such as an altered liver texture or contour, or a mass lesion on ultrasound, computed tomography or other imaging undertaken for reasons unrelated to the liver

#### Serological abnormality

- Detection of a liver-related autoantibody

### Ascites

Causes	Associated clinical findings
<b>Exudative (high protein)</b> Carcinoma	Weight loss Abdominal mass
Tuberculosis	'Craggy' hepatomegaly Weight loss ± fever
<b>Transudative (low protein)</b> Cirrhosis Renal failure (including nephrotic syndrome) Congestive heart failure	Stigmata of cirrhosis (see above) Severe generalised oedema Elevated jugular venous pressure Peripheral oedema

### 5 Assessment of liver size

Clinical assessment of hepatomegaly is important in diagnosing liver disease.

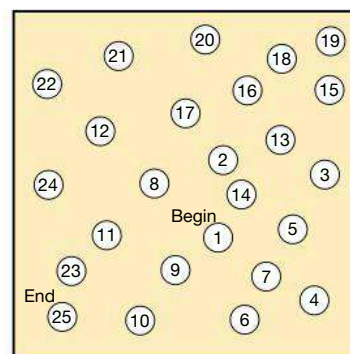

- Start in the right iliac fossa.
- Press hand gently up towards ribcage as patient breathes in.
- Progress up the abdomen 2 cm with each breath.
- Detect if smooth or irregular, tender or non-tender; ascertain the shape.
- Confirm the lower border of the liver by percussion.
- Identify the upper border by percussion.

### 1 Assessment of encephalopathy

**Flapping tremor.** Jerky forward movements every 5–10 secs, when arms are outstretched and hands are dorsiflexed, suggest hepatic encephalopathy. The movements are coarser than those seen in tremor.

**Number connection test.** These 25 numbered circles can normally be joined together within 30 secs. Serial observations may provide useful information, as long as the position of the numbers is varied to avoid the patient learning their pattern.

**Constructional apraxia.** Drawing stars and clocks may reveal marked abnormality.

## Functional anatomy and physiology

### Applied anatomy

#### Normal liver structure and blood supply

The liver weighs 1.2–1.5 kg and has multiple functions, including roles in metabolism, control of infection, and elimination of toxins and by-products of metabolism. It is classically divided into left and right lobes by the

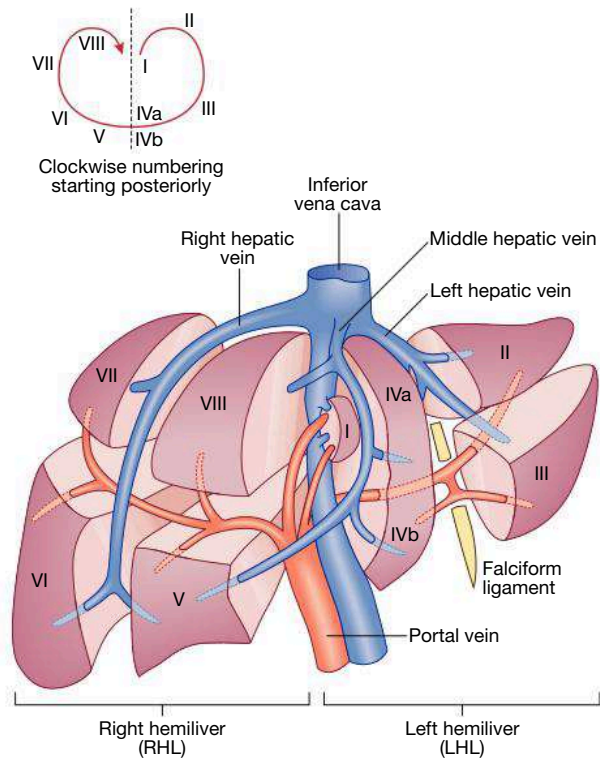

Fig. 24.1 Liver blood supply.

falciform ligament, but a more useful functional division is into the right and left hemilivers, based on blood supply (Fig. 24.1). These are further divided into eight segments, according to subdivisions of the hepatic and portal veins. Each segment has its own branch of the hepatic artery and biliary tree. The segmental anatomy of the liver has an important influence on imaging and treatment of liver tumours, given the increasing use of surgical resection. A liver segment is made up of multiple smaller units known as lobules, comprised of a central vein, radiating sinusoids separated from each other by single liver cell (hepatocyte) plates, and peripheral portal tracts containing terminal branches of the hepatic artery, portal vein and bile duct. The functional unit of the liver is the hepatic acinus (Fig. 24.2).

Blood flows into the acinus via a single branch of the portal vein and hepatic artery situated centrally in the portal tract. Blood flows outwards along the hepatic sinusoids into one of several tributaries of the hepatic vein at the periphery of the acinus. Bile is excreted by hepatocytes into channels called cholangioles, which lie between them, and flows in the opposite direction from the periphery of the acinus back to the interlobular bile duct in the portal tract. The hepatocytes in each acinus lie in three zones, depending on their position relative to the portal tract. Those in zone 1 are closest to the terminal branches of the portal vein and hepatic artery, and are richly supplied with oxygenated blood, and with blood containing the highest concentration of nutrients and toxins. Conversely, hepatocytes in zone 3 are furthest from the portal tracts and closest to the hepatic veins, and are therefore relatively hypoxic and exposed to lower concentrations of nutrients and toxins compared to zone 1. The different perfusion and toxin exposure patterns, and thus vulnerability, of hepatocytes in the different zones contribute to the often patchy nature of liver injury.

#### Liver cells

Hepatocytes comprise 80% of liver cells. The remaining 20% are the endothelial cells lining the sinusoids, cholangiocytes lining the intra-hepatic bile ducts, cells of the immune system including macrophages (Kupffer cells) and key populations of non-parenchymal cells, including hepatic stellate cells (Ito cells) and other myofibroblast precursors.

Endothelial cells line the sinusoids (Fig. 24.3), a network of capillary vessels that differ from other capillary beds in the body, in that there is no basement membrane. The endothelial cells have gaps between them

Fig. 24.2 Liver structure and microstructure. **A** Liver anatomy showing relationship with pancreas, bile duct and duodenum. **B** Hepatic lobule. **C** Hepatic acinus.

(fenestrae) of about 0.1  $\mu\text{m}$  in diameter, allowing free flow of fluid and particulate matter to the hepatocytes. Individual hepatocytes are separated from the leaky sinusoids by the space of Disse, which contains stellate cells that store vitamin A and play an important part in regulating liver blood flow. They may also be immunologically active and play a role in the liver's contribution to defence against pathogens. The key role of stellate cells in terms of pathology is in the development of hepatic fibrosis, the precursor of cirrhosis. They undergo activation in response to cytokines produced following liver injury, differentiating into myofibroblasts, which are the major producers of the collagen-rich matrix that forms fibrous tissue (Fig. 24.4).

**Fig. 24.3 Non-parenchymal liver cells.** (B cell = B lymphocyte; NK cell = natural killer cell; PMN cell = polymorphonuclear leucocyte; T cell = T lymphocyte).

### Blood supply

The liver is unique as an organ, as it has dual perfusion. The majority of its blood supply (50%–90%) is via the portal vein, which drains blood from the gut via the superior mesenteric vein and from the spleen, and is the principal route for nutrient trafficking to the liver. A minority of inflow is oxygenated blood from the hepatic artery. The dual perfusion system, and the variable contribution from portal vein and hepatic artery, can have important effects on the clinical expression of liver ischaemia (which typically exhibits a less dramatic pattern than ischaemia in other organs, a fact that can sometimes lead to it being missed clinically), and can raise practical challenges in liver surgery.

### Biliary system and gallbladder

Hepatocytes provide the driving force for bile flow by creating osmotic gradients of bile acids, which form micelles in bile (bile acid-dependent bile flow), and of sodium (bile acid-independent bile flow). Hepatocytes secrete bile into the biliary canaliculi that then progressively merge into a system of interlobular, septal and major ducts. The right and left hepatic ducts join as they emerge from the liver to form the common hepatic duct, which becomes the common bile duct after joining the cystic duct (see Fig. 24.2). The common bile duct is approximately 5 cm long and 4–6 mm wide. The distal portion of the duct passes through the head of the pancreas and usually joins the pancreatic duct before entering the duodenum through the ampullary sphincter (sphincter of Oddi). It should be noted, though, that the anatomy of the lower common bile duct can vary widely. Common bile duct pressure is maintained by rhythmic contraction and relaxation of the sphincter of Oddi; this pressure exceeds gallbladder pressure in the fasting state, so that bile normally flows into the gallbladder, where it is concentrated 10-fold by resorption of water and electrolytes.

**Fig. 24.4 Pathogenic mechanisms in hepatic fibrosis.** Stellate cell activation occurs under the influence of cytokines released by other cell types in the liver, including hepatocytes, Kupffer cells (tissue macrophages), platelets and lymphocytes. Once stellate cells become activated, they can perpetuate their own activation by synthesis of transforming growth factor beta ( $\text{TGF-}\beta_1$ ), and platelet-derived growth factor (PDGF) through autocrine loops. Activated stellate cells produce  $\text{TGF-}\beta_1$ , stimulating the production of collagen matrix, as well as inhibitors of collagen breakdown. The inhibitors of collagen breakdown, matrix metalloproteinase 2 and 9 (MMP2 and MMP9), are inactivated in turn by tissue inhibitors TIMP1 and TIMP2, which are increased in fibrosis. Inflammation also contributes to fibrosis, with the cytokine profile produced by Th2 lymphocytes, such as interleukin-6 and 13 (IL-6 and IL-13). Activated stellate cells also produce endothelin 1 (ET1), which may contribute to portal hypertension. (EGF = epidermal growth factor; IGF<sub>1</sub> = insulin-like growth factor 1; ROS = reactive oxygen species)

The gallbladder is a pear-shaped sac typically lying under the right hemiliver, with its fundus located anteriorly behind the tip of the 9th costal cartilage. Anatomical variation is common. The function of the gallbladder is to concentrate, and provide a reservoir for, bile. Gallbladder tone is maintained by vagal activity, and cholecystokinin released from the duodenal mucosa during feeding causes gallbladder contraction and reduces sphincter pressure, so that bile flows into the duodenum. The body and neck of the gallbladder pass posteromedially towards the porta hepatis, and the cystic duct then joins it to the common hepatic duct. The cystic duct mucosa has prominent crescentic folds (valves of Heister), giving it a beaded appearance on cholangiography.

## Hepatic function

### Carbohydrate, amino acid and lipid metabolism

The liver plays a central role in carbohydrate, lipid and amino acid metabolism, and is also involved in metabolising drugs and environmental toxins (Fig. 24.5). An important and increasingly recognised role for the liver is in the integration of metabolic pathways, regulating the response of the body to feeding and starvation. Abnormality in metabolic pathways and their regulation can play an important role both in liver disease (e.g. non-alcoholic fatty liver disease, NAFLD) and in diseases that are not conventionally regarded as diseases of the liver (such as type 2 diabetes and inborn errors of metabolism). Hepatocytes have specific pathways to handle each of the nutrients absorbed from the gut and carried to the liver via the portal vein:

- Amino acids from dietary proteins are used for synthesis of plasma proteins, including albumin. The liver produces 8–14 g of albumin per day, and this plays a critical role in maintaining oncotic pressure in the vascular space and in the transport of small molecules like bilirubin, hormones and drugs throughout the body. Amino acids that are not required for the production of new proteins are broken down, with the amino group being converted ultimately to urea.
- Following a meal, more than half of the glucose absorbed is taken up by the liver and stored as glycogen or converted to glycerol and fatty acids, thus preventing hyperglycaemia. During fasting, glucose is synthesised (gluconeogenesis) or released from glycogen (glycogenolysis) in the liver, thereby preventing hypoglycaemia.
- The liver plays a central role in lipid metabolism, producing very low-density lipoproteins and further metabolising low- and high-density lipoproteins (see Fig. 19.12).

Fig. 24.5 Important liver functions.

## Clotting factors

The liver produces key proteins that are involved in the coagulation cascade. Many of these coagulation factors (II, VII, IX and X) are post-translationally modified by vitamin K-dependent enzymes, and their synthesis is impaired in vitamin K deficiency. Reduced clotting factor synthesis is an important and easily accessible biomarker of liver function in the setting of liver injury. The short half-life of clotting factors makes the prothrombin time (PT; or the International Normalised Ratio, INR) a rapidly responsive measure of hepatocyte function. However, the deranged PT or INR seen in liver disease does not directly equate to increased bleeding risk, as these tests do not capture the concurrent reduced synthesis of *anticoagulant* factors, including protein C and protein S. In stable patients with liver disease the coagulation is rebalanced by these offsetting factors that restore a neutral or marginally pro-thrombotic state (balanced coagulopathy). Correction of PT using blood products before minor invasive procedures should be guided by clinical risk rather than the absolute value of the PT.

## Bilirubin metabolism and bile

The liver plays a central role in the metabolism of bilirubin and is responsible for the production of bile (Fig. 24.6). Between 425 and 510 mmol (250–300 mg) of unconjugated bilirubin is produced from the catabolism of haem daily. Bilirubin in the blood is normally almost all unconjugated and, because it is not water-soluble, is bound to albumin and does not pass into the urine. Unconjugated bilirubin is taken up by hepatocytes at the sinusoidal membrane, where it is conjugated in the endoplasmic reticulum by UDP-glucuronyl transferase, producing bilirubin mono- and diglucuronide. Impaired conjugation by this enzyme is a cause of inherited hyperbilirubinaemias (see Box 24.18). These bilirubin conjugates are water-soluble and are exported into the bile canaliculi by specific carriers on the hepatocyte membranes. The conjugated bilirubin is excreted in the bile and passes into the duodenal lumen.

Once in the intestine, conjugated bilirubin is metabolised by colonic bacteria to form stercobilinogen, which may be further oxidised to stercobilin. Both stercobilinogen and stercobilin are then excreted in the stool, contributing to its brown colour. Biliary obstruction results in reduced stercobilinogen in the stool, and the stools become pale. A small amount of stercobilinogen (4 mg/day) is absorbed from the bowel, passes through

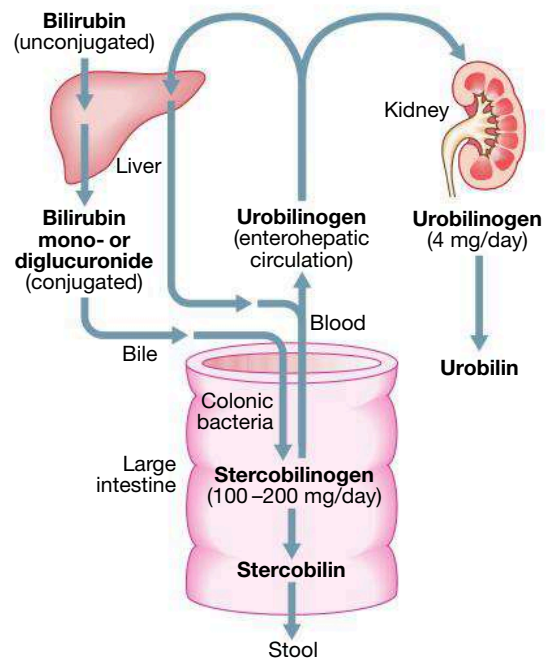

Fig. 24.6 Pathway of bilirubin excretion.

**Fig. 24.7 Biliary transporter proteins.** On the hepatocyte basolateral membrane, sodium taurocholate co-transporting polypeptide (NTCP) mediates uptake of conjugated bile acids from portal blood. At the canalicular membrane, bile salts are secreted via the bile salt export pump (BSEP) into bile. Multidrug resistance protein 3 (MDR3) transports (flips) phospholipid onto the outer side of the canalicular membrane. The ATP-binding cassette subgroup G 5 and 8 transporters (ABCG5/8) transport sterols including cholesterol into bile. These lipids form mixed micelles with bile salts and protect the membranes lining the biliary tree against the detergent action of bile salts. Familial intrahepatic cholestasis 1 (FIC1), now known as ATP8B1, transports phosphatidylserine to the outer side of the canalicular membrane and is essential for normal bile flow. Mutations in FIC1 can result in either progressive familial intrahepatic cholestasis (PFIC) in children or benign recurrent intrahepatic cholestasis (BRIC). Organic anion transporter protein (OATP) transports bilirubin and organic anions from portal blood into hepatocytes. Multidrug resistance protein 2 (MRP2) transports bilirubin, a range of organic anions and conjugates into bile.

the liver and is excreted in the urine, where it is known as urobilinogen or, following further oxidation, urobilin. The liver secretes 1–2L of bile daily. Bile contains bile acids (formed from cholesterol), phospholipids, bilirubin and cholesterol. Several biliary transporter proteins have been identified (Fig. 24.7). Mutations in genes encoding these proteins have been identified in inherited intrahepatic biliary diseases presenting in childhood, and in adult-onset disease such as intrahepatic cholestasis of pregnancy and gallstone formation.

### Storage of vitamins and minerals

Vitamins A, D and B<sub>12</sub> are stored by the liver in large amounts, while others, such as vitamin K and folate, are stored in smaller amounts and disappear rapidly if dietary intake is reduced. The liver is also able to metabolise vitamins to more active compounds, e.g. 7-dehydrocholesterol to 25(OH) vitamin D. Vitamin K is a fat-soluble vitamin and so the inability to absorb fat-soluble vitamins, as occurs in biliary obstruction, results in a coagulopathy. The liver also stores minerals such as iron, in ferritin and haemosiderin, and copper, which is excreted in bile.

### Immune regulation

Approximately 9% of the normal liver is composed of immune cells (see Fig. 24.3). Cells of the innate immune system include Kupffer cells derived from blood monocytes, the liver macrophages and natural killer (NK) cells, as well as 'classical' B and T cells of the adaptive immune response. Additional populations of atypical lymphocytes, with phenotypic features of both T cells and NK cells, are thought to play an

important role in host defence through linking of innate and adaptive immunity. The enrichment of such cells in the liver reflects the unique importance of the liver in preventing microorganisms from the gut from entering the systemic circulation.

Kupffer cells constitute the largest single mass of tissue-resident macrophages in the body and account for 80% of the phagocytic capacity of this system. They remove aged and damaged red blood cells, bacteria, viruses, antigen–antibody complexes and endotoxin. They also produce a wide variety of inflammatory mediators that can act locally or may be released into the systemic circulation.

The immunological environment of the liver is unique in that antigens presented within it tend to induce immunological tolerance. This is of importance in liver transplantation, where classical major histocompatibility (MHC) barriers may be crossed, and also in chronic viral infections, when immune responses may be attenuated. The mechanisms that underlie this phenomenon have not been fully defined.

## Investigation of liver and hepatobiliary disease

Investigations play an important role in the management of liver disease in three settings:

- identifying the presence of liver disease in those with risk factors
- establishing the aetiology in those with incidentally found liver disease
- understanding disease severity (in particular, identification of fibrosis which leads to cirrhosis with its complications).

When planning investigations, it is important to be clear as to which of these goals is being addressed.

Suspicion of the presence of liver disease is normally based on blood biochemistry abnormality ('liver function tests', or 'LFTs').

Aetiology is typically established through a combination of history, specific blood tests and, where appropriate, imaging and liver biopsy.

Staging of disease involves the assessment of fibrosis and identification of cirrhosis and its complications. Although histology remains the gold standard for staging liver fibrosis, it has been largely replaced by non-invasive approaches, including novel imaging modalities, elastography, serum markers of fibrosis and predictive scoring systems.

The aims of investigation in patients with suspected liver disease are shown in Box 24.1.

### Liver blood biochemistry

Liver blood biochemistry (LFTs) includes the measurement of serum bilirubin, aminotransferases, alkaline phosphatase,  $\gamma$ -glutamyl transferase and albumin. Most analytes measured by LFTs are not truly 'function' tests but enzymes that are released by injured hepatocytes and provide biochemical evidence of liver cell damage. The pattern of liver enzyme abnormalities can help to distinguish the likely cause of injury (hepatic or cholestatic). Liver function per se is best assessed by the serum bilirubin, albumin and prothrombin time because of the role played by the liver in clearance of bilirubin and in synthesis of albumin and clotting factors. These measures reflect the severity of liver disease

#### 24.1 Aims of investigations in patients with suspected liver disease

- Detect hepatic abnormality
- Measure the severity of liver damage
- Detect the pattern of liver function test abnormality: hepatitis, cholestatic or mixed
- Identify the specific cause
- Investigate possible complications

and are related to clinical outcomes, reflected by their use in several prognostic scores: the Child–Pugh and MELD (Model for End-stage Liver Disease) scores in cirrhosis (see [Boxes 24.31](#) and [24.32](#)), the Glasgow score in alcoholic hepatitis (see [Box 24.49](#)) and the King's College Hospital criteria for liver transplantation in acute liver failure (see [Box 24.18](#)).

## Bilirubin

The degree of elevation of bilirubin can reflect the degree of liver damage. A raised bilirubin often occurs earlier in the natural history of biliary disease (e.g. primary sclerosing cholangitis) than in disease of the liver parenchyma (e.g. cirrhosis), where the hepatocytes are primarily involved. Swelling of the liver within its capsule in inflammation can, however, sometimes impair bile flow and cause an elevation of bilirubin level that is disproportionate to the degree of liver injury. Caution is therefore needed in interpreting the level of liver injury purely on the basis of bilirubin elevation. Bilirubin may also be elevated in the absence of liver injury as a result of haemolysis (resulting in increased bilirubin production) or inherited disorders of bilirubin metabolism (see [Box 24.12](#)).

## Albumin

Serum albumin levels are often low in patients with cirrhosis. This is due to a change in the volume of distribution of albumin, and to reduced synthesis. Since the plasma half-life of albumin is about 2 weeks, albumin levels may be normal in acute liver failure but are almost always reduced in chronic liver failure. Albumin is not a specific marker of liver disease and is reduced in a range of conditions, including sepsis, malnutrition, nephrotic syndrome and protein-losing enteropathy.

## Alanine aminotransferase and aspartate aminotransferase

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are intracellular enzymes that are released during damage to hepatocytes. Although AST may also be released from heart or skeletal muscle, expression of ALT outside the liver is relatively low and this enzyme is therefore considered more specific for hepatocellular damage. Large increases of aminotransferase activity favour hepatocellular damage, and this pattern of enzyme abnormality is known as 'hepatic'.

The AST level is usually lower than the ALT, resulting in an AST/ALT ratio of less than 0.8. This ratio reverses in two situations: in alcohol-related liver disease (particularly in alcoholic hepatitis where the ratio can be  $> 2$ ), or as an indicator of advanced fibrosis in non-alcohol-related liver disease such as hepatitis C or NAFLD.

## Alkaline phosphatase and $\gamma$ -glutamyl transferase

Alkaline phosphatase (ALP) is the collective name given to several different enzymes that hydrolyse phosphate esters at alkaline pH. These enzymes are widely distributed in the body but the main sites of production are the liver, bone and placenta. ALPs are post-translationally modified, resulting in the production of several different isoenzymes, which differ in abundance in different tissues. ALP enzymes in the liver are located in cell membranes of the hepatic sinusoids and the biliary canaliculi. Accordingly, levels rise with biliary injury and with sinusoidal obstruction, as occurs in infiltrative liver disease.

Gamma-glutamyl transferase (GGT) is a microsomal enzyme found in many cells and tissues of the body. The highest concentrations are located in the liver, where it is produced by hepatocytes and biliary epithelium.

The pattern of a modest increase in aminotransferase activity and large increases in ALP and GGT activity suggests impaired bile flow and is commonly described as 'cholestatic' ([Box 24.2](#)). Isolated elevation of the serum GGT is relatively common and may occur during ingestion of

### 24.2 'Hepatic' and 'cholestatic' liver function tests

Pattern	AST/ALT	GGT	ALP
Cholestasis	↑	↑↑	↑↑↑
Hepatitis	↑↑↑	↑	↑
Alcohol/enzyme-inducing drugs	N/↑	↑↑	N

N = normal; ↑ mild elevation ( $<$  twice normal); ↑↑ moderate elevation (2–5 times normal); ↑↑↑ marked elevation ( $>$  5 times normal).

(ALT = alanine aminotransferase; ALP = alkaline phosphatase; AST = aspartate aminotransferase; GGT = gamma-glutamyltransferase)

### 24.3 Drugs that increase levels of $\gamma$ -glutamyltransferase

- Ethanol
- Phenytoin
- Carbamazepine
- Valproate
- Barbiturates
- Oral contraceptive pill
- Griseofulvin
- Isotretinoin

microsomal enzyme-inducing drugs, including alcohol ([Box 24.3](#)), but also in NAFLD. Elevated ALP with normal GGT is suggestive of non-hepatic origin, e.g. bone disease or pregnancy.

## Other biochemical tests

Other widely available biochemical tests may become altered in patients with liver disease:

- Hyponatraemia occurs in severe liver disease despite a high total body sodium content due to increased production of vasopressin (antidiuretic hormone, ADH; see [Fig. 19.7](#)), and may be exacerbated by diuretic use. A low sodium level predicts a poor prognosis in cirrhosis.
- Serum urea may be reduced in hepatic failure or due to loss of muscle mass, whereas levels of urea may be increased following gastrointestinal haemorrhage.
- Ferritin is elevated in patients with haemochromatosis, systemic inflammatory disease and a range of conditions causing significant parenchymal inflammation, including alcohol excess and NAFLD.

**Fig. 24.8** Ultrasound showing a stone in the gallbladder (A) with acoustic shadow (S).

## Haematological tests

### Blood count

The peripheral blood count is often abnormal and can give a clue to the underlying diagnosis:

- *A normochromic normocytic anaemia* may reflect anaemia of chronic disease or recent gastrointestinal haemorrhage, whereas chronic blood loss is characterised by a hypochromic microcytic anaemia secondary to iron deficiency. A high erythrocyte mean cell volume (macrocytosis) is associated with alcohol misuse or haemolysis, but target cells in any jaundiced patient also result in a macrocytosis.
- *Leucopenia* may complicate portal hypertension and hypersplenism, whereas leucocytosis may occur with cholangitis, alcoholic hepatitis and hepatic abscesses. Atypical lymphocytes are seen in infectious mononucleosis, which may be complicated by an acute hepatitis.
- *Thrombocytopenia* is common in cirrhosis and is due to reduced platelet production and increased breakdown because of hypersplenism. Thrombopoietin, required for platelet production, is produced in the liver and levels fall with worsening liver function. Thus platelet levels are usually more depressed than white cells and haemoglobin in the presence of hypersplenism in patients with cirrhosis. Thrombocytosis is unusual in patients with liver disease but may occur in those with active gastrointestinal haemorrhage and, rarely, in hepatocellular carcinoma.

### Coagulation tests

These are often abnormal in patients with liver disease. An increased PT is an indicator of impaired liver function. The normal half-lives of the vitamin K-dependent coagulation factors in the blood are short (5–72 hours), and so changes in the PT occur relatively quickly following liver damage; these changes provide valuable prognostic information in patients with both acute and chronic liver failure. Vitamin K does not reverse this deficiency if it is due to liver disease, but will correct the PT if the cause is vitamin K deficiency, as may occur with cholestasis due to malabsorption of fat-soluble vitamins, or poor diet.

## 24.4 Chronic liver disease screen

- Hepatitis B surface antigen
- Hepatitis C antibody
- Liver autoantibodies (antinuclear antibody, smooth muscle antibody, antimitochondrial antibody, anti-liver–kidney microsomal antibody)
- Immunoglobulins
- Ferritin
- $\alpha_1$ -antitrypsin
- Caeruloplasmin

## Immunological tests

A variety of tests are available to evaluate the aetiology of hepatic disease (Boxes 24.4 and 24.5). The presence of liver-related autoantibodies can be suggestive of autoimmune liver disease (although false-positive results can occur in other inflammatory diseases such as NAFLD). Elevation in overall serum immunoglobulin levels (either IgG or IgM) can also indicate autoimmunity. In contrast, elevated serum IgA may be seen in alcohol-related liver disease and NAFLD.

## Imaging

Several imaging techniques can be used to determine the site and nature of structural lesions in the liver and biliary tree. In general, however, imaging techniques are unable to identify hepatic inflammation and have poor sensitivity for liver fibrosis unless advanced cirrhosis with portal hypertension is present.

## Ultrasound

Ultrasound is non-invasive and most commonly used as a 'first-line' test to identify gallstones, biliary obstruction (Fig. 24.8) or thrombosis in the hepatic vasculature. Ultrasound may show changes of cirrhosis (nodular liver contour, coarse echotexture, right lobe atrophy and left lobe hypertrophy) or portal hypertension (splenomegaly, ascites) but has a relatively low sensitivity for diagnosing compensated cirrhosis. Focal lesions, such as tumours, may not be detected if they are less than 2 cm in diameter

## 24.5 How to identify the cause of liver function test (LFT) abnormality

Diagnosis	Clinical clue	Initial test	Additional tests
Alcohol-related liver disease	History	LFTs AST > ALT; high MCV	Random blood alcohol
Non-alcoholic fatty liver disease (NAFLD)	Metabolic syndrome (central obesity, diabetes, hypertension)	LFTs Ultrasound showing fatty liver	
Chronic hepatitis B	Born in high-prevalence area; injection drug use; blood transfusion	HBsAg	HBeAg, HBeAb HBV-DNA
Chronic hepatitis C	Injection drug use; blood transfusion	HCV antibody	HCV-RNA
Primary biliary cholangitis	Itch; raised ALP	AMA Raised IgM	
Primary sclerosing cholangitis	Inflammatory bowel disease	MRCP	
Autoimmune hepatitis	Other autoimmune diseases	ASMA, ANA, LKM, raised IgG	Liver biopsy
Haemochromatosis	Diabetes/joint pain	Transferrin saturation, ferritin	HFE gene test
Wilson's disease	Neurological signs; haemolysis	Caeruloplasmin	24-hour urinary copper
Alpha-1-antitrypsin deficiency	Lung disease	$\alpha_1$ -antitrypsin level	$\alpha_1$ -antitrypsin genotype
Drug-induced liver disease	Drug/herbal remedy history	LFTs	Liver biopsy

(ALP = alkaline phosphatase; ALT = alanine aminotransferase; AMA = antimitochondrial antibody; ANA = antinuclear antibody; ASMA = anti-smooth muscle antibody; AST = aspartate aminotransferase; HBeAb = antibody to hepatitis B e antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HFE = haemochromatosis (high iron/Fe); IgM = immunoglobulin M; IgG = immunoglobulin G; LKM = liver–kidney microsomal antibody; MCV = mean cell volume; MRCP = magnetic resonance cholangiopancreatography)

and have similar echogenicity to normal liver tissue. Bubble-based contrast media can enhance discriminant capability. Doppler ultrasound allows blood flow in the hepatic artery, portal vein and hepatic veins to be investigated. Endoscopic ultrasound provides high-resolution images of the pancreas, biliary tree and liver (see below and Fig. 24.46).

### Computed tomography and magnetic resonance imaging

Computed tomography (CT) detects smaller focal lesions in the liver, especially when combined with contrast injection (Fig. 24.9). Magnetic resonance imaging (MRI) can also be used to localise and confirm the aetiology of focal liver lesions, particularly primary and secondary tumours.

Hepatic angiography is seldom used nowadays as a diagnostic tool, since CT and MRI are both able to provide images of hepatic vasculature, but it still has a therapeutic role in the embolisation of vascular tumours, such as hepatocellular carcinoma. Hepatic venography is now rarely performed.

### Cholangiography

Cholangiography can be undertaken by magnetic resonance cholangiopancreatography (MRCP; Fig. 24.10), endoscopy (endoscopic retrograde cholangiopancreatography, ERCP) or the percutaneous approach (percutaneous transhepatic cholangiography, PTC). The latter does not allow the ampulla of Vater or pancreatic duct to be visualised. Endoscopic ultrasound can also provide high-quality biliary imaging safely (see below). MRCP is as good as ERCP at providing images of the biliary tree but is safer, and there is now little, if any, role for diagnostic ERCP. Both endoscopic and percutaneous approaches allow therapeutic interventions, such as the insertion of biliary stents across bile duct strictures. The percutaneous approach is used only if it is not possible to access the bile duct endoscopically.

### Endoscopic ultrasound

Endoscopic ultrasound (EUS) is complementary to MRCP in the diagnostic evaluation of the extrahepatic biliary tree, ampulla of Vater and pancreas. With the ultrasonic probe in the duodenum, high-quality images are obtained, tissue sampling can be performed and, increasingly, therapeutic drainage of biliary obstruction can be performed. EUS has the advantage over ERCP of not exposing patients to the risk of pancreatitis, among other complications of bile duct cannulation.

**Fig. 24.9** Computed tomography in a patient with cirrhosis. The liver is small and has an irregular outline (black arrow), the spleen is enlarged (long white arrow), fluid (ascites) is seen around the liver, and collateral vessels are present around the proximal stomach (short white arrow).

**Fig. 24.10** Magnetic resonance cholangiopancreatography showing a biliary stricture due to cholangiocarcinoma in the distal common bile duct (arrow). The proximal common bile duct (CBD) is dilated but the pancreatic duct (PD) is normal.

### Non-invasive markers of hepatic fibrosis

Fibrosis is a key predictor of prognosis in chronic liver disease, and can help to guide monitoring and treatment decisions. This is now largely assessed by non-invasive markers of liver fibrosis. A number of indirect fibrosis markers have been described, including bilirubin, AST/ALT ratio and platelet count. Simple scoring systems such as the FIB-4 score and NAFLD fibrosis score combine routinely available blood tests and clinical risk factors, and are often used as screening tests for fibrosis risk. These tests have a high negative predictive value, with a normal value making advanced fibrosis very unlikely, but a relatively low positive predictive value. Whilst these have been validated across a range of aetiologies, the cut-off values used (e.g. for FIB-4) may differ according to aetiology, and serum-based tests are less reliable in alcohol-related liver disease.

Fibrosis can also be assessed using more specific serum tests. Fibrotest® combines five serum markers including  $\alpha_2$ -macroglobulin, haptoglobin and apolipoprotein A1. The Enhanced Liver Fibrosis (ELF®) serological assay provides direct assessment of fibrogenesis and fibrolysis using a combination of hyaluronic acid, procollagen peptide III (PIIINP) and tissue inhibitor of metalloproteinase 1 (TIMP1).

An alternative to serological markers is transient elastography (Fibroscan®), in which ultrasound-based shock waves are sent through the liver to measure stiffness as a surrogate for hepatic fibrosis. This is quick, non-invasive and provides immediate results. Depending on the threshold used, this can exclude significant fibrosis or diagnose cirrhosis. However, results can be influenced by the presence of severe inflammation and become less reliable with increasing obesity. Magnetic resonance elastography appears more reliable and is not influenced by obesity, but is costly and not widely available.

### Histological examination

A liver biopsy can confirm the severity of liver damage and provide aetiological information. It is performed percutaneously with a Trucut or Menghini needle, usually through an intercostal space under local anaesthesia, or radiologically using a transjugular approach.

Percutaneous liver biopsy is a relatively safe procedure if the conditions detailed in Box 24.6 are met, but carries a mortality of about 0.01%. The main complications are abdominal and/or shoulder pain, bleeding and biliary peritonitis. Liver biopsies can be carried out in patients with defective haemostasis if:

- the defect is corrected with fresh frozen plasma and platelet transfusion,
- the biopsy is obtained by the transjugular route, or

### 24.6 Conditions required for safe percutaneous liver biopsy

- Cooperative patient
- It is recommended that for non-lesional liver biopsy in patients with chronic liver disease a transvenous route should be used if INR > 1.4
- For percutaneous lesional biopsies the INR should be < 2
- Platelet count > 50 × 10<sup>9</sup>/L
- Exclusion of bile duct obstruction, localised skin infection, advanced chronic obstructive pulmonary disease, marked ascites and severe anaemia
- Liver biopsy should be avoided in unstable patients with uncontrolled bleeding, bacterial infection and significant renal impairment.

(INR = International Normalised Ratio)

- the procedure is conducted percutaneously under ultrasound control and the needle track is then plugged with procoagulant material.

In patients with potentially resectable malignancy, biopsy should be avoided due to the potential risk of tumour dissemination (biopsy track seeding). Operative or laparoscopic liver biopsy may sometimes be valuable.

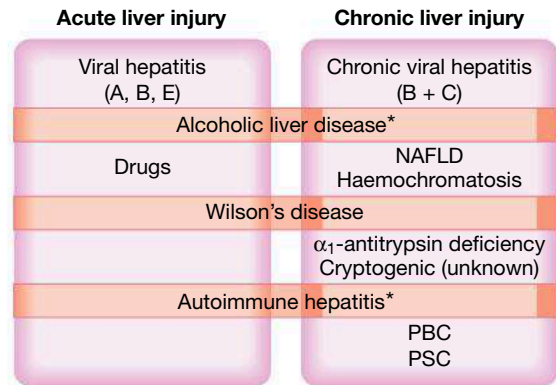

Liver biopsy is used where there is uncertainty as to the cause of liver disease, or to quantify the degree of inflammation ('grade') or fibrosis ('stage'). Semi-quantitative scoring systems may be used to describe the degree of inflammation or fibrosis. Although often regarded as the 'gold standard' investigation for liver disease, liver biopsies are limited by sampling error, with studies showing significant variation in both grade and stage between simultaneous paired biopsies. The use of special histological stains can help in determining aetiology. The clinical features and prognosis of these changes are dependent on the underlying aetiology and are discussed in the relevant sections below.

## Presenting problems in liver disease

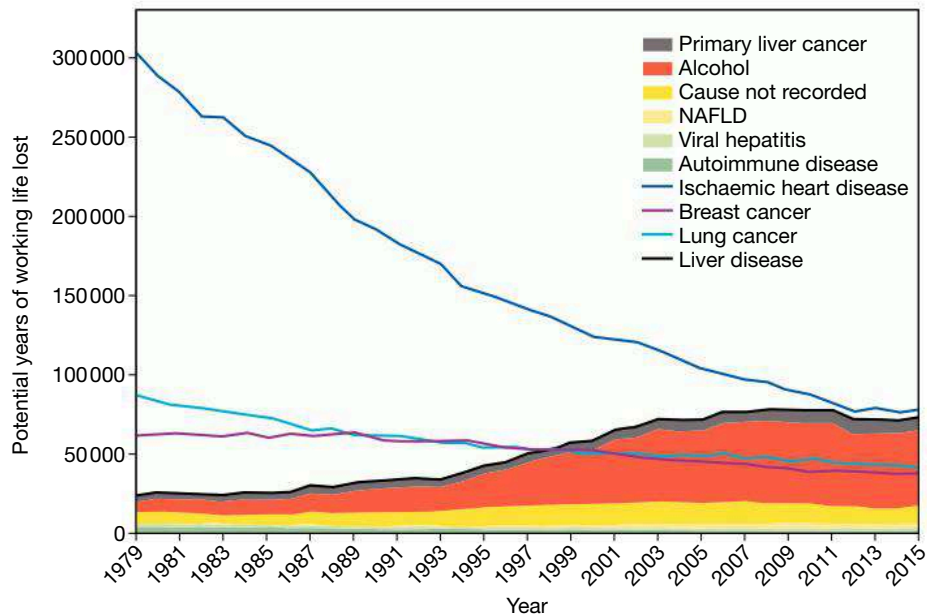

Liver injury may be either acute or chronic. The main causes are listed in Fig. 24.11 and discussed in detail later in the chapter. In the UK, liver disease is the only one of the top causes of mortality that is steadily increasing (Fig. 24.12). Mortality rates have risen substantially over the last 30 years, with a near-fivefold increase in liver-related mortality in

people younger than 65 years. The rate of increase is substantially higher in the UK than in other countries in Western Europe.

- *Acute liver injury* may present with non-specific symptoms of fatigue and abnormal LFTs, or with jaundice and acute liver failure.
- *Chronic liver injury* is defined as hepatic injury, inflammation and/or fibrosis occurring in the liver for more than 6 months. In the early stages, patients can be asymptomatic with fluctuating abnormal LFTs. With more severe liver damage, however, the presentation can be with jaundice, portal hypertension or other signs of cirrhosis and hepatic decompensation (Box 24.7). Patients with clinically silent chronic liver disease frequently present when abnormalities in liver function are observed on routine blood testing, or when clinical events, such as an intercurrent infection or surgical intervention, cause the liver to decompensate. Patients with compensated cirrhosis can undergo most forms of surgery without significantly increased risk. Surgical complications are more common in patients with decompensated cirrhosis and the presence of portal hypertension with intra-abdominal varices can make abdominal surgery more hazardous. The possibility of undiagnosed liver disease should be borne

**Fig. 24.11 Causes of acute and chronic liver injury.** \*Although there is often evidence of chronic liver disease at presentation, may present acutely with jaundice. In alcoholic liver disease this is due to superimposed alcoholic hepatitis. (NAFLD = non-alcoholic fatty liver disease; PBC = primary biliary cholangitis; PSC = primary sclerosing cholangitis)

**Fig. 24.12 Potential years of working life lost (before 65 years of age) estimated with Office for National Statistics mortality data for 1979–2015.** From Williams R, Alexander G, Armstrong I, et al. Disease burden and costs from excess alcohol consumption, obesity, and viral hepatitis: fourth report of the Lancet Standing Commission on Liver Disease in the UK. Reprinted with permission from Elsevier (The Lancet 2018; 391:1097–1107).

24.7 Presentation of liver disease		
Severity	Acute liver injury	Chronic liver injury
Mild/moderate	Abnormal liver function tests	Abnormal liver function tests
Severe	Jaundice	Signs of cirrhosis ± portal hypertension
Very severe	Acute liver failure	Chronic liver failure* Jaundice Ascites Hepatic encephalopathy Portal hypertension with variceal bleeding

\*May not occur until several years after cirrhosis has presented.

24.8 Liver disease in old age	
•	<b>Alcoholic liver disease:</b> 10% of cases present over the age of 70 years, when disease is more likely to be severe and has a worse prognosis.
•	<b>Hepatitis A:</b> causes more severe illness and runs a more protracted course.
•	<b>Primary biliary cholangitis:</b> one-third of cases are over 65 years.
•	<b>Liver abscess:</b> more than 50% of all cases in the UK are over 60 years.
•	<b>Hepatocellular carcinoma:</b> approximately 50% of cases in the UK present over the age of 65 years.
•	<b>Surgery:</b> older people are less likely to survive liver surgery (including transplantation) because comorbidity is more prevalent.

in mind in all patients in at-risk groups undergoing significant surgery. Many liver disorders are more common in older age and can pursue a more aggressive course (Box 24.8).

## Abnormal liver function tests

LFTs are frequently requested in patients who have no symptoms or signs of liver disease, as part of routine health checks, insurance medicals or drug monitoring. The prevalence of abnormal LFTs has been reported to be as high as 10%–20% in some studies. In the majority of cases, these will not reflect significant underlying liver disease. However, many patients with chronic liver disease are asymptomatic or have vague, non-specific symptoms. The most common abnormalities are alcohol-related or non-alcoholic fatty liver disease. Since effective medical treatments are now available for many types of chronic liver disease, further evaluation is usually warranted to make sure the patient does not have a treatable condition. Biochemical abnormalities in chronic liver disease often fluctuate over time; even mild abnormalities can therefore indicate significant underlying disease and so warrant follow-up and investigation.

When abnormal LFTs are detected, a thorough history should be compiled to determine the patient's alcohol consumption, drug use (prescribed, over-the-counter or recreational), risk factors for viral hepatitis (e.g. blood transfusion, injection drug use, tattoos), the presence of autoimmune diseases, family history, neurological symptoms and the presence of features of the metabolic syndrome, including diabetes and/or obesity (see Box 24.5 and Fig. 22.6). Stigmata of chronic liver disease should be looked for but further investigations are indicated even in the absence of these signs.

Both the pattern of enzyme abnormality (hepatic or cholestatic) and the degree of elevation are helpful in determining the cause of underlying liver disease (Boxes 24.9 and 24.10). The investigations that make up a standard liver screen and additional or confirmatory tests are shown in Boxes 24.4 and 24.5. An algorithm for investigating abnormal LFTs is provided in Fig. 24.13.

## Jaundice

Jaundice is usually detectable clinically when the plasma bilirubin exceeds 40 µmol/L (~2.5 mg/dL). The causes of jaundice overlap with the causes of abnormal LFTs discussed above. In a patient with jaundice it is useful to

consider whether the cause might be pre-hepatic, hepatic or post-hepatic, and there are often important clues in the history (Box 24.11).

## Pre-hepatic jaundice

This is caused either by haemolysis or by congenital hyperbilirubinaemia, and is characterised by an isolated raised bilirubin level.

In haemolysis, destruction of red blood cells or their marrow precursors causes increased bilirubin production. Jaundice due to haemolysis is usually mild because a healthy liver can excrete a bilirubin load six-times greater than normal before unconjugated bilirubin accumulates in the plasma. This does not apply to newborns, who have less capacity to metabolise bilirubin.

The most common form of non-haemolytic hyperbilirubinaemia is Gilbert syndrome, an inherited disorder of bilirubin metabolism (Box 24.12). Other inherited disorders of bilirubin metabolism are very rare.

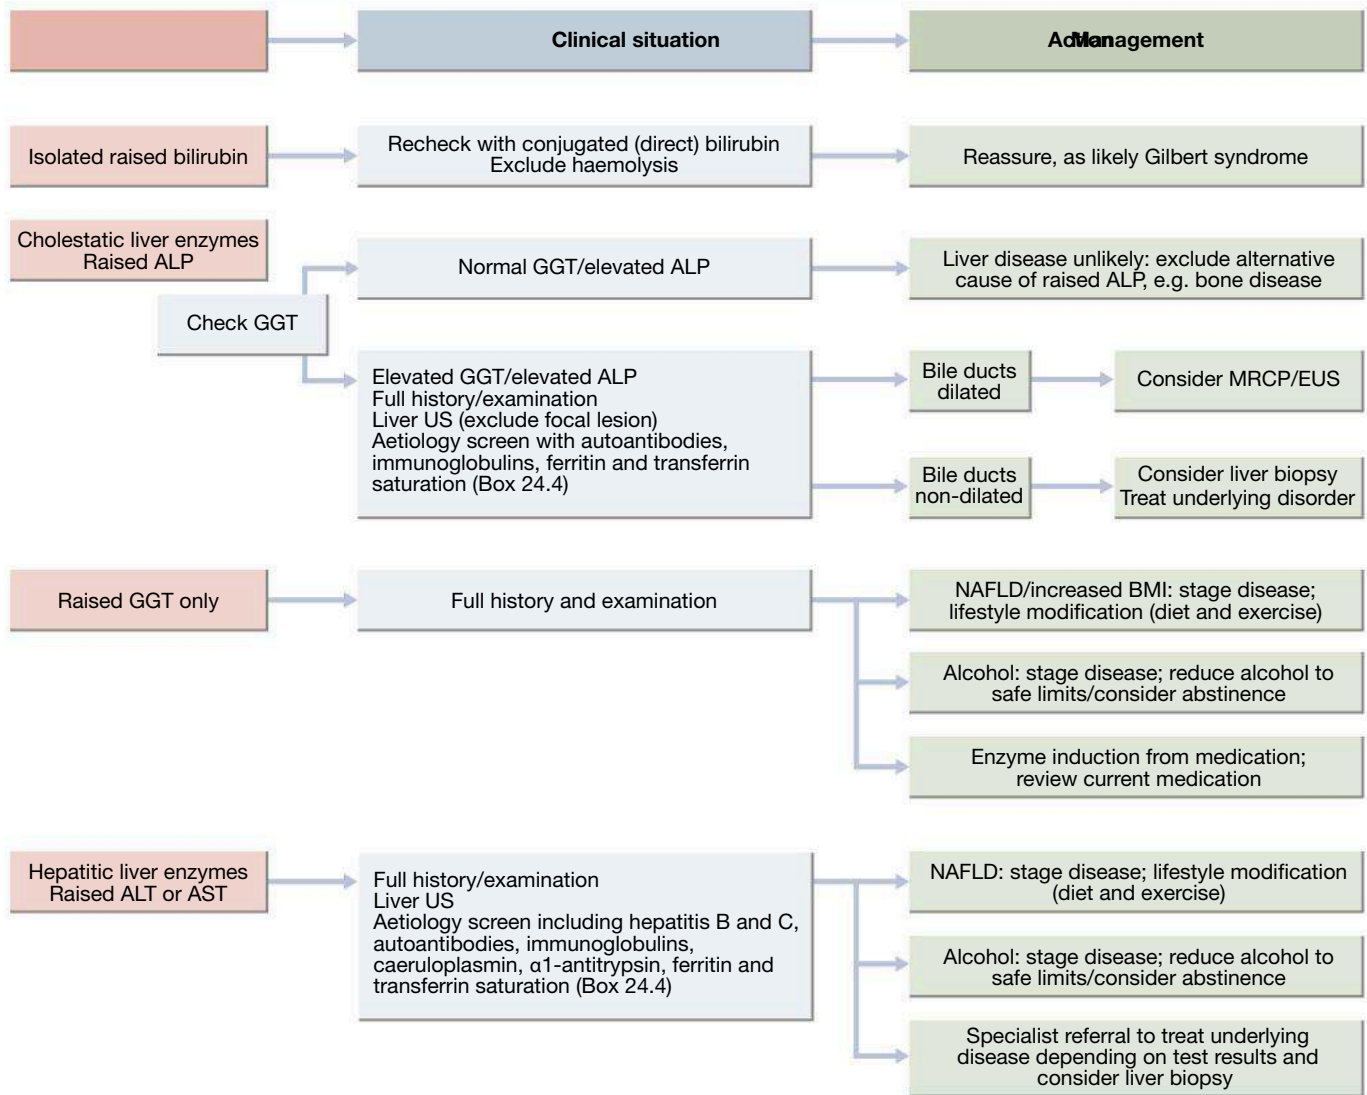

## Hepatic jaundice

This is characterised by jaundice due to hepatic dysfunction (usually indicated by abnormal liver enzymes) but normal biliary imaging. This can be due to acute hepatocellular injury (see Box 24.9), intrahepatic cholestasis (see Box 24.10) or decompensation of cirrhosis. 'Hepatic' jaundice can be a manifestation of extrahepatic disease such as sepsis or right heart failure. In all of these, jaundice results from an inability of the liver to transport bilirubin into the bile, occurring at any point between uptake of unconjugated bilirubin into the cells and transport of conjugated bilirubin into the canaliculi. In addition, swelling of cells and oedema resulting

24.9 Common causes of elevated serum transaminases	
<b>Minor elevation (&lt; 100 U/L*)</b>	
• Chronic hepatitis C	• Alcoholic hepatitis
• Chronic hepatitis B	• Haemochromatosis
• Fatty liver disease	
<b>Moderate elevation (100–300 U/L*)</b>	
As above plus:	
• Non-alcoholic steatohepatitis	• Wilson's disease
• Autoimmune hepatitis	
<b>Major elevation (&gt; 300 U/L*)</b>	
• Drugs (e.g. paracetamol)	• Toxins (e.g. <i>Amanita phalloides</i> poisoning)
• Acute viral hepatitis	• Flare of chronic hepatitis B
• Autoimmune hepatitis	
• Ischaemic hepatitis	

\*These ranges are indicative but do not rigidly discriminate between different aetiologies.

24.10 Causes of cholestatic jaundice	
<b>Hepatic</b>	
• Primary biliary cholangitis	• Cystic fibrosis
• Primary sclerosing cholangitis	• Sepsis
• Alcohol	• Pregnancy
• Drugs	• Inherited cholestatic liver disease (e.g. benign recurrent intrahepatic cholestasis)
• Hepatic infiltrations (lymphoma, granuloma, amyloid, metastases)	• Right heart failure
<b>Post-hepatic</b>	
• Carcinoma: Ampullary Pancreatic Bile duct (cholangiocarcinoma) Liver metastases	• Cholelithiasis • Primary sclerosing cholangitis • Parasitic infection • Traumatic biliary strictures • Chronic pancreatitis • IgG4 cholangitis

**Fig. 24.13** Suggested management of abnormal liver function tests in asymptomatic patients. (ALP = alkaline phosphatase; ASP = aspartate aminotransferase; BMI = body mass index; EUS = endoscopic ultrasound; GGT =  $\gamma$ -glutamyl transferase; MRCP = magnetic resonance cholangiopancreatography; NAFLD = non-alcoholic fatty liver disease; US = ultrasound)

### 24.11 Key history points in patients with jaundice

#### Symptoms\*

- Itch
- Abdominal pain (suggests gallstones)
- Weight loss (chronic liver disease and malignancy)
- Dark urine and pale stools
- Fever  $\pm$  rigors
- Dry eyes/dry mouth

#### Recent drug history

#### Other

- Alcohol history
- Exposure to intravenous drugs or blood transfusions
- Travel history and country of birth
- Metabolic syndrome (increased body mass index  $\pm$  type 2 diabetes/hypertension)
- Autoimmune disease history
- Inflammatory bowel disease
- Family history of liver disease, autoimmune disease or the metabolic syndrome

\*Symptoms may be absent and abnormal liver function tests detected incidentally.

from parenchymal damage may cause obstruction of the biliary canaliculi. Consequently, the concentrations of both unconjugated and conjugated bilirubin in the blood increase. Jaundice due to acute parenchymal liver disease is associated with increases in transaminases (AST/ALT), but increases in cholestatic enzymes (GGT/ALP) may occur and suggest specific aetiologies (see below). Acute jaundice in the presence of an ALT of  $> 1000$  U/L is highly suggestive of an infectious cause (e.g. hepatitis A, B or E), drugs (e.g. paracetamol) or hepatic ischaemia. Imaging is essential, not only to exclude a post-hepatic cause but to identify features suggestive of cirrhosis or portal hypertension, and to define the patency of the hepatic vasculature. Liver biopsy has an important role in defining the aetiology of unexplained hepatocellular jaundice and the extent of liver injury.

### Post-hepatic jaundice

Post-hepatic jaundice may be caused by obstruction of the larger bile ducts, usually between the hilum and the ampulla of Vater, resulting in biliary dilatation on imaging.

The causes of post-hepatic jaundice are listed in [Box 24.10](#). Post-hepatic jaundice is most commonly due to diseases affecting the

24.12 Congenital non-haemolytic hyperbilirubinaemia				
Syndrome	Inheritance	Abnormality	Clinical features	Treatment
<b>Unconjugated hyperbilirubinaemia</b>				
Gilbert	Typically autosomal recessive, although autosomal dominant forms are also described	↓Glucuronyl transferase ↓Bilirubin uptake	Mild jaundice, especially with fasting	None necessary
Crigler–Najjar: Type I	Autosomal recessive	Absent glucuronyl transferase	Rapid death in neonate (kernicterus)	
Type II	Autosomal recessive	↓↓Glucuronyl transferase	Presents in neonate	Phenobarbital, phototherapy or liver transplant
<b>Conjugated hyperbilirubinaemia</b>				
Dubin–Johnson	Autosomal recessive	↓Canalicular excretion of organic anions, including bilirubin  Pigmentation of liver biopsy tissue	Mild jaundice	None necessary
Rotor	Autosomal recessive	↓Bilirubin uptake  ↓Intrahepatic binding	Mild jaundice	None necessary

24.13 Clinical features and complications of cholestatic jaundice	
<b>Cholestasis</b>	
<b>Early features</b>	
<ul style="list-style-type: none"> <li>• Jaundice</li> <li>• Dark urine</li> </ul>	<ul style="list-style-type: none"> <li>• Pale stools</li> <li>• Pruritus</li> </ul>
<b>Late features</b>	
<ul style="list-style-type: none"> <li>• Malabsorption (vitamins A, D, E and K): weight loss, steatorrhea, osteomalacia, bleeding tendency</li> </ul>	<ul style="list-style-type: none"> <li>• Xanthelasma and xanthomas</li> </ul>
<b>Cholangitis</b>	
<ul style="list-style-type: none"> <li>• Fever</li> <li>• Rigors</li> </ul>	<ul style="list-style-type: none"> <li>• Pain (if gallstones present)</li> </ul>

extrahepatic bile ducts, which are often amenable to surgical or endoscopic correction.

Clinical features (Box 24.13) comprise those due to cholestasis itself, those due to secondary infection (cholangitis) and those of the underlying condition (Box 24.14). Post-hepatic jaundice is characteristically associated with pale stools, dark urine and itch, although these features also occur with intrahepatic cholestasis. If the gallbladder is palpable, the jaundice is unlikely to be caused by biliary obstruction due to gallstones, probably because a chronically inflamed, stone-containing gallbladder cannot readily dilate. This is Courvoisier's Law, and suggests that jaundice is due to a malignant biliary obstruction (e.g. pancreatic cancer). Cholangitis is characterised by 'Charcot's triad' of jaundice, right upper quadrant pain and fever.

Cholestatic jaundice is characterised by a relatively greater elevation of ALP and GGT than ALT, although a high ALT is often seen with ductal gallstones presumably due to a cholangitic element. Ultrasound is usually the first-line imaging to determine whether there is dilatation of the biliary tree (Fig. 24.14). MRCP provides a more detailed assessment of the biliary tree, especially where ductal stones are suspected, whereas CT is preferred for assessing malignant lesions. EUS provides an additional modality for investigation of lower common bile duct obstruction.

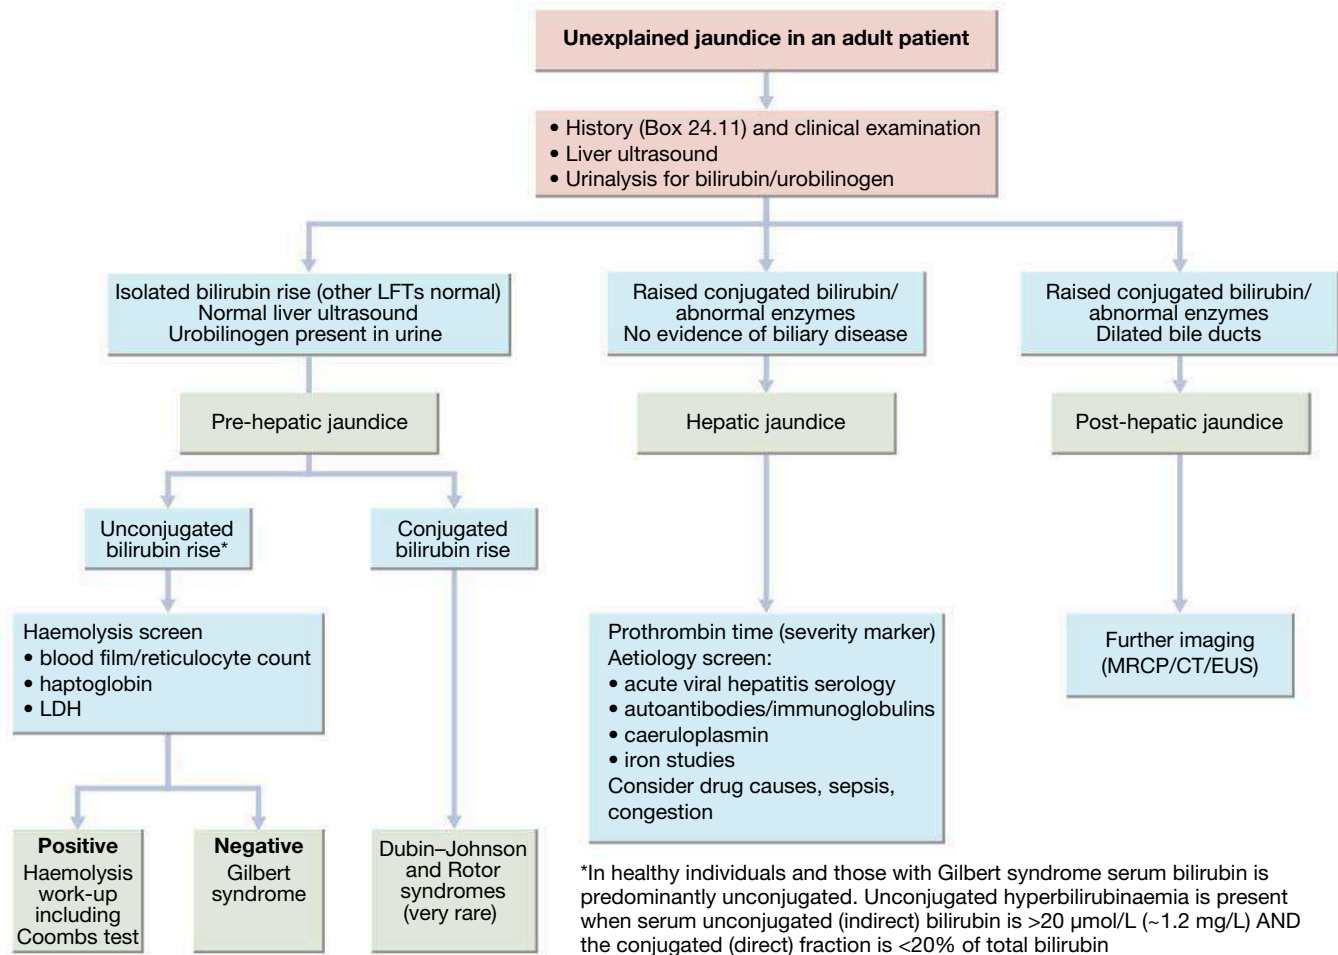

Management of post-hepatic jaundice depends on the underlying cause and is discussed in the relevant sections below.

24.14 Clinical features suggesting an underlying cause of cholestatic jaundice*	
Clinical feature	Causes
<b>Jaundice</b>	
Static or increasing	Carcinoma Primary biliary cholangitis Primary sclerosing cholangitis
Fluctuating	Choledocholithiasis Stricture Pancreatitis Choledochal cyst Primary sclerosing cholangitis
<b>Abdominal pain</b>	Choledocholithiasis Pancreatitis Choledochal cyst
<b>Cholangitis</b>	Choledocholithiasis Stricture Choledochal cyst
<b>Abdominal scar</b>	Stone Stricture
<b>Irregular hepatomegaly</b>	Hepatic carcinoma
<b>Palpable gallbladder</b>	Carcinoma below cystic duct (usually pancreas)
<b>Abdominal mass</b>	Carcinoma Pancreatitis (cyst) Choledochal cyst
<b>Occult blood in stools</b>	Ampullary tumour
*Each of these diseases can give rise to almost any of the clinical features shown but the box indicates the most likely cause of the clinical features listed.	

## Acute liver failure

Acute liver failure is a rare but life-threatening condition characterised by a rapid progressive deterioration in liver function. A variety of insults can lead to marked elevation of transaminases, or acute liver injury. This is considered severe if it results in jaundice and coagulopathy. A small number of such patients will go on to develop encephalopathy, which is the cardinal feature of acute liver failure. The absence of evidence of

**Fig. 24.14 Investigation of jaundice.** (CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; LDH = lactate dehydrogenase; LFTs = liver function tests; MRCP = magnetic resonance cholangiopancreatography)

pre-existing liver disease distinguishes it from encephalopathy due to decompensated cirrhosis or acute-on-chronic liver failure. It is critical, therefore, to understand whether liver failure is a truly acute event or an acute deterioration on a background of pre-existing injury (which may itself not have been diagnosed). Although liver biopsy may ultimately be necessary, it is the presence or absence of the clinical features suggesting chronicity that guides the clinician.

Acute liver failure may be subclassified into hyperacute, acute and subacute, according to the interval between onset of jaundice and encephalopathy (Box 24.15). This can help to identify likely cause and predict prognosis. Patients with subacute liver failure are more likely to be drug-induced or of indeterminate cause, and have a worse outcome with medical care alone than those with a hyperacute course.

### Pathophysiology

Any cause of hepatocyte damage can produce acute liver failure, provided it is sufficiently severe (Fig. 24.15). Acute viral hepatitis is the most common cause worldwide, whereas paracetamol toxicity is the most frequent cause in the UK. Acute liver failure occurs occasionally with other drugs (prescription, recreational or herbal), or from *Amanita phalloides* (mushroom) poisoning, in autoimmune hepatitis, in acute fatty liver of pregnancy, in Wilson's disease, following shock and, rarely, in extensive malignant disease of the liver. In 10% of cases, the cause of acute liver failure remains unknown and these patients are often labelled as having 'non-A-E viral hepatitis' or 'cryptogenic' acute liver failure.

### Clinical assessment

Cerebral disturbance (hepatic encephalopathy and/or cerebral oedema) is the cardinal manifestation of acute liver failure. The initial clinical features

i 24.15 Classification of acute liver failure			
Type	Time: jaundice to encephalopathy	Cerebral oedema	Common causes
Hyperacute	< 7 days	Common	Viral, paracetamol
Acute	8–28 days	Common	Cryptogenic, drugs
Subacute	29 days to 12 weeks	Uncommon	Cryptogenic, drugs, autoimmune hepatitis

are often subtle and include reduced alertness and poor concentration, progressing through behavioural abnormalities, such as restlessness and aggressive outbursts, to drowsiness and coma (Box 24.16). Cerebral oedema may occur due to increased intracranial pressure, causing unequal or abnormally reacting pupils, fixed pupils, hypertensive episodes, bradycardia, hyperventilation, profuse sweating, local or general myoclonus, focal fits or decerebrate posturing. Papilloedema occurs rarely and is a late sign.

More general symptoms include weakness, nausea and vomiting. The patient may be jaundiced but jaundice may not be present at the outset (e.g. in paracetamol overdose), and there are a number of exceptions, including Reye syndrome, in which jaundice is rare. Occasionally, death may occur in hyperacute liver failure before jaundice develops. Fetor hepaticus can be present. The liver is usually of normal size but later

**Fig. 24.15** Causes of acute liver failure in the UK. The relative frequency of the different causes varies according to geographical area.

24.16 How to assess clinical grade of hepatic encephalopathy	
Clinical grade	Clinical signs
Grade 1	Poor concentration, slurred speech, slow mentation, disordered sleep rhythm
Grade 2	Drowsy but easily rousable, occasional aggressive behaviour, lethargic
Grade 3	Marked delirium, drowsy, sleepy but responds to pain and voice, gross disorientation
Grade 4	Unresponsive to voice, may or may not respond to painful stimuli, unconscious

becomes smaller. Hepatomegaly is unusual and, in the presence of a sudden onset of ascites, suggests venous outflow obstruction as the cause (Budd–Chiari syndrome, p. 909). Splenomegaly is uncommon and never prominent. Ascites and oedema are late developments and may be a consequence of fluid therapy.

### Investigations

The patient should be investigated to determine the cause of the liver failure and the prognosis (Boxes 24.17 and 24.18). Hepatitis B core IgM antibody is the best screening test for acute hepatitis B infection, as liver damage is due to the immunological response to the virus, which has often been eliminated, and the test for hepatitis B surface antigen (HBsAg) may be negative by the time liver failure develops. The PT rapidly becomes prolonged as coagulation factor synthesis fails; this is the laboratory test of greatest prognostic value and should be carried out at least twice daily. Vitamin K should be given to ensure that the PT is not prolonged as a result of underlying vitamin K deficiency, but fresh frozen plasma should be avoided except in major bleeding as it will interfere with the use of PT for monitoring. Factor V levels can be used instead of the PT to assess the degree of liver impairment. Plasma bilirubin also predicts outcome in non-paracetamol causes of acute liver failure. Plasma aminotransferase activity is particularly high after paracetamol overdose, reaching 100–500 times normal, but falls as liver damage progresses and is not helpful in determining prognosis. Plasma albumin remains normal unless the course is prolonged. Percutaneous liver biopsy is contraindicated because of the severe coagulopathy, but biopsy can be undertaken using the transjugular route if appropriate.

24.17 Investigations to determine the cause of acute liver failure	
<ul style="list-style-type: none"> <li>Toxicology screen of blood and urine</li> <li>HBsAg, IgM anti-HBc</li> <li>IgM anti-HAV</li> <li>Anti-HEV, HCV, cytomegalovirus, herpes simplex, Epstein–Barr virus</li> <li>Caeruloplasmin, serum copper, urinary copper, slit-lamp eye examination</li> <li>Autoantibodies: ANA, ASMA, LKM, SLA</li> <li>Immunoglobulins</li> <li>Ultrasound of liver and Doppler of hepatic veins</li> </ul>	<p>(ANA = antinuclear antibody; anti-HBc = antibody to hepatitis B core antigen; ASMA = anti-smooth muscle antibody; HAV = hepatitis A virus; HBsAg = hepatitis B surface antigen; HCV = hepatitis C virus; HEV = hepatitis E virus; IgM = immunoglobulin M; LKM = liver–kidney microsomal antibody; SLA = soluble liver antigen)</p>

<p><sup>1</sup>Predict a mortality rate of ≥ 90% and are an indication for possible liver transplantation. <sup>2</sup>In the absence of encephalopathy INR &gt; 2 after vitamin K repletion is mandatory. (INR = International Normalised Ratio)</p>	

## Management

Patients with acute liver failure should be treated in a high-dependency or intensive care unit as soon as progressive prolongation of the PT occurs or hepatic encephalopathy is identified (Box 24.19), so that prompt treatment of complications can be initiated (Box 24.20). Conservative treatment aims to support other organ systems in the hope that hepatic regeneration will occur. *N*-acetylcysteine therapy should be given early to all patients in whom paracetamol toxicity is suspected, although the benefits are less clear in non-paracetamol-induced acute liver failure. Liver transplantation is an increasingly important treatment option for acute liver failure, and criteria have been developed to identify patients unlikely to survive without a transplant (see Box 24.18). Patients should, wherever possible, be transferred to a transplant centre before these criteria are met to allow time for assessment and to maximise the time for a donor liver to become available. Survival following liver transplantation for acute liver failure is improving and 1-year survival rates of 80%–90% can be expected. A number of artificial liver support systems have been developed and evaluated for use as a bridge to either transplantation or recovery. None, however, has entered routine clinical use.

## Hepatomegaly

Hepatomegaly may occur as the result of a general enlargement of the liver or because of primary or secondary liver tumour (Box 24.21). The most common liver tumours in Western countries are liver metastases, whereas primary liver cancer complicating chronic viral hepatitis is more

common in the Far East. Unlike carcinoma metastases, those from neuro-endocrine tumours typically cause massive hepatomegaly but without significant weight loss. Cirrhosis can be associated with either hepatomegaly or reduced liver size in advanced disease.

## Ascites

Ascites is present when there is accumulation of free fluid in the peritoneal cavity. Small amounts of ascites are asymptomatic, but with larger accumulations of fluid (> 1 L) there is abdominal distension, fullness in the flanks, shifting dullness on percussion and, when the ascites is marked, a fluid thrill/fluid wave. Other features include eversion of the umbilicus, herniae, abdominal striae, divarication of the recti and scrotal oedema. Dilated superficial abdominal veins may be seen if the ascites is due to portal hypertension.

## Pathophysiology

The most common causes of ascites are cirrhosis, intra-abdominal malignancy and heart failure. Many primary disorders of the peritoneum and visceral organs can also cause ascites, and these need to be considered even in a patient with chronic liver disease (Box 24.22). Splanchnic arterial vasodilatation is thought to be the main factor leading to ascites in cirrhosis. This is mediated by vasodilators (mainly nitric oxide) that are released when portal hypertension causes shunting of blood into the systemic circulation. Systemic arterial pressure falls due to pronounced splanchnic

### 24.19 Monitoring in acute liver failure

#### Cardiorespiratory

- Pulse
- Blood pressure
- Central venous pressure
- Respiratory rate

#### Neurological

- Signs of intracranial hypertension including pupillary responses. Invasive intracranial pressure monitor is now less commonly used
- Conscious level

#### Fluid balance

- Hourly output (urine, vomiting, diarrhoea)
- Input: oral, intravenous

#### Blood analyses

- Arterial blood gases
- Peripheral blood count (including platelets)
- Sodium, potassium, HCO<sub>3</sub><sup>-</sup>, calcium, magnesium
- Creatinine, urea
- Glucose (2-hourly in acute phase)
- Prothrombin time

#### Infection surveillance

- Cultures: blood, urine, throat, sputum, cannula sites
- Chest X-ray
- Temperature

### 24.20 Complications of acute liver failure

- Encephalopathy and cerebral oedema
- Hypoglycaemia
- Metabolic acidosis
- Infection (bacterial, fungal)
- Renal failure
- Multi-organ failure (hypotension and respiratory failure)

### 24.21 Causes of change in liver size

#### Large liver (hepatomegaly)

- Liver metastases
- Cirrhosis (early): non-alcoholic fatty liver disease, alcohol, haemochromatosis
- Right heart failure
- Multiple or large hepatic cysts
- Hepatic vein outflow obstruction
- Infiltration: amyloid

#### Small liver

- Cirrhosis (late)

### 24.22 Causes of ascites

#### Low SAAG

#### Common causes

Malignant disease:  
Hepatic  
Peritoneal

#### Other causes

Acute pancreatitis  
Lymphatic obstruction  
Infection:  
Tuberculosis  
Nephrotic syndrome  
Protein-losing enteropathy  
Severe malnutrition

#### Rare causes

Hypothyroidism  
Meigs syndrome<sup>2</sup>

#### High SAAG

Cirrhosis  
Cardiac failure

Hepatic venous occlusion:  
Budd–Chiari syndrome<sup>1</sup>  
Sinusoidal obstruction syndrome  
(Veno-occlusive disease)

Constrictive pericarditis

<sup>1</sup>Early Budd–Chiari syndrome presents with ascites with high protein content (> 25 g/L) and elevated SAAG. In chronic Budd–Chiari syndrome the protein concentration may fall but SAAG remains elevated. <sup>2</sup>Meigs syndrome is the association of a right pleural effusion with or without ascites and a benign ovarian tumour. The ascites resolves on removal of the tumour. Although usually reported as being associated with a low SAAG, it can also be seen with a high SAAG. (SAAG = serum–ascites albumin gradient; see text)

vasodilatation as cirrhosis advances. This leads to activation of the renin–angiotensin system with secondary aldosteronism, increased sympathetic nervous activity, increased atrial natriuretic hormone secretion and altered activity of the kallikrein–kinin system (Fig. 24.16). These systems tend to normalise arterial pressure initially but produce salt and water retention. In this setting, the combination of splanchnic arterial vasodilatation and portal hypertension alters intestinal capillary permeability, promoting accumulation of fluid within the peritoneum.

### Investigations

Ultrasonography is the best means of detecting ascites, particularly in the obese and those with small volumes of fluid. Paracentesis (if necessary under ultrasonic guidance) can be used to obtain ascitic fluid for analysis. The

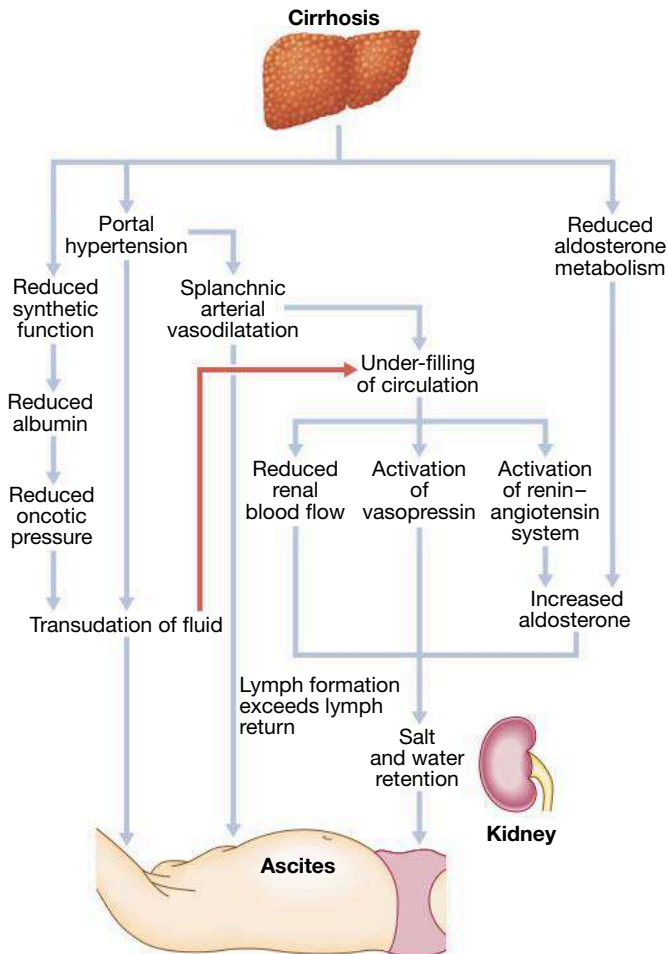

Fig. 24.16 Pathogenesis of ascites.

i	24.23 Ascitic fluid: appearance and analysis
<b>Cause/appearance</b>	
<ul style="list-style-type: none"> <li>• Cirrhosis: clear, straw-coloured or light green</li> <li>• Malignant disease: bloody</li> <li>• Infection: cloudy</li> <li>• Biliary communication: heavy bile staining</li> <li>• Lymphatic obstruction: milky-white (chylous)</li> </ul>	
<b>Useful investigations</b>	
<ul style="list-style-type: none"> <li>• Total albumin (plus serum albumin) and protein*</li> <li>• Amylase</li> <li>• Neutrophil count</li> <li>• Cytology</li> <li>• Microscopy and culture</li> </ul>	
*To calculate the serum–ascites albumin gradient (SAAG).	

appearance of ascitic fluid may point to the underlying cause (Box 24.23). Pleural effusions are found in about 10% of patients, usually on the right side (hepatic hydrothorax); most are small and identified only on chest X-ray, but occasionally a massive hydrothorax occurs. Pleural effusions, particularly those on the left side, should not be assumed to be due to the ascites.

Measurement of the protein concentration and the serum–ascites albumin gradient (SAAG) can be a useful tool to distinguish ascites of different aetiologies. Cirrhotic patients typically develop ascites with a low protein concentration ('transudate'; protein concentration <25 g/L (2.5 g/dL)) and relatively few cells. In up to 30% of patients, however, the total protein concentration is >30 g/L (3.0 g/dL). In these cases, it is useful to calculate the SAAG by subtracting the concentration of the ascites fluid albumin from the serum albumin. A gradient of >11 g/L (1.1 g/dL) is 96% predictive that ascites is due to portal hypertension. Venous outflow obstruction due to cardiac failure or hepatic venous outflow obstruction can also cause a SAAG of >11 g/L (1.1 g/dL) but, unlike in cirrhosis, the total protein content is usually >25 g/L (2.5 g/dL). Conversely, conditions including nephrotic syndrome, protein-losing enteropathy and severe malnutrition result in ascites with low protein concentration and a SAAG of <11 g/L (1.1 g/dL) due to diminished serum oncotic pressure.

High protein ascites ('exudate'; protein concentration >25 g/L (2.5 g/dL) or a SAAG of <11 g/L (1.1 g/dL) raises the possibility of infection (especially tuberculosis), malignancy, pancreatic ascites or, rarely, hypothyroidism. Ascitic amylase activity of >1000 U/L identifies pancreatic ascites, whereas low ascites glucose concentrations suggest malignant disease or tuberculosis. Cytological examination may reveal malignant cells but has a low sensitivity unless large volumes are sent. Polymorphonuclear leucocyte counts of >250 × 10<sup>6</sup>/L strongly suggest infection (spontaneous bacterial peritonitis; see below). Laparoscopy can be valuable in detecting peritoneal disease.

The presence of triglyceride at a level >1.1 g/L (110 mg/dL) is diagnostic of chylous ascites and suggests anatomical or functional abnormality of lymphatic drainage from the abdomen. Chylous ascites has a characteristic milky-white appearance.

### Management

Successful treatment relieves discomfort but does not prolong life; if over-vigorous, it can produce serious disorders of fluid/electrolyte balance, and precipitate hepatic encephalopathy (see below). Treatment of transudative ascites is based on restricting sodium intake, promoting urine output with diuretics and, if necessary, removing ascites directly by paracentesis. Exudative ascites due to malignancy is treated with paracentesis but fluid replacement is generally not required. During management of ascites, the patient should be weighed regularly. Diuretics should be titrated to remove no more than 1 L of fluid (or 1 kg body weight) daily to avoid excessive fluid depletion.

#### Sodium restriction

Restriction of dietary sodium intake is essential to achieve negative sodium balance and a few patients can be managed satisfactorily by this alone. Restriction of sodium intake to 100 mmol/24 hrs ('no added salt diet') is usually adequate. Drugs containing relatively large amounts of sodium, and those promoting sodium retention, such as non-steroidal anti-inflammatory drugs (NSAIDs), must be avoided (Box 24.24). Restriction of water intake to 1.0–1.5 L/24 hrs is rarely needed unless the plasma sodium falls below 125 mmol/L.

#### Diuretics

Most patients require diuretics in addition to sodium restriction. Spironolactone (100–400 mg/day) is the first-line drug because it is a powerful aldosterone antagonist; it can, however, cause painful gynaecomastia and hyperkalaemia, in which case amiloride (5–10 mg/day) can be substituted. This is often combined with a loop diuretic, such as furosemide (40–160 mg/day). Patients must be monitored for electrolyte imbalance and renal dysfunction. Diuresis may be improved if patients are rested in bed, perhaps because renal blood flow increases in the horizontal position. Patients who do not respond to maximal doses of

### 24.24 Some drugs containing relatively large amounts of sodium or causing sodium retention

#### High sodium content

- Alginates
- Antacids
- Antibiotics
- Phenytoin
- Effervescent preparations (e.g. aspirin, calcium, paracetamol)
- Sodium valproate

#### Sodium retention

- Carbenoxolone
- Glucocorticoids
- Metoclopramide
- Non-steroidal anti-inflammatory drugs
- Oestrogens

spironolactone and furosemide (diuretic-resistant), or who are unable to tolerate these doses due to hyponatraemia or renal impairment (diuretic-intolerant), are considered to have refractory ascites and should be treated by other measures.

#### Paracentesis

First-line treatment of refractory ascites is large-volume paracentesis. Paracentesis to dryness is safe, provided the circulation is supported with an intravenous colloid such as human albumin (6–8 g per litre of ascites removed, usually as 100 mL of 20% or 25% human albumin solution (HAS) for every 2–3 L of ascites drained). Paracentesis can be used as an initial therapy or when other treatments fail. Drains should be removed after 6–12 hours to reduce risk of infection.

#### Transjugular intrahepatic portosystemic stent shunt

A transjugular intrahepatic portosystemic stent shunt (TIPSS; p. 883) can relieve resistant ascites but does not prolong life; it may be an option where the only alternative is frequent, large-volume paracentesis. TIPSS can be used in patients awaiting liver transplantation or in those with reasonable liver function, but can aggravate encephalopathy in those with poor function.

### Complications

#### Renal failure

Renal dysfunction is commonly seen in patients with liver cirrhosis, related to pre-renal, intrinsic and post-renal causes. It is most frequently related to dehydration, diuretic therapy and/or sepsis. However, patients with cirrhosis and ascites may develop a distinct type of renal dysfunction termed hepatorenal syndrome (HRS).

#### Hepatorenal syndrome

HRS is renal dysfunction that occurs due to reduced renal perfusion, resulting from both haemodynamic alterations in the arterial circulation (splanchnic vasodilatation/renal vasoconstriction) and overactivity of endogenous vasoactive systems. HRS has traditionally been classified into two subtypes but the terminology has recently changed to reflect changes in the understanding and definition of both acute kidney injury (AKI) and chronic kidney disease (CKD).

Type-1 HRS (now termed HRS-AKI) involves a rapid reduction in renal function (AKI) that is usually precipitated by an acute event, including bacterial infection, GI haemorrhage, alcoholic hepatitis or acute liver failure, which disturbs the abnormal renal haemodynamics and has a poor prognosis.

Traditionally HRS was diagnosed with a serum creatinine cutoff of  $>1.5$  g/dL ( $>133$   $\mu$ mol/L) but this has been modified to use a change in renal function from baseline and removing the cutoff threshold. This was necessary to avoid delay in diagnosis and initiation of treatment for HRS. The diagnostic criteria from HRS AKI are shown in [Box 24.25](#).

Type II HRS (now termed HRS non-acute kidney injury or HRS-NAKI) is a stable or slowly progressive form of renal dysfunction developing over weeks to months, in the absence of an obvious precipitant. It is characterised clinically by diuretic-resistant ascites.

### 24.25 Diagnostic criteria for HRS-AKI

- Diagnosis of cirrhosis, acute liver failure, acute on chronic liver failure
- Increase in serum creatinine  $\geq 26.5$   $\mu$ mol/L ( $\geq 0.3$  mg/dl) within 48 hours or  $\geq 50\%$  from baseline according to IAC-AKI criteria and/or
- Urinary output  $\leq 0.5$  ml/kg per hr for  $\geq 6$  hrs
- No response after 2 consecutive days of diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 g/kg body weight to a maximum of 100 g
- Absence of shock
- No current or recent treatment with nephrotoxic drugs
- Absence of parenchymal kidney disease, as defined as
  - 1 Absence of proteinuria ( $>500$  mg/day)
  - 2 Absence of microhaematuria ( $>50$  RBC per high power field)
  - 3 Normal findings on renal ultrasound

(AKI = acute kidney injury; HRS = hepatorenal syndrome; IAC = International Ascites Club; RBC = red blood cells)

Management of HRS-AKI involves identifying and treating precipitating factors. Diuretics and beta-blockers should be discontinued. Nephrotoxic drugs including vasodilators and non-steroidal anti-inflammatories should be stopped. Infections should be sought and treated. Volume replacement should be used to treat fluid loss/deficits. Intravenous albumin infusions in combination with terlipressin (1–2 mg every 4–6 hours) have been shown to improve short-term survival. In countries where terlipressin is not available, a combination of midodrine, octreotide and albumin may be used. TIPSS may be effective for treatment of HRS in highly selected patients. Haemodialysis may be considered in patients who fail to respond to treatment as either a bridge to transplant (in suitable patients) or as a bridge to recovery in patients with a reversible liver injury (typically acute liver failure).

#### Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP) is the most common bacterial infection in patients with cirrhosis, and results from translocation of bacteria from the intestine into ascites. It may present with abdominal pain or fever in a patient with obvious features of cirrhosis and ascites. However, abdominal signs are mild or absent in about one-third of patients, and it may present with hepatic encephalopathy or a non-specific deterioration. SBP is associated with a high rate of acute kidney injury and mortality, and prompt recognition is critical. Diagnostic paracentesis may show cloudy fluid, and an ascites neutrophil count of  $>250 \times 10^6$ /L almost invariably indicates infection. Most organisms isolated are of enteric origin and *Escherichia coli* is the most frequently found. Ascitic culture in blood culture bottles gives the highest yield of organisms. SBP needs to be differentiated from other intra-abdominal emergencies, and the finding of multiple organisms on culture should arouse suspicion of a perforated viscus.

Treatment should be started immediately with broad-spectrum antibiotics, such as cefotaxime or piperacillin/tazobactam). Patients with jaundice or renal impairment also benefit from intravenous albumin (1.5 g/kg on day 1 and 1.0 g/kg on day 3). Recurrence of SBP is common, but is reduced by prophylactic antibiotics such as norfloxacin (400 mg/day), ciprofloxacin (750 mg/week) or cotrimoxazole (960 mg/day). Primary antibiotic prophylaxis also reduces the incidence of SBP in patients with low ascitic protein  $<15$  g/L.

#### Prognosis

Only 10%–20% of patients survive for 5 years from the first appearance of ascites due to cirrhosis. The outlook is not universally poor, however, and is best in those with well-maintained liver function and a good response to therapy. The prognosis is also better when a treatable cause for the underlying cirrhosis is present or when a precipitating cause for ascites, such as excess salt intake, is found. The mortality at 1 year is 50% following the first episode of bacterial peritonitis.

## Hepatic encephalopathy

Hepatic encephalopathy is a neuropsychiatric syndrome caused by liver disease that occurs in 30%–40% of patients with cirrhosis. It causes a spectrum of symptoms ranging from mild fluctuating cognitive impairment to coma. The degree of encephalopathy can be graded from 1 to 4, and this is useful in assessing progression or response to therapy (see [Box 24.10](#)). The earliest features are very mild and easily overlooked, but as the condition becomes more severe, inability to concentrate, delirium, disorientation, drowsiness, slurring of speech and eventually coma develop. Seizures are rare. Examination usually shows a flapping tremor (asterixis), inability to perform simple mental arithmetic tasks or to draw objects such as a star (constructional apraxia, p. 861) and, as the condition progresses, hyper-reflexia and bilateral extensor plantar responses. Hepatic encephalopathy rarely causes focal neurological signs; if these are present, other causes must be sought. Fetor hepaticus, a sweet musty odour to the breath, is usually present but is more a sign of liver failure and portosystemic shunting than of hepatic encephalopathy. Rarely, chronic hepatic encephalopathy (hepatocerebral degeneration) gives rise to variable combinations of cerebellar dysfunction, Parkinsonian syndromes, spastic paraplegia and dementia.

Many conditions can cause similar presentations to encephalopathy. Simple delirium needs to be differentiated from infection, alcohol withdrawal and Wernicke's encephalopathy, and coma from subdural haematoma, which can occur after a fall, especially in alcohol misuse ([Box 24.26](#)). When an episode develops acutely, a precipitating factor may be found ([Box 24.27](#)).

### Pathophysiology

Hepatic encephalopathy is thought to be due to a disturbance of brain function provoked by circulating gut-derived neurotoxins that are normally metabolised by the liver and excluded from the systemic circulation. Affected patients usually have evidence of both liver failure and portosystemic shunting of blood, but the balance between these varies between individuals. Some degree of liver failure is a key factor, as portosystemic shunting of blood alone hardly ever causes encephalopathy. The 'neurotoxins' causing encephalopathy are unknown but are thought to be mainly nitrogenous substances produced in the gut, at least in part by bacterial action. Ammonia has traditionally been considered an important factor, but the correlation between serum ammonia levels and encephalopathy is poor. Recent interest has focused on  $\gamma$ -aminobutyric acid (GABA) as a mediator, along with octopamine, amino acids, mercaptans and fatty acids that can act as neurotransmitters. The brain in cirrhosis may also be sensitised to other factors, such as drugs that can precipitate hepatic encephalopathy (see [Box 24.27](#)). Disruption of the function of the blood–brain barrier is a feature of acute hepatic failure and may lead to cerebral oedema.

### 24.26 Differential diagnosis of hepatic encephalopathy

- Intracranial bleed (subdural/extradural haematoma)
- Drug or alcohol intoxication
- Delirium tremens/alcohol withdrawal
- Wernicke's encephalopathy
- Primary psychiatric disorders
- Hypoglycaemia
- Neurological Wilson's disease
- Post-ictal state

### 24.27 Factors precipitating hepatic encephalopathy

- Drugs (especially sedatives, antidepressants)
- Dehydration (including diuretics, paracentesis)
- Portosystemic shunting
- Infection
- Hypokalaemia
- Hyponatraemia
- Constipation
- ↑Protein load (including gastrointestinal bleeding)

### Investigations

The diagnosis can usually be made clinically; when doubt exists, an electroencephalogram shows diffuse slowing of the normal alpha waves with eventual development of delta waves. The arterial ammonia is usually increased in patients with hepatic encephalopathy. Increased concentrations can, however, occur in the absence of clinical encephalopathy, rendering this investigation of little diagnostic value.

### Management

The principles are to treat or remove precipitating causes ([Box 24.27](#)) and to suppress the production of neurotoxins by bacteria in the bowel. Lactulose (15–30 mL 3 times daily) is increased gradually until the bowels are moving twice daily. It produces an osmotic laxative effect, reduces the pH of the colonic content, thereby limiting colonic ammonia absorption, and promotes the incorporation of nitrogen into bacteria. Phosphate enemas may be required in patients where the oral route is compromised or in patients with refractory constipation. Rifaximin (550 mg twice daily) is a well-tolerated, non-absorbed antibiotic that acts by reducing the bacterial content of the bowel and is effective in reducing episodes of recurrent hepatic encephalopathy. There is some evidence to support the amino acid combination l-ornithine l-arginine (LOLA) in lowering ammonia levels and improving encephalopathy. In cases of reduced conscious level, endotracheal intubation may be required for airway protection. Dietary protein restriction is no longer recommended because it can

**Fig. 24.17** Varices: endoscopic views. **A** Oesophageal varices (arrows) at the lower end of the oesophagus with a prominent white fibrin plug at the site of recent haemorrhage. **B** Gastric varices (arrows). **C** Appearance of oesophageal varices following application of strangulating bands (band ligation, arrows).

lead to a worsening nutritional state in already malnourished patients. Chronic or refractory encephalopathy is one of the main indications for liver transplantation.

## Variceal bleeding

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices (Fig. 24.17) is common in chronic liver disease. Investigation and management are discussed on page 797 and the specific management of variceal bleeding on page 882.

## Cirrhosis

Cirrhosis is characterised by diffuse hepatic fibrosis and nodule formation. It can occur at any age, has significant morbidity and is an important cause of premature death. It is the most common cause of portal hypertension. Worldwide, the most common causes are chronic viral hepatitis, prolonged excessive alcohol consumption and NAFLD, but any condition leading to persistent or recurrent hepatocyte injury may lead to cirrhosis. The causes of cirrhosis are listed in Box 24.28.

Cirrhosis may also occur in prolonged biliary injury, as is found in primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC) and post-surgical biliary strictures. Persistent impairment of venous return from the liver, such as is found in sinusoidal obstruction syndrome (SOS; veno-occlusive disease), Budd–Chiari syndrome and cardiac hepatopathy, can also result in cirrhosis.

### Pathophysiology

Following liver injury, stellate cells in the space of Disse (see Fig. 24.3) are activated by cytokines produced by Kupffer cells and hepatocytes. This transforms the stellate cell into a myofibroblast-like cell, capable of producing collagen, pro-inflammatory cytokines and other mediators that promote hepatocyte damage and tissue fibrosis (see Fig. 24.4).

Cirrhosis is technically a histological diagnosis (Fig. 24.18), although most cases will be diagnosed on a combination of imaging, clinical signs and fibrosis markers. Fibrosis evolves over years, and the progression can be described semi-quantitatively (Fig. 24.19). Fibrosis and widespread hepatocyte loss lead to distortion of the normal liver architecture that disrupts the hepatic vasculature, causing portosystemic shunts. These changes usually affect the whole liver, but in biliary cirrhosis (e.g. PBC) they can be patchy.

### Clinical features

The clinical presentation is highly variable. Some patients are asymptomatic and the diagnosis is made incidentally at ultrasound or at surgery. Others present with isolated hepatomegaly, splenomegaly, signs of portal hypertension or hepatic insufficiency. When symptoms are present, they are often non-specific and include weakness, fatigue, muscle cramps, weight loss, anorexia, nausea and upper abdominal discomfort (Box 24.29). Cirrhosis will occasionally present because of shortness of breath due to a large right pleural effusion, or with hepatopulmonary syndrome (p. 909).

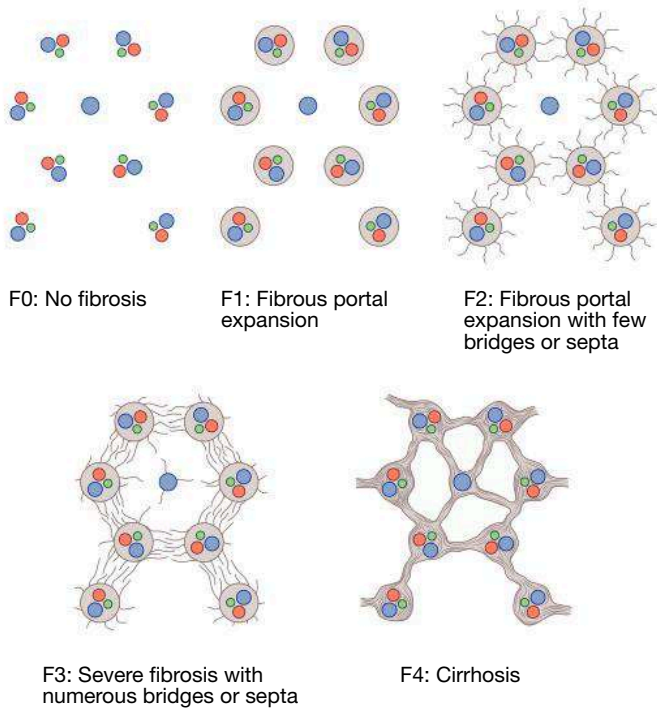

**Fig. 24.18** Histological features in normal liver, hepatic fibrosis and cirrhosis. **A** Normal liver. Columns of hepatocytes 1–2 cells thick radiate from the portal tracts (PT) to the central veins. The portal tract contains a normal intralobular bile duct branch of the hepatic artery and portal venous radical. **B** Bridging fibrosis (stained pink, arrows) spreading out around the hepatic vein and single liver cells (pericellular) and linking adjacent portal tracts and hepatic veins. **C** A cirrhotic liver. The liver architecture is disrupted. The normal arrangement of portal tracts and hepatic veins is now lost and nodules of proliferating hepatocytes are broken up by strands of pink/orange-staining fibrous tissue (arrows) forming cirrhotic nodules (CN).

## i

### 24.28 Causes of cirrhosis

- Alcohol
- Chronic viral hepatitis (B or C)
- Non-alcoholic fatty liver disease
- Immune:
  - Primary sclerosing cholangitis
  - Autoimmune liver disease
- Biliary:
  - Primary biliary cholangitis
  - Secondary biliary cirrhosis
  - Cystic fibrosis
- Genetic:
  - Haemochromatosis
  - Wilson's disease
  - Alpha-1-antitrypsin deficiency
- Cryptogenic (unknown – 15%)
- Chronic venous outflow obstruction
- Cardiac hepatopathy with chronic hepatic congestion
- Any chronic liver disease

Hepatomegaly is common when the cirrhosis is due to alcoholic liver disease or haemochromatosis. Progressive hepatocyte destruction and fibrosis gradually reduce liver size as the disease progresses in other causes of cirrhosis. The liver is often hard, irregular and non-tender. Jaundice is mild when it first appears and is due primarily to a failure to excrete bilirubin. Palmar erythema (redness over the thenar and hypothenar eminences) can be seen early in the disease but is of limited diagnostic value, as it occurs in many other conditions associated with a hyper-dynamic circulation, including pregnancy, as well as being found in some healthy people. Spider telangiectasias (or spider naevi) occur and comprise a central arteriole (that occasionally raises the skin surface), from which small vessels radiate. They blanch with pressure and refill from the centre outwards, are usually found on the hands, face and upper chest. One or two small spider telangiectasias may be present in up to 15% of young healthy adults and may occur transiently in greater numbers in the third trimester of pregnancy, but otherwise multiple spider telangiectasias are a strong

**Fig. 24.19** Progressive liver fibrosis assessed semi-quantitatively using Metavir scoring system.

**i** **24.29 Clinical features of hepatic cirrhosis**

- Hepatomegaly (although liver may also be small)
- Jaundice
- Ascites
- Circulatory changes: spider telangiectasia, palmar erythema
- Endocrine changes: loss of libido, hair loss
  - Men: gynaecomastia, testicular atrophy, impotence
  - Women: breast atrophy, irregular menses, amenorrhoea
- Haemorrhagic tendency: bruises, purpura, epistaxis
- Portal hypertension: splenomegaly, collateral vessels, variceal bleeding
- Hepatic encephalopathy
- Other features: pigmentation (haemochromatosis), Dupuytren's contracture (alcohol excess)

indicator of liver disease. Florid spider telangiectasia and gynaecomastia are most common in alcohol-related cirrhosis, possibly related to phyto-oestrogens in alcoholic drinks. Pigmentation is most striking in haemochromatosis and in any cirrhosis associated with prolonged cholestasis. Clubbing of the fingers and toes is not a sign of cirrhosis but is seen in combination with hypoxia in hepatopulmonary syndrome.

Endocrine changes are noticed more readily in men, who show loss of male hair distribution and testicular atrophy. Gynaecomastia is common and can be due to drugs such as spironolactone. Easy bruising becomes more frequent as cirrhosis advances.

Splenomegaly and collateral vessel formation are features of portal hypertension, which occurs in more advanced disease (see below).

Jaundice, ascites, encephalopathy and variceal bleeding signify advanced disease, and are associated with a worse prognosis. The term 'hepatic decompensation' or 'decompensated liver disease' is often used when any of these are present.

Other clinical and laboratory features may be present (Box 24.30); these include peripheral oedema, renal failure, and hypoalbuminaemia and coagulation abnormalities due to defective protein synthesis.

### **i** 24.30 Features of chronic liver failure

- Worsening synthetic liver function:
  - Prolonged prothrombin time
  - Low albumin
- Jaundice
- Variceal bleeding
- Hepatic encephalopathy
- Ascites:
  - Spontaneous bacterial peritonitis
  - Hepatorenal failure

Anaemia is common and often multifactorial, due to a combination of chronic inflammation, bone marrow suppression, haemolysis or chronic blood loss.

#### **Management**

This includes treatment of the underlying cause, maintenance of nutrition and treatment of complications, including ascites, hepatic encephalopathy, portal hypertension and varices.

#### **Nutrition in cirrhosis**

Malnutrition is a frequent complication, affecting up to 50% of patients with decompensated cirrhosis. Loss of muscle mass (sarcopenia) is associated with a higher rate of complications including infections, encephalopathy and ascites. Although BMI is the most widely used measure of nutritional status, sarcopenia can coexist with obesity especially in patients with NAFLD. Handgrip strength is a simple and inexpensive way to assess muscle function, and predicts morbidity and mortality in cirrhosis. Daily calorie intake should be no lower than 35 kcal/kg body weight with a daily protein intake of 1.2–1.5 g/kg. A late evening snack will help to minimise overnight fasting which could otherwise trigger a catabolic state in cirrhosis. If patients are unable to achieve adequate oral intake, enteral feeding should be considered.

#### **Screening for complications**

Once the diagnosis of cirrhosis is made, endoscopy should be considered to screen for oesophageal varices. As cirrhosis is associated with an increased risk of hepatocellular carcinoma, patients should be placed under regular surveillance for it. Cirrhosis is associated with an increased risk of osteoporosis and associated fractures, and bone mineral density measurement is recommended.

Chronic liver failure due to cirrhosis can also be treated by liver transplantation. This currently accounts for about three-quarters of all liver transplants.

#### **Prognosis**

Most chronic liver diseases run a gradually progressive course, although many patients present with advanced disease and/or serious complications that carry a high mortality. Prognosis is more favourable when the underlying cause can be corrected. Cirrhosis can be categorised into two prognostic groups: compensated and decompensated. Decompensated cirrhosis is defined by the presence of complications, including ascites, variceal bleeding, jaundice and encephalopathy, which are the main determinants of patient survival. Compensated patients have a relatively good prognosis with median survival >12 years. However, in decompensated cirrhosis median survival is around 2 years, albeit with significant patient-to-patient variability.

Raised bilirubin, low albumin and prolonged PT reflect impaired liver function. Along with renal dysfunction and hyponatraemia, these are all bad prognostic features (Box 24.31 and Fig. 24.20). Prognostic scores including Child–Pugh and MELD (Model for End-stage Liver Disease) scores can be used to assess prognosis in chronic liver disease. MELD is a complex algorithm including serum creatinine, serum bilirubin and INR (Box 24.32). The MELD-Na score incorporates serum sodium into this calculation and provides better prognostic accuracy in predicting mortality in patients awaiting liver transplantation. The UKELD (United Kingdom Model of End-stage Liver Disease) score is based on the

same variables as MELD-Na and is used in the United Kingdom to determine the need for liver transplantation. A score  $\geq 49$  indicates a 9% 1-year risk of death and is the minimum score required for listing for liver transplantation for liver failure. Although these scores give a guide to prognosis, the course of cirrhosis is unpredictable, being heavily influenced by the incidence of sporadic decompensating events (e.g. sepsis, variceal bleeding, etc.).

24.31 Child–Pugh classification of prognosis in cirrhosis			
Score	1	2	3
<b>Encephalopathy</b>	None	Mild	Marked
<b>Bilirubin (<math>\mu\text{mol/L}</math> (<math>\text{mg/dL}</math>))*</b>			
Primary biliary cholangitis/sclerosing cholangitis	< 68 (4)	68–170 (4–10)	> 170 (10)
Other causes of cirrhosis	< 34 (2)	34–50 (2–3)	> 50 (3)
<b>Albumin (<math>\text{g/L}</math> (<math>\text{g/dL}</math>))</b>	> 35 (3.5)	28–35 (2.8–3.5)	< 28 (2.8)
<b>Prothrombin time (secs prolonged)</b>	< 4	4–6	> 6
<b>Ascites</b>	None	Mild	Marked
Add the individual scores: < 7 = Child's A, 7–9 = Child's B, > 9 = Child's C			
*To convert bilirubin in $\mu\text{mol/L}$ to $\text{mg/dL}$ , divide by 17.			

Fig. 24.20 Survival in cirrhosis by Child–Pugh score.

24.32 One-year survival rate depending on MELD score		
MELD score	1-year survival (%)	
	No complications	Complications*
< 9	97	90
10–19	90	85
20–29	70	65
30–39	70	50
<b>MELD from SI units</b>		
$10 \times (0.378 [\ln \text{ serum bilirubin } (\mu\text{mol/L})] + 1.12 [\ln \text{ INR}] + 0.957 [\ln \text{ serum creatinine } (\mu\text{mol/L})] + 0.643)$		
<b>MELD from non-SI units</b>		
$3.8 [\ln \text{ serum bilirubin } (\text{mg/dL})] + 11.2 [\ln \text{ INR}] + 9.3 [\ln \text{ serum creatinine } (\text{mg/dL})] + 6.4$		
ln = natural log. To calculate online, go to <a href="https://optn.transplant.hrsa.gov/resources/allocation-calculators/meld-calculator/">https://optn.transplant.hrsa.gov/resources/allocation-calculators/meld-calculator/</a>		
*Complications* means the presence of ascites, encephalopathy or variceal bleeding. (INR = International Normalised Ratio; MELD = Model for End-stage Liver Disease)		

## Acute on chronic liver failure

Acute on chronic liver failure (ACLF) is a term used to describe acute decompensation of chronic liver disease with features of liver failure (jaundice and coagulopathy) and other extra-hepatic organ failures. It is associated with a high short-term mortality. Common triggering events include alcoholic hepatitis, systemic infection or viral hepatitis. However up to 40% of patients have no identifiable precipitant. Persistent inflammation and immune dysfunction results in a systemic inflammatory response syndrome leading to extra-hepatic organ failure. The number of extra-hepatic organs involved determines prognosis. The 28-day mortality with single organ failure (typically renal failure or hepatic encephalopathy) is 23%, increasing to 32% in patients with two organ failures and >75% in patients with three or more organ failures. Management involves identification and treatment of the precipitating event and organ support as required.

## Portal hypertension

Portal hypertension frequently complicates cirrhosis but has other causes. The normal hepatic venous pressure gradient (HVPG – difference between the wedged hepatic venous pressure (WHVP) and free hepatic venous pressure (FHVP); see below) is 5–6 mmHg. Clinically significant portal hypertension is present when the gradient exceeds 10 mmHg and risk of variceal bleeding increases beyond a gradient of 12 mmHg. Causes are classified in accordance with the main sites of obstruction to blood flow in the portal venous system (Fig. 24.21). Extrahepatic portal vein obstruction is the usual source of portal hypertension in childhood and adolescence, while cirrhosis causes at least 90% of cases of portal hypertension in adults in developed countries. Schistosomiasis is the most common cause of portal hypertension worldwide but is infrequent outside endemic areas, such as Egypt.

### Clinical features

The clinical features result principally from portal venous congestion and collateral vessel formation (Box 24.33). Splenomegaly is a cardinal finding and a diagnosis of portal hypertension is unusual when splenomegaly cannot be detected clinically or by ultrasonography. The spleen is rarely enlarged more than 5 cm below the left costal margin in adults but more marked splenomegaly can occur in childhood and adolescence. Collateral vessels may be visible on the anterior abdominal wall and occasionally several radiate from the umbilicus to form a ‘caput medusae’ (p. 860). Rarely, a large umbilical collateral vessel has a blood flow sufficient to give a venous hum on auscultation (Cruveilhier–Baumgarten syndrome). The most important collateral vessel formation occurs in the oesophagus and stomach, as this can be a source of severe bleeding. Rectal varices also cause bleeding and are often mistaken for haemorrhoids (which are no more common in portal hypertension than in the general population). Feter hepaticus results from portosystemic shunting of blood, which allows mercaptans to pass directly to the lungs.

Ascites occurs as a result of renal sodium retention and portal hypertension that may be due, for example, to post-hepatic causes (hepatic outflow obstruction, p. 875) or cirrhosis.

The most important consequence of portal hypertension is variceal bleeding, which commonly arises from oesophageal varices located within 3–5 cm of the gastro-oesophageal junction, or from gastric varices. The size of the varices, endoscopic variceal features such as red spots and stripes, high portal pressure and liver failure are all factors that predispose to bleeding. Drugs capable of causing mucosal erosion, such as salicylates and NSAIDs, can also precipitate bleeding. Variceal bleeding is often severe, and recurrent if preventative treatment is not given.

**Fig. 24.21** Classification of portal hypertension according to site of vascular obstruction. \*Most common cause. Note that splenic vein occlusion can also follow pancreatitis, leading to gastric varices.

### 24.33 Complications of portal hypertension

- Variceal bleeding: oesophageal, gastric, other (rare)
- Congestive gastropathy
- Hypersplenism
- Ascites
- Iron deficiency anaemia
- Renal failure
- Hepatic encephalopathy

### Pathophysiology

Increased portal vascular resistance leads to a gradual reduction in the flow of portal blood to the liver and simultaneously to the development of collateral vessels, allowing portal blood to bypass the liver and enter the systemic circulation directly. Portosystemic shunting occurs, particularly in the gastrointestinal tract and especially the distal oesophagus, stomach and rectum, in the anterior abdominal wall, and in the renal, lumbar, ovarian and testicular vasculature. Stomal varices can also occur at the site of an ileostomy. As collateral vessel formation progresses, more than half of the portal blood flow may be shunted directly to the systemic circulation. Increased portal flow contributes to portal hypertension but is not the dominant factor.

### Investigations

The diagnosis is often made clinically. Portal venous pressure measurements are rarely needed for clinical assessment or routine management but can be used to confirm portal hypertension and to differentiate sinusoidal and pre-sinusoidal forms. Pressure measurements are made by

using a balloon catheter inserted using the transjugular route (via the inferior vena cava into a hepatic vein and then hepatic venule) to measure the WHVP. This is an indirect measurement of portal vein pressure. Thrombocytopenia is common due to hypersplenism, and platelet counts are usually in the region of  $100 \times 10^9/L$ ; values below  $50 \times 10^9/L$  are uncommon. Leucopenia occurs occasionally but anaemia is seldom attributed directly to hypersplenism.

Endoscopy is the most useful investigation to determine whether gastro-oesophageal varices are present (see Fig. 24.17). When cirrhosis is diagnosed, endoscopy should be performed to screen for oesophageal varices (and repeated every 2–3 years if initially absent). However, this may not be needed in patients with a normal platelet count and low liver stiffness ( $<20\text{kPa}$ ) who are at low risk of significant varices. Ultrasonography often shows features of portal hypertension, such as splenomegaly and collateral vessels, and can sometimes indicate the cause, such as cirrhosis or portal vein thrombosis. CT and magnetic resonance angiography can identify the extent of portal vein clot and check hepatic vein patency.

### Management

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices is a common manifestation of chronic liver disease. In the presence of portal hypertension, the risk of a variceal bleed occurring within 2 years varies from 7% for small varices up to 30% for large varices. The mortality following a variceal bleed has improved to around 15% overall but is still about 45% in those with poor liver function (i.e. Child–Pugh C).

The management of portal hypertension is largely focused on the prevention and/or control of variceal haemorrhage. It is important to remember, though, that bleeding can also result from peptic ulceration, which is more common in patients with liver disease than in the general population. The investigation and management of gastrointestinal bleeding are dealt with in more detail on page 797.

### Primary prevention of variceal bleeding

If non-bleeding varices are identified at endoscopy, non-selective  $\beta$ -adrenoceptor antagonist ( $\beta$ -blocker) therapy with propranolol (80–160 mg/day) or nadolol (40–240 mg/day) is effective in reducing portal venous pressure. Administration of these drugs at doses that reduce the heart rate by 25% has been shown to be effective in the primary prevention of variceal bleeding. In patients with cirrhosis, treatment with propranolol reduces variceal bleeding by 47% (number needed to treat for benefit (NNT<sub>B</sub>) 10), death from bleeding by 45% (NNT<sub>B</sub> 25) and overall mortality by 22% (NNT<sub>B</sub> 16). The efficacy of  $\beta$ -blockers in primary prevention is similar to that of prophylactic banding, which may also be considered, particularly in patients who are unable to tolerate or adhere to  $\beta$ -blocker therapy. Carvedilol, a non-cardioselective vasodilating  $\beta$ -blocker, is also effective and may be better tolerated at doses of 6.25–12.5 mg/day.

### Management of acute variceal bleeding

The priority in acute bleeding is to restore the circulation, not least because shock reduces liver blood flow and causes further deterioration of liver function. However, restrictive transfusion (aiming for a haemoglobin level  $>70\text{g/L}$ ) is associated with better outcomes than liberal transfusion. The source of bleeding should always be confirmed by endoscopy because about 20% of patients are bleeding from non-variceal lesions. Management of acute variceal bleeding is described in Box 24.34 and illustrated in Fig. 24.22. All patients with cirrhosis and gastrointestinal bleeding should receive prophylactic broad-spectrum antibiotics, such as intravenous cephalosporin or piperacillin/tazobactam, because sepsis is common and treatment with antibiotics improves survival. The measures used to control acute variceal bleeding include vasoactive medications (e.g. terlipressin), endoscopic therapy (banding), balloon tamponade and TIPSS.

**Pharmacological reduction of portal venous pressure** Terlipressin is a synthetic vasopressin analogue that, in contrast to vasopressin, can be given by intermittent injection rather than continuous infusion. It reduces

24.34 Emergency management of bleeding	
Management	Reason
Intravenous fluids	To replace extracellular volume
Vasopressor (terlipressin)*	To reduce portal pressure, acute bleeding and risk of early rebleeding
Prophylactic antibiotics (cephalosporin IV)	To reduce incidence of spontaneous bacterial peritonitis
Emergency endoscopy	To confirm variceal rather than ulcer bleed
Variceal band ligation	To stop bleeding
Proton pump inhibitor	To prevent peptic ulcers
Phosphate enema and/or lactulose	To prevent hepatic encephalopathy
*Caution in patients with significant coronary artery, peripheral or other vascular disease.	

portal blood flow and/or intrahepatic resistance and hence brings down portal pressure. It lowers mortality in the setting of acute variceal bleeding. The dose of terlipressin is 2 mg intravenously 4 times daily until bleeding stops, and then 1 mg 4 times daily for up to 72 hours. Caution is needed in patients with severe ischaemic heart disease or peripheral vascular disease because of the drug's vasoconstrictor properties. In countries where terlipressin is not available, octreotide is a frequently used alternative.

**Variceal ligation ('banding')** This is the most widely used initial treatment and is undertaken, if possible, at the time of diagnostic endoscopy (see Fig. 24.17C). It stops variceal bleeding in over 90% of patients and can be repeated if bleeding recurs. Band ligation involves the varices being sucked into a cap placed on the end of the endoscope, allowing them to be occluded with a tight rubber band. The occluded varix subsequently sloughs with variceal obliteration. Banding is repeated every 2–4 weeks until all varices are obliterated. Regular follow-up endoscopy is required to identify and treat any recurrence of varices. Band ligation has fewer side-effects than sclerotherapy, a technique in which varices were injected with a sclerosing agent, and has largely replaced it. Prophylactic acid suppression with proton pump inhibitors may reduce the risk of secondary bleeding from banding-induced ulceration.

In the case of gastric varices, banding is less effective and so endoscopic therapy relies on injection of agents such as thrombin or cyanoacrylate glue directly into the varix to induce thrombosis. Although highly effective, cyanoacrylate injection treatment may be complicated by 'glue embolism' to the lungs.

Active bleeding may make endoscopic therapy difficult. Protection of the patient's airway with endotracheal intubation aids the endoscopist, facilitating therapy and significantly reducing the risk of pulmonary aspiration.

**Balloon tamponade** This technique employs a Minnesota tube, which consists of two balloons that can be positioned in the fundus of the stomach and in the lower oesophagus, respectively (Fig. 24.23). Additional lumens allow contents to be aspirated from the stomach and from the oesophagus. This technique may be used in the event of life-threatening haemorrhage if early endoscopic therapy is not available or is unsuccessful.

Endotracheal intubation prior to tube insertion reduces the risk of pulmonary aspiration. The tube should be passed through the mouth into the stomach. The gastric balloon should be inflated with 200–250 mL of air, and gentle traction applied to compress the gastro-oesophageal junction. Inadvertent inflation in the oesophagus can result in oesophageal rupture so, ideally, the gastric balloon should be inflated under direct endoscopic vision. Tamponade of the gastro-oesophageal junction with the gastric balloon will almost always control bleeding from oesophageal

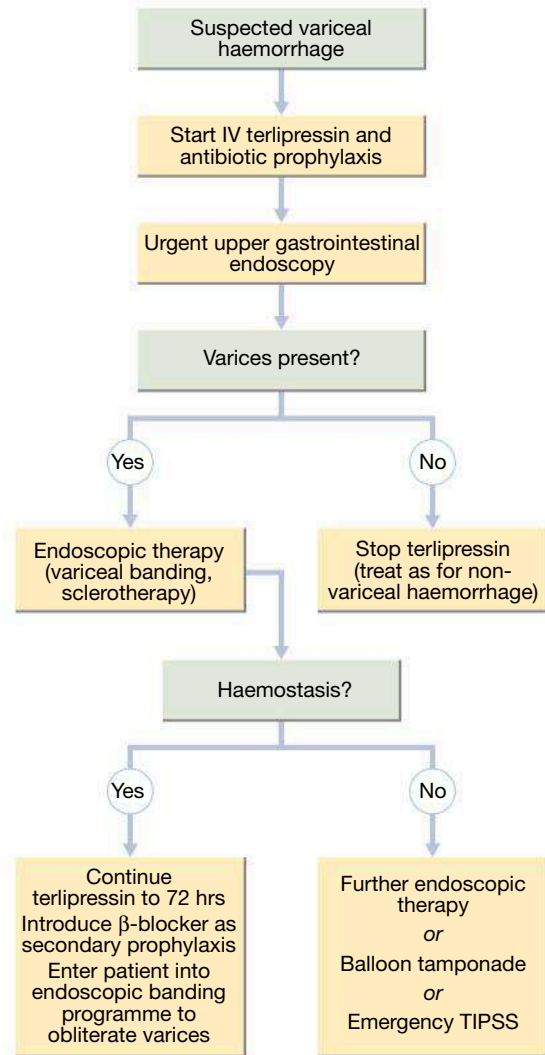

Fig. 24.22 Management of acute bleeding from oesophageal varices. (TIPSS = transjugular intrahepatic portosystemic stent shunt)

varices and inflation of the oesophageal balloon is rarely required. If the oesophageal balloon needs to be used because of continued bleeding, pressure should be monitored with a sphygmomanometer (to maintain <40 mmHg) and it should be deflated for about 10 minutes every 3 hours to avoid oesophageal mucosal damage. Balloon tamponade is only a bridge to more definitive therapy. Novel endoscopic therapies such as self-expanding removable oesophageal stents and haemostatic powder spray also appear to be effective short-term alternatives in small case series.

**TIPSS** This technique uses a stent placed between the portal vein and the hepatic vein within the liver to provide a portosystemic shunt and reduce portal pressure (Fig. 24.24). It is carried out under radiological control via the internal jugular vein; prior patency of the portal vein must be determined angiographically, coagulation deficiencies may require correction with fresh frozen plasma, and antibiotic cover is provided. Successful shunt placement stops and prevents further variceal bleeding, and is an effective treatment for both oesophageal and gastric varices. Further bleeding necessitates investigation and treatment (e.g. angioplasty) because it is usually associated with shunt narrowing or occlusion. Hepatic encephalopathy occurs in up to a third of patients following TIPSS and may require reducing the shunt diameter. Although TIPSS is associated with less rebleeding than endoscopic therapy, survival is not improved.

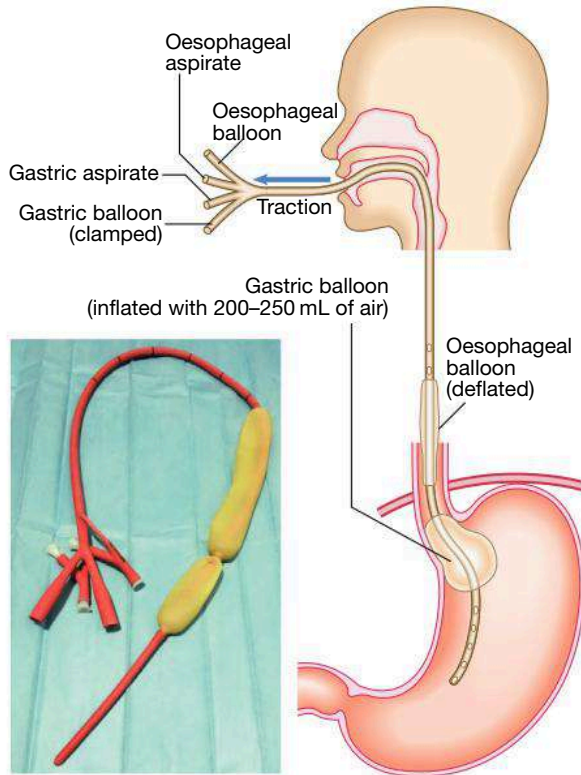

Fig. 24.23 Minnesota tube.

Fig. 24.24 Transjugular intrahepatic portosystemic stent shunt (TIPSS). X-ray showing placement of a TIPSS, allowing blood to flow from the portal vein (PV) into the hepatic vein (HV). Contrast can also be seen in gastric varices (GV). Arrows show the outline of the gastric balloon of a Sengstaken tube.

**Portosystemic shunt surgery** Surgery prevents recurrent bleeding but carries a high mortality and often leads to encephalopathy. In practice, portosystemic shunts are now reserved for when other treatments have not been successful and are offered only to patients with good liver function.

**Oesophageal transection** Rarely, surgical transection of the varices may be performed as a last resort when bleeding cannot be controlled by other means but operative mortality is high.

### Secondary prevention of variceal bleeding

Beta-blockers are used as a secondary measure to prevent recurrent variceal bleeding. Following successful endoscopic therapy, patients should be entered into an oesophageal banding programme with repeated sessions of therapy at 2–4-week intervals until the varices are obliterated. There is some evidence that early TIPSS after successful endoscopic therapy may improve survival in selected patients with advanced liver disease.

### Congestive ‘portal hypertensive’ gastropathy

Long-standing portal hypertension causes chronic gastric congestion, which is recognisable at endoscopy as multiple areas of punctate erythema (‘portal hypertensive gastropathy’ or ‘snakeskin gastropathy’) in the proximal stomach. Similar lesions may also occur more distally in the gastrointestinal tract (enteropathy and colopathy). These areas may become eroded, causing oozing from multiple sites. Acute bleeding can occur but repeated minor bleeding causing iron deficiency anaemia is more common. Anaemia may be prevented by oral iron supplements but repeated blood transfusions can become necessary. Reduction of the portal pressure using propranolol (80–160 mg/day) is the best initial treatment. In selected cases TIPSS procedure can be considered.

Gastric antral vascular ectasia (GAVE) is an alternative cause of mucosal oozing in patients with cirrhosis. This is characterised by red spots in the distal stomach, often arranged in stripes around the pylorus (‘watermelon stomach’). Therapy for GAVE is focused on endoscopic ablation using argon plasma coagulation (APC) or radiofrequency ablation (RFA).

## Infections and the liver

The liver may be subject to a number of different infections. These include hepatotropic viral infections and bacterial and protozoal infections. Each has specific clinical features and requires targeted therapies.

### Viral hepatitis

This must be considered in anyone presenting with hepatitic liver blood tests (high transaminases). The causes are listed in [Box 24.35](#).

All these viruses cause illnesses that have similar clinical and pathological features and are frequently anicteric or even asymptomatic. They differ in their tendency to cause acute and chronic infections. The features of the major hepatitis viruses are shown in [Box 24.36](#).

#### Clinical features of acute infection

A non-specific prodromal illness characterised by headache, myalgia, arthralgia, nausea and anorexia usually precedes the development of jaundice by a few days to 2 weeks. Vomiting and diarrhoea may follow and abdominal discomfort is common. Dark urine and pale stools may precede jaundice. There are usually few physical signs. The liver is often tender but only minimally enlarged. Occasionally, mild splenomegaly and

### 24.35 Causes of viral hepatitis

#### Common

- Hepatitis A

- Hepatitis C
- Hepatitis E

#### Less common

- Cytomegalovirus
- Epstein–Barr virus

#### Rare

- Herpes simplex
- Yellow fever

### 24.36 Features of the main hepatitis viruses

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
<b>Virus</b>					
Group	Enterovirus	Hepadnavirus	Flavivirus	Incomplete virus	Calicivirus
Nucleic acid	RNA	DNA	RNA	RNA	RNA
Size (diameter)	27 nm	42 nm	30–38 nm	35 nm	27 nm
<b>Incubation</b> (weeks)	2–4	4–20	2–26	6–9	3–8
<b>Spread*</b>					
Faeces	Yes	No	No	No	Yes (1–2)
Ingestion of infected meat	No	No	No	No	Yes (3–4)
Blood	Uncommon	Yes	Yes	Yes	No
Saliva	Yes	Yes	Yes	Unknown	Unknown
Sexual	Uncommon	Yes	Uncommon	Yes	Unknown
Vertical	No	Yes	Uncommon	Yes	No
<b>Chronic infection</b>	No	Yes	Yes	Yes	No (except immune-compromised)
<b>Prevention</b>					
Active	Vaccine	Vaccine	No	Prevented by hepatitis B vaccination	No
Passive	Immune serum globulin	Hyperimmune serum globulin	No		No

\*All body fluids are potentially infectious, although some (e.g. urine) are less infectious than others.

### 24.37 Complications of acute viral hepatitis

- Acute liver failure
- Cholestatic hepatitis (hepatitis A)
- Aplastic anaemia
- Chronic liver disease and cirrhosis (hepatitis B and C)
- Relapsing hepatitis

cervical lymphadenopathy are seen. These features are more frequent in children or those with Epstein–Barr virus (EBV) infection. Symptoms rarely last longer than 3–6 weeks. Complications may occur but are rare (Box 24.37).

#### Investigations

A hepatic pattern of LFTs develops, with serum transaminases typically between 200 and 2000 U/L in an acute infection (usually lower and fluctuating in chronic infections). The ALP rarely exceeds twice the upper limit of normal. The plasma bilirubin and prothrombin time (PT) reflect the degree of liver damage. Prolongation of the PT rarely exceeds 25 seconds, except in rare cases of acute liver failure. The white cell count is usually normal with a relative lymphocytosis. Serological tests confirm the aetiology of the infection.

#### Management

Most individuals do not need hospital care. Drugs such as sedatives and narcotics, which are metabolised in the liver, should be avoided. Alcohol should not be taken during the acute illness. Elective surgery should be avoided in cases of acute viral hepatitis, as there is a risk of post-operative liver failure.

Liver transplantation is very rarely indicated for acute viral hepatitis complicated by liver failure.

## Hepatitis A

The hepatitis A virus (HAV) belongs to the picornavirus group of enteroviruses. HAV is highly infectious and is spread by the faecal–oral route. Risk of infection is associated with a lack of safe water and poor

sanitation. In occasional outbreaks, water and shellfish have been the vehicles of transmission. Infection may be asymptomatic or produce symptoms after an average incubation period of 28 days. The likelihood of symptoms relates to age, with most children under 6 years of age having no symptoms but most adults developing jaundice. Up to 30% of adults will have serological evidence of past infection but give no history of jaundice. Infected individuals excrete the virus in faeces for about 2–3 weeks before the onset of symptoms and then for a further 2 weeks or so.

In contrast to hepatitis B and C, chronic infection does not occur. Almost all cases will recover fully with lifelong immunity, but a very small proportion develop acute liver failure (0.1%) and may die. Infection in patients with pre-existing chronic liver disease may cause serious or life-threatening disease. In adults, a cholestatic phase with elevated ALP levels may complicate infection.

#### Investigations

Diagnosis of HAV infection is based on antibody testing. Only one HAV antigen has been found and infected people make an antibody to this antigen (anti-HAV). Anti-HAV immunoglobulin (Ig) M antibody is detectable in the blood 5–10 days before the onset of symptoms and falls to low levels within about 3 months of recovery, so is diagnostic of acute HAV infection. Anti-HAV IgG antibody persists for years after infection, and is a marker of previous HAV infection with resulting immunity.

#### Management

Infection in the community is best prevented by improving social conditions, especially overcrowding and poor sanitation. Individuals can be given substantial protection from infection by active immunisation with an inactivated virus vaccine. Immunisation should be considered for those at particular risk, such as people travelling to endemic areas, close contacts of HAV-infected patients, older individuals, those with other major disease (including chronic liver disease) and perhaps pregnant women.

Immediate protection can also be provided by immune serum globulin if this is given soon after exposure to the virus. The protective effect of immune serum globulin is attributed to its anti-HAV content. Intramuscular injection of immune serum globulin is recommended for close contacts of infected individuals who are less able to respond to

vaccination, such as those aged 60 years or over, immunocompromised individuals or those with chronic liver disease. It may also be effective in an outbreak of hepatitis, in a school or nursery, as injection of those at risk prevents secondary spread to families.

There is no role for antiviral drugs in the therapy of HAV infection.

## Hepatitis B

The hepatitis B virus (HBV) consists of a core containing DNA and a DNA polymerase enzyme needed for virus replication, surrounded by surface protein (Fig. 24.25). The virus and an excess of its surface protein (known as hepatitis B surface antigen, HBsAg) circulate in the blood. The virus replicates and assembles within hepatocytes but is not directly cytotoxic; hepatocyte damage occurs during immune-mediated clearance of infected hepatocytes.

Hepatitis B is one of the most common causes of chronic liver disease and hepatocellular carcinoma worldwide. Approximately 250 million people have chronic HBV infection. There is large regional variation, with the highest rates seen in the Western Pacific and African regions.

Hepatitis B can cause acute or chronic infection. The risk of developing chronic HBV infection depends on the source and timing of exposure. Infections may occur via a number of routes (Box 24.38). In endemic areas, vertical transmission from mother to child in the perinatal period is the most common cause of infection and carries the highest risk of ongoing chronic infection (90%–95%). In contrast, exposure to HBV at an older age is much more likely to result in an acute hepatitis, with chronic infection developing in less than 5% of adult-acquired HBV.

In perinatal infection, adaptive immune responses to HBV may be absent initially, with apparent immunological tolerance. Although HBV-specific T-cells are detectable in this setting, they are weak and functionally impaired. The mechanisms underlying this are incompletely understood.

Chronic hepatitis can lead to cirrhosis or hepatocellular carcinoma, usually after decades of infection (Fig. 24.26). Chronic HBV infection is a dynamic process that can be divided into five phases (Box 24.39); these are not necessarily strictly sequential, however, and not all patients will go through all phases. Phases are considered as either 'infection' where circulating HBsAg is detectable but is not resulting in any current liver injury, or 'hepatitis' where this is accompanied by liver inflammation and fibrosis.

### Investigations

Assessment of hepatitis B infection relies on looking at a combination of viral markers (surface antigen, e-antigen and viral load) and liver markers (ALT and fibrosis markers) to determine the stage of disease.

**Fig. 24.25 Schematic diagram of the hepatitis B virus.** Hepatitis B surface antigen (HBsAg) is a protein that makes up part of the viral envelope. Hepatitis B core antigen (HBcAg) is a protein that makes up the capsid or core part of the virus (found in the liver but not in blood). Hepatitis B e antigen (HBeAg) is part of the HBcAg that can be found in the blood and indicates infectivity. (HBV = hepatitis B virus)

### 24.38 Risk factors for the acquisition of hepatitis B infection

#### Vertical transmission

- Hepatitis B surface antigen (HBsAg)-positive mother (especially if e-antigen-positive)

#### Horizontal transmission

- Sexual transmission
- Intravenous drug use
- Infected unscreened blood products
- Tattoos/acupuncture needles
- Needlestick injury
- Sharing toothbrush/razor
- Close living quarters/playground play as a toddler (may contribute to high rate of horizontal transmission in Africa)

### Serology

HBV contains several antigens to which infected persons can make immune responses (Fig. 24.27); these antigens and their antibodies are important in identifying the stage of HBV infection (see Box 24.39 and Box 24.40), in addition to direct assessment of viral load by polymerase chain reaction (PCR) for HBV DNA.

**Hepatitis B surface antigen** Hepatitis B surface antigen (HBsAg) is the main indicator of active infection, and a negative test for HBsAg makes HBV infection very unlikely. The exception is in acute liver failure from hepatitis B, where the liver damage is mediated by viral clearance and so HBsAg may be negative at presentation, with evidence of recent infection provided by the presence of hepatitis B core (anti-HBc) IgM (see below). In resolving acute HBV infection, antibody to HBsAg (anti-HBs) usually appears after about 3–6 months and persists for many years or perhaps permanently. Anti-HBs implies either a previous infection, in which case anti-HBc (see below) is usually also present, or previous vaccination, in which case anti-HBc is not present.

**Hepatitis B core antigen** Hepatitis B core antigen (HBcAg) is not found in the blood, but antibody to it (anti-HBc) appears early in the illness and rapidly reaches a high titre, which subsides gradually but then persists. Anti-HBc is initially of IgM type, with IgG antibody appearing later (see Fig. 24.27 and Box 24.40).

**Hepatitis B e antigen** Hepatitis B e antigen (HBeAg) is part of the core antigen that is detectable in the blood and can be used as an indicator of viral replication. Seroconversion to e antigen (i.e. loss of HBeAg and development of anti-HBe antibody) indicates a partial immune control of the virus and is associated with a significant drop in viral load. This typically occurs after 10–30 years in perinatally acquired infection, but within 3–6 months in adult-acquired acute infections.

### Viral load and genotype

HBV-DNA can be measured by PCR in the blood. Viral loads are usually highest (in excess of  $10^7$  copies/mL) in HBeAg-positive infection, making this the most infectious phase. Once patients undergo HBeAg seroconversion, viral loads drop to less than  $10^5$  copies/mL in HBeAg-negative infection. Around 15%–20% of patients will subsequently develop further rises in viral load, due to mutations in the pre-core or core promoter region (Fig. 24.28). Such patients are classified as having HBeAg-negative chronic hepatitis.

Measurement of viral load is important in detecting flares of HBeAg-negative hepatitis and in monitoring response to antiviral therapy. Ten HBV genotypes (A–J) can also be identified using PCR. These affect the likelihood of response to pegylated interferon.

### Management of acute hepatitis B

Full spontaneous recovery occurs in more than 95% of adults following acute HBV infection. Fulminant liver failure due to acute hepatitis B

**Fig. 24.26** Natural history of chronic hepatitis B virus (HBV) infection. There is an initial immunotolerant phase with high levels of virus and normal liver biochemistry. An immunological response to the virus then occurs, with elevation in serum transaminases, which causes liver damage: chronic hepatitis. If this response is sustained over many years and viral clearance does not occur promptly, chronic hepatitis may result in cirrhosis. In individuals with a successful immunological response, viral load falls, HBe antibody (HBeAg) develops and there is no further liver damage. Some individuals may subsequently develop HBV-DNA mutants that escape from immune regulation, and viral load again rises with further chronic hepatitis. Mutations in the core protein result in the virus's inability to secrete HBe antigen despite high levels of viral replication; such individuals have HBeAg-negative chronic hepatitis. (ALT = alanine aminotransferase; AST = aspartate aminotransferase)

24.39 The five phases of chronic hepatitis B virus (HBV) infection						
Phase	HBsAg	HBeAg	Viral load	ALT	Histology	Notes
<b>HBeAg positive chronic infection</b>	+	+	+++ ( $> 10^7$ IU/ml)	Normal	Normal/minimal necroinflammation	Prolonged in perinatally infected individuals; may be short or absent if infected as an adult. High viral load and so very infectious. Previously known as 'immune-tolerant'
<b>HBeAg-positive chronic hepatitis</b>	+	+	++ ( $10^4$ – $10^7$ IU/ml)	Raised	Moderate/severe necroinflammation	May last weeks or years. Risk of cirrhosis or HCC if prolonged. Previously known as 'immune-reactive'
<b>HBeAg-negative chronic infection</b>	+	–	+/- ( $< 2000$ IU/ml)	Normal	Normal/minimal necroinflammation	Low risk of cirrhosis or HCC in majority. Previously known as 'inactive carrier'.
<b>HBeAg-negative chronic hepatitis</b>	+	–	Fluctuating +/+ ( $> 2000$ IU/ml)	Raised/ fluctuating	Moderate/severe necroinflammation	May represent late immune reactivation or presence of 'pre-core mutant' HBV. High risk of cirrhosis or HCC
<b>HBeAg-negative phase</b>	–	–	-/±	Normal	Normal	Ultrasensitive techniques may detect low-level HBV DNA even after HBeAg loss

(HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HCC = hepatocellular carcinoma)

occurs in fewer than 1% of cases but can be life-threatening and require liver transplantation. The remaining <5% develop chronic infection.

Treatment of acute HBV infection is supportive, with monitoring for acute liver failure. Antiviral therapy is usually only considered in those with evidence of severe liver injury with coagulopathy (INR > 1.5) or a protracted course with persistent symptoms for > 4 weeks.

Recovery from acute HBV infection occurs within 6 months and is characterised by the appearance of antibody to viral antigens. Persistence of HBeAg or HBsAg indicates chronic infection.

### Management of chronic hepatitis B

Once hepatitis B infection has been present for more than 6 months, spontaneous clearance is uncommon. Most patients with chronic hepatitis B are asymptomatic and develop complications, such as cirrhosis

and hepatocellular carcinoma, only after many years (see Fig. 24.26). Fibrosis accumulates during periods of liver injury (the 'hepatitis' phases) and results in cirrhosis in 15%–20% of patients with chronic HBV over 5–20 years. The rate of progression to cirrhosis is higher in HBeAg-negative hepatitis (8%–10% incidence per annum) than HBeAg-positive hepatitis (2%–5% per annum).

The ideal goal of treatment would be to achieve long-term viral clearance with loss of HBsAg, but this is rarely achieved with current therapies. Instead, treatment is aimed at suppressing viral replication to prevent disease progression to cirrhosis or hepatocellular carcinoma. The goals of treatment are therefore HBeAg seroconversion, reduction in HBV-DNA and normalisation of the LFTs. Only a proportion (10%–40%) of patients with chronic hepatitis B will require treatment. This is usually targeted at those in the 'hepatitis' phases with high viral load and

**Fig. 24.27** Serological responses to hepatitis B virus infection. (anti-HBc = antibody to hepatitis B core antigen; anti-HBe = antibody to HBeAg; anti-HBs = antibody to HBsAg; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; IgM = immunoglobulin M)

24.40 How to interpret the serological tests of acute hepatitis B virus infection				
Interpretation	HBsAg	Anti-HBc IgM	Anti-HBc IgG	Anti-HBs
<b>Incubation period</b>	+	+	-	-
<b>Acute hepatitis</b>				
Early	+	+	-	-
Established	+	+	+	-
<b>Convalescence</b>

<b>Post-infection</b>	-	-	+	±
<b>Immunisation without infection</b>	-	-	-	+

+ = positive; - = negative; ± = present at low titre or absent.  
(anti-HBc IgM/IgG = antibody to hepatitis B core antigen of immunoglobulin M/G type; anti-HBs = antibody to HBsAg; HBsAg = hepatitis B surface antigen)

accompanying liver injury, either in terms of necroinflammation (raised ALT) or established fibrosis (on biopsy or raised liver stiffness on transient elastography). All patients with cirrhosis should be treated to prevent decompensation. Treatment may also be initiated during pregnancy in the absence of liver injury to prevent mother-to-child transmission.

Two different types of drug are used to treat hepatitis B: direct-acting nucleoside/nucleotide analogues and pegylated interferon-alfa.

#### Direct-acting nucleoside/nucleotide antiviral agents

Orally administered nucleoside/nucleotide antiviral agents are the mainstay of therapy. These act by inhibiting the reverse transcription of pre-genomic RNA to HBV-DNA by HBV-DNA polymerase but do not directly affect the covalently closed circular DNA (cccDNA) template for viral replication, and so relapse is common if treatment is withdrawn. One major concern is the selection of antiviral-resistant mutations with long-term treatment. This is particularly important with some of the older agents, such as lamivudine, as mutations induced by previous antiviral exposure may also induce resistance to newer agents. Entecavir and tenofovir (see below) are potent antivirals with a high barrier to genetic resistance and so are the most appropriate first-line agents.

**Lamivudine** Although initially effective, long-term therapy is often complicated by the development of HBV-DNA polymerase mutants (e.g. the 'YMDD variant'), which lead to viral resistance. These occur in around half of patients after 3 years and are characterised by a rise in viral load

**Fig. 24.28** The site of hepatitis B virus (HBV)-DNA mutations. HBV-DNA encodes four proteins: a DNA polymerase needed for viral replication (P), a surface protein (S), a core protein (C) and an X protein. The pre-C and C regions encode a core protein and an e antigen. Although mutations in the hepatitis B virus are frequent, certain mutations have important clinical consequences. Pre-C encodes a signal sequence needed for the C protein to be secreted from the liver cell into serum as e antigen. A mutation in the pre-core region leads to a failure of secretion of e antigen into serum, and so individuals have high levels of viral production but no detectable e antigen in the serum. Mutations can also occur in the surface protein and may lead to the failure of vaccination to prevent infection, since surface antibodies are produced against the native S protein. Mutations also occur in the DNA polymerase during antiviral treatment with lamivudine.

during treatment. Outside resource-limited settings, this agent is now seldom used for the treatment of HBV but may be used to prevent reactivation in patients with past HBV infection (HBsAg-negative but HBeAb-positive) if they are undergoing treatment with rituximab or chemotherapy.

**Entecavir and tenofovir** Monotherapy with entecavir or tenofovir is substantially more effective than lamivudine in reducing viral load in HBeAg-positive and HBeAg-negative chronic hepatitis. Antiviral resistance mutations occur very rarely, in < 1% after 5 years of entecavir and with no evidence of resistance after 8 years of tenofovir. Both drugs have action against human immunodeficiency virus (HIV) and so their use as monotherapy is contraindicated in HIV-positive patients, as it may lead to HIV antiviral drug resistance. Current European guidelines advise that the other nucleoside/nucleotide antivirals should not be used as first-line monotherapy due to the induction of viral mutations, unless entecavir or tenofovir are not available or appropriate.

#### Pegylated interferon-alfa

Pegylated interferon-alfa (PEG-IFN) acts by augmenting the host immune response. This is most effective in patients with a pre-treatment low viral load and serum transaminases greater than twice the upper limit of normal. Treatment is for a finite period (typically around 1 year), and is associated with higher rates of HBsAg and HBeAg seroconversion than nucleoside/nucleotide agents but with greater side-effects. Interferon is contraindicated in the presence of cirrhosis, as it may cause a rise in serum transaminases and precipitate liver failure. In HBeAg-positive chronic hepatitis, PEG-IFN results in sustained HBeAg seroconversion in around 30%, and HBsAg seroconversion in 3%–5%. Response rates are higher in those with genotype A or B virus, and those with low viral load and high ALT. Sustained response rates are lower in HBeAg-negative chronic hepatitis.

#### Liver transplantation

Patients with advanced liver disease or hepatocellular carcinoma (HCC) may require liver transplantation. The use of nucleoside/nucleotide analogues post-transplant (with hepatitis B immunoglobulin in high-risk individuals) has made recurrent disease due to graft re-infection very uncommon, and outcomes are comparable with other indications.

### Hepatocellular carcinoma risk

Chronic HBV infection is associated with an increased risk of hepatocellular carcinoma, even in the absence of cirrhosis. This risk increases with age, male sex, smoking, diabetes, family history of HCC and high viral loads. A number of scoring systems (such as REACH-B and PAGE-B) have been developed to identify high-risk non-cirrhotic patients who may benefit from HCC screening.

### Prevention

Individuals are most infectious when high levels of HBV-DNA are present in the blood, typically in the HBeAg-positive infection phase. HBV-DNA can be found in saliva, urine, semen and vaginal secretions (although urine is not usually considered to be capable of transmitting infection). The virus is about ten times more infectious than hepatitis C.

A recombinant hepatitis B vaccine containing HBsAg is available (Engerix) and is capable of producing active immunisation in 95% of normal individuals. The vaccine should be offered to those at increased risk of infection who are not already immune, as evidenced by anti-HBs in the blood (Box 24.41). The vaccine is ineffective in those already infected by HBV. Following known exposure, infection can also be prevented or minimised by the intramuscular injection of specific hepatitis B immunoglobulin (HBIG) prepared from blood containing anti-HBs. This should be given within 48 hours, or at most a week, of exposure to infected blood (e.g. needlestick injury, contamination of cuts or mucous membranes). Vaccine can be given together with HBIG (active-passive immunisation).

Neonates born to hepatitis B-infected mothers should be immunised at birth and given immunoglobulin. Hepatitis B serology should then be checked at 12 months of age.

### Co-infection with HIV

Around 10% of the HIV-infected population has concurrent HBV and this figure may be as high as 25% in areas where both viruses are prevalent. Up to half of injection drug users with HIV are co-infected with HBV. Co-infection increases the morbidity and mortality compared to either infection alone: there are greater levels of HBV viraemia, faster progression to chronic infection and greater risk of cirrhosis and hepatocellular carcinoma than with HBV infection alone. The immunosuppression that is seen in HIV infection can lead to loss of anti-HBs antibodies, reactivation of infection and a poorer antibody response to HBV vaccination. Pregnancy poses particular problems in co-infected patients, with increased risk of perinatal transmission of HBV to the child.

Treatment can also be problematic. Several nucleoside analogues have dual antiviral activity and some regimens have been associated with emergence of drug resistance. Co-infection is also associated with diminished response to interferons and increased resistance to lamivudine in some patients. Co-infection should be managed by specialists with expertise in this area and combinations of antiviral agents need to be thought through carefully. Antiviral therapy should be considered for co-infected pregnant women, using drugs with dual activity, e.g. tenofovir with emtricitabine or lamivudine.

Globally, there is a need to identify co-infected patients earlier, especially in endemic areas, as well as a need for early effective interventions, particularly in pregnant women, to reduce perinatal transmission.

#### **i** 24.41 At-risk groups meriting hepatitis B vaccination in low-endemic areas

- Parenteral drug users
- Men who have sex with men
- Close contacts of infected individuals:
  - Newborn of infected mothers
  - Regular sexual partners
- Patients on chronic haemodialysis
- Patients with chronic liver disease
- Medical, nursing and laboratory personnel

### Hepatitis D (Delta virus)

The hepatitis D virus (HDV) is an RNA-defective virus that has no independent existence; it requires HBV for replication and has the same sources and modes of spread. It can infect individuals simultaneously with HBV or can superinfect those who already have chronic HBV. Simultaneous infections give rise to acute hepatitis, which is often severe but is limited by recovery from the HBV infection. Infections in individuals with chronic HBV can cause acute hepatitis with spontaneous recovery, and occasionally there is simultaneous cessation of the chronic HBV infection. Chronic infection with HBV and HDV can also occur, and this frequently causes rapidly progressive chronic hepatitis and eventually cirrhosis.

HDV has a worldwide distribution. It is endemic in parts of the Mediterranean basin, Africa and South America, where transmission is mainly by close personal contact and occasionally by vertical transmission from mothers with HBV. In non-endemic areas, transmission is mainly a consequence of parenteral drug misuse.

### Investigations

HDV contains a single antigen to which infected individuals make an antibody (anti-HDV). Delta antigen appears in the blood only transiently, and in practice diagnosis depends on detecting anti-HDV. Simultaneous infection with HBV and HDV, followed by full recovery, is associated with the appearance of low titres of anti-HDV IgM within a few days of the onset of the illness. This antibody generally disappears within 2 months but persists in a few patients. Super-infection of patients with chronic HBV infection leads to the production of high titres of anti-HDV, initially IgM and later IgG. Such patients may then develop chronic infection with both viruses, in which case anti-HDV titres plateau at high levels.

### Management

Effective management of hepatitis B prevents hepatitis D.

### Hepatitis C

This is caused by an RNA flavivirus. Acute symptomatic infection with hepatitis C is rare. Most individuals are unaware of when they became infected and are identified only when they develop chronic liver disease. Around 70% of individuals exposed to the virus become chronically infected and late spontaneous viral clearance is rare. It is estimated that around 70 million individuals have chronic hepatitis C worldwide, with the highest prevalence in the Eastern Mediterranean region. There is no active or passive protection against hepatitis C virus (HCV).

Hepatitis C infection is usually identified in asymptomatic individuals screened because they have risk factors for infection, such as previous injecting drug use (Box 24.42), or have incidentally been found to have abnormal liver blood tests. Although most people remain asymptomatic until progression to cirrhosis occurs, fatigue can complicate chronic infection and is unrelated to the degree of liver damage.

If hepatitis C infection is left untreated, progression from chronic hepatitis to cirrhosis may occur, with 20% developing cirrhosis over 20 years. Risk factors for progression include male gender, immunosuppression (such as co-infection with HIV), prothrombotic states and heavy alcohol misuse. Once cirrhosis is present, 2%–5% per year will develop primary hepatocellular carcinoma, although this rate falls by around 75% following successful antiviral therapy.

### Investigations

#### Serology and virology

The HCV genome encodes a large polypeptide precursor that is modified post-translationally to at least 10 proteins, including several antigens that give rise to antibodies in an infected person; these are used in diagnosis. Following an acute infection (such as a needlestick injury), HCV RNA can be detected in the blood within 2–4 weeks but it may take 6–12 weeks for antibodies to appear. Anti-HCV antibodies persist in serum even after

### 24.42 Risk factors for the acquisition of chronic hepatitis C infection

- Intravenous drug use (95% of new cases in the UK)
- Unscreened infected blood products
- Vertical transmission (3% risk)
- Needlestick injury (3% risk)
- Iatrogenic parenteral transmission (e.g. contaminated vaccination needles)
- Sharing toothbrushes/razors
- Sexual transmission (uncommon)

viral clearance, whether spontaneous or post-treatment. Anti-HCV antibodies are used as the initial screening test for chronic infection but if positive, the presence of serum HCV RNA or hepatitis C core antigen is required to confirm active infection. In cases of suspected acute infection, negative testing should be repeated after 4 weeks.

#### Molecular analysis

There are six common viral genotypes, the distribution of which varies worldwide. The most common genotypes are 1 (45%) and 3 (25%). Genotype has no effect on progression of liver disease but historically had a major effect on response to treatment: genotype 1 was less easy to eradicate than genotypes 2 and 3 with traditional pegylated interferon alfa-/ribavirin-based treatments. All genotypes now have highly successful treatment options, although genotype may still be used to guide the choice of direct-acting antiviral drugs.

#### Liver function tests

LFTs may be normal or show fluctuating serum transaminases between 50 and 200 U/L. Jaundice can occasionally occur during acute infection and confers an increased likelihood of spontaneous viral clearance, but otherwise only appears in end-stage cirrhosis.

#### Fibrosis assessment

Serum transaminase levels in hepatitis C are a poor predictor of the degree of liver fibrosis. This should be assessed at diagnosis using transient elastography, blood biomarkers or non-invasive fibrosis scoring systems such as the Fibrosis-4 (FIB4) score or aspartate aminotransferase to platelet ratio index (APRI). Where there is diagnostic uncertainty, a liver biopsy may be required to stage the extent of liver damage.

#### Management

The aim of treatment is to eradicate infection and all patients with chronic HCV infection should be treated where possible. Sustained virological response (SVR) refers to undetectable HCV RNA at least 12 weeks after treatment completion, and carries a very low chance (<1%) of subsequent relapse. In recent years, there have been substantial advances in treatment, with rates of SVR rising from less than 40% a decade ago to levels approaching 100% with newer direct-acting antivirals (DAAs). Whilst the cost of these new treatments initially posed a significant financial challenge, the price of DAAs has fallen significantly in recent years and the challenges now include identification and engagement of patients with infection.

Until 2013, the treatment of choice was combination therapy with pegylated interferon and ribavirin for up to 48 weeks. Treatment had many side-effects and a low SVR rate of 40%–70% depending on genotype.

Since 2013, new classes of DAAs have allowed interferon-free regimens with substantially shorter treatment duration, minimal side-effects and high cure rates. There are four main classes of DAA, which are defined according to their mechanism of action and therapeutic target (Box 24.43). These compounds are targeted to specific steps in the hepatitis C viral life cycle to disrupt viral replication (Fig. 24.29). These drugs are now frequently combined into single pill combinations that can be taken once daily for 8–12 weeks with SVR rates of over 95%. Whilst some DAA combinations are only licensed for specific viral genotypes, several pan-genotypic treatments are now available.

Liver transplantation should be considered when complications of cirrhosis occur. However, DAAs can be safely used even in patients with

### 24.43 Direct-acting antiviral agents for hepatitis C

Drug class	Therapeutic target	Selected drugs
<b>Protease inhibitors (PIs)</b>	Non-structural viral protein NS3/4A (protease that cleaves the HCV polyprotein)	Paritaprevir Grazoprevir Voxilaprevir Glecaprevir
<b>Nucleoside polymerase inhibitors (NPIs)</b>	Non-structural viral protein NS5B (RNA-dependent RNA polymerase needed for viral replication)	Sofosbuvir
<b>Non-nucleoside polymerase inhibitors (NNPIs)</b>	Non-structural viral protein NS5B (RNA-dependent RNA polymerase needed for viral replication)	Dasabuvir
<b>NS5A replication complex inhibitors</b>	Non-structural viral protein NS5A (assembly of viral replication complex)	Velpatasvir Ledipasvir Ombitasvir Elbasvir Pibrentasvir
<b>Host-targeting antiviral drugs (HTAs)</b>	Cyclophilin (pharmacological inhibitor targets host cell functions involved in the HCV life cycle)	Alisporivir

(HCV = hepatitis C virus)

decompensated cirrhosis, and successful treatment can be associated with an improvement in liver function. It is therefore becoming less common to require liver transplantation for liver failure secondary to hepatitis C, although it may still be required for hepatocellular carcinoma. Whilst most patients will now be able to have successful anti-viral treatment before transplantation, DAAs can also be used post-transplant and recurrent hepatitis C in the transplanted liver is now very rare.

## Hepatitis E

Hepatitis E virus (HEV) is an RNA virus that is now thought to be the most common cause of acute viral hepatitis worldwide. Four major genotypes are described. Genotypes 1 and 2 exclusively infect humans via the faecal–oral route and cause waterborne epidemics, mainly in Asia. Genotypes 3 and 4 are mostly zoonotic (in pigs, wild boars and deer) and are transmitted to humans through undercooked meat. HEV can rarely be transmitted by blood transfusion, and blood donations in the United Kingdom are now routinely screened for hepatitis E.

HEV causes a self-limiting acute hepatitis that does not require any specific treatment. However, it can cause chronic hepatitis, progressing to cirrhosis, in immunocompromised patients, especially organ-transplant recipients. This may require a reduction in the level of immunosuppression and/or treatment with ribavirin.

Infection with genotype 1 or 2 virus during pregnancy carries a high risk of acute liver failure, which has a high mortality. Hepatitis E also causes more severe disease in those with underlying cirrhosis, resulting in decompensation or acute-on-chronic liver failure. Extrahepatic manifestations are increasingly recognised and include neurological problems such as Guillain-Barré syndrome and neuralgic amyotrophy.

Diagnosis of acute infection is usually based on detection of anti-HEV IgM antibodies but it is possible to measure HEV RNA or capsid antigen in the blood and stool (especially in immunocompromised patients).

## Other forms of viral hepatitis

Non-A–E hepatitis is the term used to describe hepatitis thought to be due to a virus that is not HAV, HBV, HCV or HEV. Although the viruses

**Fig. 24.29 Direct-acting antiviral agents.** These compounds are targeted to specific steps in the hepatitis C viral life cycle to disrupt replication. (NS = non-structural viral protein)

above account for the majority of clinically significant hepatitis infections, other viruses can affect the liver. Cytomegalovirus and EBV infection causes abnormal LFTs in most patients and occasionally jaundice occurs. Herpes simplex is a rare cause of hepatitis in adults, most of whom are immunocompromised but can be very severe in pregnancy. Abnormal LFTs are also common in chickenpox, measles, rubella, acute HIV and COVID-19 infection.

## HIV infection and the liver

Several causes of abnormal LFTs occur in HIV infection, as shown in Box 24.44. This topic is discussed in more detail in Chapter 14. Co-infection with HIV and HBV is discussed on page 889.

## Liver abscess

Liver abscesses are classified as pyogenic (bacterial), hydatid (protozoal) or amoebic.

## Pyogenic liver abscess

Pyogenic liver abscesses are uncommon but important because they are potentially curable but carry significant morbidity and mortality if untreated. The mortality of liver abscesses is 5%–25%. Mortality is higher in those with multiple abscesses, underlying malignancy or other comorbidities, and delayed diagnosis.

### Pathophysiology

Infection can reach the liver in several ways (Box 24.45). Pyogenic abscesses are most common in older patients and usually result from ascending infection due to biliary obstruction (cholangitis) or contiguous spread from an empyema of the gallbladder. They can also complicate dental sepsis or colonic pathology, e.g. cancer, diverticulitis or inflammatory bowel disease causing portal pyaemia. Abscesses complicating suppurative appendicitis used to be common in young adults but are now rare. Immunocompromised or diabetic patients are particularly likely to develop liver abscesses. Multiple abscesses are usually due to biliary obstruction and may be polymicrobial. *Escherichia coli*, *Klebsiella pneumonia* and *Streptococcus milleri* are the most common organisms;

## 24.44 Causes of abnormal liver blood tests in HIV infection

### Hepatic blood tests

- Chronic hepatitis C
- Chronic hepatitis B
- Antiretroviral drugs
- Cytomegalovirus

### Cholestatic blood tests

- Tuberculosis
- Atypical mycobacterium
- Sclerosing cholangitis due to cryptosporidia

## 24.45 Causes of pyogenic liver abscesses

- Biliary obstruction (cholangitis)
- Haematogenous:
  - Portal vein (intra-abdominal infections)
  - Hepatic artery (bacteraemia)
- Direct extension (cholecystitis)
- Trauma:
  - Penetrating or non-penetrating
- Infection of liver tumour or cyst

anaerobes such as *Bacteroides* can often be found when infection has been transmitted from large bowel pathology.

### Clinical features

Patients are generally ill with fever and sometimes rigors and weight loss. Right upper quadrant abdominal pain is common, sometimes with radiation to the right shoulder. The pain may be pleuritic in nature. Tender hepatomegaly is found in more than 50% of patients. Mild jaundice may be present, becoming severe if large abscesses cause biliary obstruction. Atypical presentations are common and include anorexia, diarrhoea, dyspnoea and pyrexia of unknown origin. Necrotic colorectal metastases can be misdiagnosed as hepatic abscess.

### Investigations

A raised white cell count and neutrophilia is common. Alkaline phosphatase is often raised and albumin levels are low. Blood cultures are

positive in 50%–80%. The chest X-ray may show a raised right diaphragm and lung collapse, or an effusion at the base of the right lung. Liver imaging is key; ultrasound will detect at least 80% of pyogenic abscesses and CT with contrast will detect over 95%. Needle aspiration under ultrasound guidance confirms the diagnosis and provides pus for culture. Abscesses caused by gut-derived organisms require active exclusion of significant colonic pathology, such as a colonoscopy to exclude colorectal carcinoma.

### Management

Pending the results of culture of blood and pus from the abscess, treatment should be commenced with a combination of antibiotics, such as ampicillin, gentamicin and metronidazole. Percutaneous aspiration or drainage with a catheter placed in the abscess under ultrasound guidance is required if the abscess is large or not responding to antibiotics. Any associated biliary obstruction and cholangitis require biliary drainage (preferably endoscopically). Surgical abscess drainage is rarely undertaken, although hepatic resection may be indicated for a chronic persistent abscess or 'pseudotumour'.

## Hydatid cysts and amoebic liver abscesses

These are described on pages 342 and 330.

## Leptospirosis

This is described on page 305.

## Alcohol-related liver disease

Alcohol is one of the most common causes of chronic liver disease worldwide, with consumption continuing to increase in some countries. Excessive alcohol consumption produces a spectrum of effects on the liver. Almost all heavy drinkers will have alcohol-related fatty liver, but only a minority will develop clinically significant liver disease (alcoholic hepatitis or cirrhosis). A number of factors influence the risk of developing the more severe features of alcohol-related liver disease (ALD):

- **Amount of alcohol consumed.** In the UK, a 'unit' of alcohol contains 8 g of ethanol (Box 24.46). There is significant variability between countries in advice with regard to alcohol consumption but current UK guidelines recommend drinking less than 14 units of alcohol per week. This threshold is based on a wide range of health issues, including cancer risk. The threshold of alcohol consumption required to develop liver disease varies considerably between individuals but begins at around 30 g/day (25–30 units/week) of ethanol. However, there is not a linear relationship between dose and liver damage. For many, consumption of more than 80 g/day, for more than 5 years, is required to confer significant risk of advanced liver disease. The average alcohol consumption of a man with cirrhosis is 160 g/day for over 8 years. However, even at this level of consumption, many patients will not develop advanced liver disease.
- **Drinking pattern.** There are conflicting data with regard to drinking pattern but it is generally thought that liver damage is more likely to occur in continuous rather than intermittent or 'binge' drinkers, as this pattern gives the liver a chance to recover. It is therefore recommended that people should have at least two alcohol-free days each week. The type of beverage does not affect risk.
- **Sex.** Women who drink heavily are at higher risk of developing cirrhosis than men. This may relate to the higher blood ethanol levels seen in women compared to men after consuming the same amount of alcohol.
- **Genetics.** Genetic factors predispose to both alcohol use disorders and risk of disease progression. Polymorphisms in genes involved in alcohol metabolism (alcohol dehydrogenase and acetaldehyde dehydrogenase) and in neurotransmitter pathways (GABA receptor

### 24.46 Amount of alcohol in an average drink

Alcohol type	% Alcohol by volume	Amount	Units*
Beer	4	568 mL (1 pint)	2.3
Wine	13	175 mL	2.3
	13	750 mL	10
'Alcopops'	6	330 mL	2
Sherry	17.5	750 mL	13
Vodka/rum/gin	37.5	25 mL	1
Whisky/brandy	40	700 mL	28
	40	1 L	40

\*1 unit = 8 g.

A2) are linked to alcohol dependence. The patatin-like phospholipase domain-containing 3 (*PNPLA3*) gene, also known as adiponutrin, is an important susceptibility gene for cirrhosis in both ALD and NAFLD (see next section).

- **Nutrition.** Being either obese or underweight increases mortality in alcohol-related liver disease. Ethanol itself produces 7 kcal/g (29.3 kJ/g) and many alcoholic drinks also contain sugar, which further increases the calorific value and may contribute to weight gain. Excess alcohol consumption is also frequently associated with nutritional deficiencies such as thiamine and folate deficiency.
- **Coexistent liver disease.** Patients with coexistent chronic hepatitis C or NAFLD who drink heavily have accelerated disease progression compared with non-drinkers.

### Pathophysiology

Alcohol reaches peak blood concentrations after about 20 minutes, although this may be influenced by stomach contents. It is metabolised almost exclusively by the liver via one of two pathways (Fig. 24.30).

Approximately 80% of alcohol is metabolised by alcohol dehydrogenase to acetaldehyde, and then by aldehyde dehydrogenase to acetate. This process converts NAD (nicotinamide adenine dinucleotide) to NADH, altering the redox potential of the cell. Up to 20% of alcohol is metabolised by the microsomal ethanol-oxidising system (MEOS), predominantly through the inducible cytochrome p450 2E1, also generating acetaldehyde along with oxygen free radicals. The CYP2E1 enzyme also metabolises acetaminophen, and hence chronic alcoholics are more susceptible to hepatotoxicity from low doses of paracetamol. Acetaldehyde from either pathway is toxic and causes structural alterations of cellular proteins. This results in altered mitochondrial function and generation of reactive oxygen species, leading to oxidative stress. The altered ratio of reduced/oxidised NAD interrupts beta-oxidation of fatty acids and causes upregulation of sterol regulatory element-binding protein 1 (SREBP1), promoting fatty acid synthesis.

Damage to hepatocytes leads to stimulation of immune cells via damage-associated molecular patterns (DAMPs) such as mitochondrial DNA or necrotic debris. Alcohol also affects the gut leading to dysbiosis and increased gut permeability, delivering pathogen-associated molecular patterns (PAMPs) such as lipopolysaccharide and bacterial DNA via the portal vein which stimulate immune cells, leading to release of tumour necrosis factor alpha (TNF- $\alpha$ ) and interleukin (IL)-1, IL-2 and IL-8. All of these cytokines have been implicated in the pathogenesis of liver fibrosis (see Fig. 24.4).

The pathological features of ALD are shown in Box 24.47. The most common manifestation is accumulation of triglycerides within hepatocytes (hepatic steatosis), or alcohol-related fatty liver. This progresses in some patients to cause hepatocyte injury and inflammation, or steatohepatitis. This can present acutely with a clinical syndrome of rapid onset jaundice (alcoholic hepatitis) or can result in progressive fibrosis leading

**Fig. 24.30** Factors involved in the pathogenesis of alcohol-related liver disease. **A** Main biochemical pathways in alcohol-related liver disease. **B** Modulating factors in pathogenesis of alcohol-related liver disease. (ADH = alcohol dehydrogenase; DAMPs = damage-associated molecular patterns; FA = fatty acid; MEOS = microsomal ethanol oxidising system; NAD = nicotinamide adenine dinucleotide; NADH = NAD-hydrogen; NADP = nicotinamide adenine dinucleotide phosphate; NADPH = NADP-hydrogen; ROS = reactive oxygen species; TGF- $\beta$  = transforming growth factor beta; TNF- $\alpha$  = tumour necrosis factor alpha)

to cirrhosis; these two presentations can coexist. Iron deposition is common and does not necessarily indicate haemochromatosis. Fig. 24.31 shows the histological features of alcohol-related liver disease, which are identical to those of non-alcoholic steatohepatitis.

### Clinical features

Three types of ALD are recognised (Box 24.48) but these may overlap. Alcohol misuse may also cause damage of other organs and this should be specifically looked for (see Box 31.24). Dupuytren's contracture (thickening of the palmar fascia) is associated with chronic alcohol excess, but is not predictive of underlying liver disease.

### Alcohol-related fatty liver disease

Alcohol-related fatty liver disease (AFLD) usually presents with an incidental finding of elevated transaminases or an echogenic liver on ultrasound. It is generally asymptomatic, has a good prognosis and steatosis usually disappears within 3 months of abstinence.

### Alcoholic hepatitis

Alcoholic hepatitis (AH) presents with rapid onset jaundice in the context of recent heavy alcohol use. This is commonly associated with tender hepatomegaly and features of the systemic inflammatory response syndrome. Unlike other types of hepatitis, the ALT level is only mildly raised

### 24.47 Pathological features of alcohol-related liver disease

- Macrovesicular steatosis
- Alcoholic hepatitis:
  - Ballooning degeneration of hepatocytes
  - Neutrophil infiltration
  - Mallory's hyaline
  - Pericellular fibrosis
- Fibrous septa, leading to cirrhosis
- Lipogranuloma
- Central hyaline sclerosis
- Mega-mitochondria

(<300) and may even be normal, but the AST/ALT ratio is often greater than 1.5–2. It carries a significant short-term risk of death, often due to sepsis or renal failure. Severe AH is associated with a 15% 1-month mortality and 50% 1-year mortality. Cirrhosis may coexist in patients with acute alcoholic hepatitis. Patients often deteriorate during the first 1–3 weeks in hospital. Even if they abstain, it may take up to 6 months for jaundice to resolve. In patients presenting with jaundice who subsequently abstain, the 3- and 5-year survival is 70%. In contrast, those who continue to drink have 3- and 5-year survival rates of 60% and 34%, respectively.

#### Alcoholic cirrhosis

Palmar erythema, spider naevi and gynaecomastia are more common in alcoholic cirrhosis than in cirrhosis of other aetiologies. Alcoholic cirrhosis often presents with a serious complication, such as variceal haemorrhage or ascites, and only half of such patients will survive for 5 years from presentation. However, most who survive the initial illness and who become abstinent will survive beyond 5 years.

#### Investigations

Investigations aim to establish alcohol misuse, exclude alternative or additional coexistent causes of liver disease, and assess the

severity of liver damage. The clinical history from patient, relatives and friends is important to establish alcohol misuse duration and severity. Biological markers, particularly macrocytosis in the absence of anaemia, may suggest and support a history of alcohol misuse. A raised GGT is commonly seen in alcohol-related fatty liver and generally falls within 2–6 weeks of abstinence but is not specific and may also be elevated in the presence of other conditions, including NAFLD. Carbohydrate-deficient transferrin (CDT) is also a serum biomarker of recent alcohol excess.

The extent of fibrosis can be assessed using either serum fibrosis markers or transient elastography. A liver biopsy is occasionally required if there is diagnostic uncertainty.

In alcoholic hepatitis, a number of prognostic scoring systems are available. The prothrombin time (PT) and bilirubin are used to calculate a 'modified discriminant function' (mDF), also known as the Maddrey score, which enables the clinician to assess prognosis (serum bilirubin in  $\mu\text{mol/L}$  is divided by 17 to convert to  $\text{mg/dL}$ ):

$$DF = [4.6 \times \text{Increase in PT (sec)}] + \text{Bilirubin (mg/dL)}$$

### 24.48 Clinical syndromes of alcohol-related liver disease

#### Fatty liver (> 90%)

- Asymptomatic abnormal liver enzymes
- Bright (echogenic) liver on ultrasound

#### Alcoholic hepatitis (10%–35%)

- Rapid onset jaundice
- High short-term mortality
- Coagulopathy
- Tender hepatomegaly

#### Cirrhosis (10%–20%)

- Stigmata of chronic liver disease
- Nodular liver (large, normal or small)
- Ascites/varices/encephalopathy
- Risk of hepatocellular carcinoma

**Fig. 24.31** Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH). Rate of progression is determined by environmental (dietary) and genetic factors. (FA = fatty acid; TGF- $\beta$  = transforming growth factor beta; TNF- $\alpha$  = tumour necrosis factor alpha; VLDL = very low-density lipoprotein)

A value over 32 implies severe disease. Historically, this group had a 40%–50% 1 month mortality but this has dropped to 15% in a recent large study, reflecting improved medical management. A second scoring system, the Glasgow Alcoholic Hepatitis Score, uses the age, white cell count and renal function, in addition to PT and bilirubin, to assess prognosis (Box 24.49). A score of 9 or more identifies an even higher risk group with a 60% 1-month mortality.

### Management

Cessation of alcohol consumption is the single most important treatment and prognostic factor. Life-long abstinence is the best advice. General health and life expectancy are improved when this occurs, irrespective of the stage of liver disease. Abstinence is even effective at preventing progression, hepatic decompensation and death once cirrhosis is present. Treatment of alcohol dependency is discussed Chapter 31. In the acute presentation of ALD it is important to identify and anticipate alcohol withdrawal and Wernicke's encephalopathy, in parallel with the liver disease.

### Nutrition

Nutrition is very important, and calorie intake correlates with survival in severe alcoholic hepatitis. Enteral feeding via a fine-bore nasogastric tube may be needed in patients unable to meet their requirements.

### Drug therapy

The optimal treatment of severe alcoholic hepatitis (Maddrey's discriminative score >32) has been widely debated. The STOPAH study was a large, multicentre, double-blind, randomised trial in patients with a clinical diagnosis of severe alcoholic hepatitis. This showed no effect of pentoxifylline (a weak anti-TNF agent) on survival. There was a borderline reduction in 28-day mortality with prednisolone, but no benefit by 3 months or 1 year. Prednisolone was associated with increased rates of sepsis and gastrointestinal bleeding. N-acetyl cysteine (NAC) may also limit oxidative stress but initial trials failed to show any benefit. A single trial has suggested a benefit of intravenous NAC in patients also treated with prednisolone. If the bilirubin has not fallen 7 days after starting glucocorticoids, the drugs are unlikely to reduce mortality and should be stopped.

### Liver transplantation

ALD is a common indication for liver transplantation in Europe and the United States. The outcome of transplantation for ALD is good, with survival rates similar to other indications and if the patient remains abstinent there is no risk of disease recurrence. The challenge is to identify patients with an unacceptable risk of returning to harmful alcohol consumption. Many programmes require a 6-month period of abstinence from alcohol before a patient is considered for transplantation. Although duration of abstinence is only one factor in predicting risk of relapse and the length

required is debatable, a period of abstinence will allow recovery of liver function sufficient to avoid transplantation in some, as well as identify those at highest risk of early recidivism. Transplantation for alcoholic hepatitis has been described in highly selected individuals with acceptable short-term outcomes but it is seldom performed due to concerns about longer-term risk of recidivism.

## Non-alcoholic fatty liver disease

Increasingly sedentary lifestyles and changing dietary patterns mean that the prevalence of obesity and insulin resistance has increased worldwide, and so fat accumulation in the liver is a common finding during abdominal imaging studies and on liver biopsy. This results in a similar spectrum of liver disease to alcohol excess, so when these changes were observed in the absence of high alcohol consumption, this was called non-alcoholic fatty liver disease (NAFLD).

NAFLD includes a spectrum of progressive liver disease. The majority will have fatty infiltration alone (steatosis) but a minority (10%–20%) will develop accompanying inflammation (non-alcoholic steatohepatitis, NASH) and/or fibrosis, and may progress to cirrhosis and primary liver cancer. NAFLD is considered by many to be the hepatic manifestation of the 'metabolic syndrome' as it is strongly associated with obesity, type 2 diabetes, dyslipidaemia and hypertension. Initial definitions used a threshold of alcohol consumption (typically 28 units per week for men or 21 units for women) for diagnosis. However, an alternative nomenclature of metabolic (dysfunction)-associated fatty liver disease, or MAFLD, has recently been proposed to reflect our better understanding of the risk factors and to describe those patients in whom this coexists with alcohol excess.

Overall, NAFLD is estimated to have a global prevalence of 24%. A large European study found NAFLD to be present in 94% of obese patients (body mass index (BMI) >30 kg/m<sup>2</sup>), 67% of overweight patients (BMI >25 kg/m<sup>2</sup>) and 25% of normal-weight patients. The overall prevalence of NAFLD in patients with type 2 diabetes ranges from 40% to 70%. The frequency of steatosis varies with ethnicity (45% in patients of Hispanic origin, 33% in those of European ancestry and 24% in those of African ancestry) and gender (in those of European descent, 42% males vs 24% females).

Fibrosis is the main determinant of outcome. Patients with cirrhosis have a high risk of liver-related adverse outcomes, whereas those with less advanced fibrosis are more likely to have extra-hepatic cancers and vascular events. Patients with NASH have significantly higher rates of fibrosis progression than those with simple steatosis. Due to its increasing prevalence, NAFLD cirrhosis is predicted to become the main aetiology in patients undergoing liver transplantation during the next 5 years.

### Pathophysiology

The initiating events in NAFLD are typically based on the development of obesity and insulin resistance, leading to increased hepatic free fatty acid flux. This imbalance between the rate of import/synthesis and the rate of export/catabolism of fatty acids in the liver leads to the development of steatosis. This may be an adaptive response through which hepatocytes store potentially toxic lipids as relatively inert triglyceride. A 'two-hit' hypothesis has been proposed to describe the pathogenesis of NAFLD, the 'first hit' causing steatosis that then progresses to NASH or fibrosis if a 'second hit' occurs. In reality, progression probably follows hepatocellular injury caused by a combination of several different 'hits', including:

- oxidative stress due to free radicals produced during fatty acid oxidation
- direct lipotoxicity from fatty acids and other metabolites in the liver
- endoplasmic reticulum stress
- gut-derived endotoxin
- cytokine release (TNF- $\alpha$  etc.) and immune-mediated hepatocellular injury.

24.49 How to assess prognosis using the Glasgow Alcoholic Hepatitis Score			
Score	1	2	3
Age	< 50	> 50	
White cell count ( $\times 10^9/L$ )	< 15	> 15	
Urea (mmol/L) (BUN mg/dl)	< 5 (14)	> 5 (14)	
PT ratio	< 1.5	1.5–2.0	> 2.0
Bilirubin ( $\mu\text{mol/L}$ ) (mg/dL)	< 125 (7.4)	125–250 (7.4–14.8)	> 250 (14.8)
A score of $\geq 9$ is associated with a 40% 28-day survival, compared to 80% for patients with a score of < 9.			
(BUN = blood urea nitrogen; PT = prothrombin time)			

Cellular damage triggers cell death and inflammation, which leads to stellate cell activation and development of hepatic fibrosis that culminates in cirrhosis (see Fig. 24.31).

As with many other liver diseases, genetic and environmental factors interact to determine disease progression:

- **Genetics.** Several genetic modifiers of disease severity have been identified, with *PNPLA3* and its product, adiponutrin, being the best validated.
- **Demographics.** Cirrhosis is more common with increasing age, although possibly just reflecting longer duration of disease. Higher rates of fibrosis progression are observed in men and post-menopausal women.
- **Diet.** Excessive alcohol consumption leads to increased fibrosis progression, whereas coffee consumption appears to be protective against fibrosis and HCC in NAFLD.
- **Intestinal microbiota.** Obesity, diabetes and NAFLD are all linked with gut dysbiosis, with several microbial signatures associated with advanced fibrosis. The gut microbiome may influence intestinal permeability and delivery of pathogen-associated molecular patterns (PAMPs) through the portal circulation that trigger liver inflammation.
- **Comorbidity.** The presence of type 2 diabetes and severe obesity are associated with higher rates of cirrhosis in NAFLD.

NAFLD should not be confused with acute fatty liver, which can occur in hepatic mitochondrial cytopathies, e.g. acute fatty liver of pregnancy or drug toxicity (sodium valproate, tetracyclines), or with bacterial toxins (e.g. *Bacillus cereus*). In these, defective mitochondrial beta-oxidation of lipids leads to fat droplet accumulation in hepatocytes and microvesicular steatosis.

### Clinical features

NAFLD is frequently asymptomatic, although it may be associated with fatigue and mild right upper quadrant discomfort. It is commonly identified as an incidental biochemical abnormality during routine blood tests or as a fatty liver on abdominal imaging. Alternatively, patients may present late in the natural history of the disease with complications of cirrhosis and portal hypertension, such as variceal haemorrhage, or with hepatocellular carcinoma.

The average age of NAFLD cirrhosis patients is currently 50–60 years; however, the emerging epidemic of childhood obesity means that NAFLD is present in increasing numbers of younger patients. NAFLD is also associated with polycystic ovary syndrome and obstructive sleep apnoea.

### Investigations

Investigation of patients with suspected NAFLD should aim to confirm the presence of fat in the liver and determine the extent of fibrosis. It is important to assess alcohol consumption as a contributory factor and check for medications that cause fatty liver, such as tamoxifen, amiodarone and corticosteroids. Investigations should exclude other coexistent liver diseases (including viral, autoimmune and inherited causes).

### Biochemical tests

There is no single diagnostic blood test for NAFLD. Serum GGT is often raised. ALT and AST may be normal or modestly raised, usually less than twice the upper limit of normal. ALT levels fall as hepatic fibrosis increases and the normal AST:ALT ratio of < 1 reverses as advanced fibrosis develops. Other laboratory abnormalities that may be present include low-titre antinuclear antibody (ANA) in 20%–30% of patients and elevated ferritin levels.

Although routine blood tests are unable to determine the degree of liver fibrosis accurately, several calculated scores, such as the NAFLD Fibrosis Score and FIB-4 Score, which are based on the results of routinely available blood tests and anthropometrics, have a high negative predictive value for advanced fibrosis/cirrhosis (Box 24.50). A low score can therefore be used to rule out advanced fibrosis in many NAFLD

patients, allowing care to focus on those most likely to have advanced disease. Specific serum fibrosis markers such as the Enhanced Liver Fibrosis panel may also be used.

### Imaging

Ultrasound is most often used and provides a qualitative assessment of hepatic fat content, as the liver appears 'bright' due to increased echogenicity; however, sensitivity is limited when fewer than 33% of hepatocytes are steatotic. CT, MRI or MR spectroscopy offer greater sensitivity for detecting lesser degrees of steatosis, but these are resource-intensive and not widely used. No routine imaging modality can distinguish simple steatosis from steatohepatitis or accurately quantify hepatic fibrosis short of cirrhosis.

### Transient elastography

Transient elastography (TE) is often used to assess those with indeterminate fibrosis scores. Liver stiffness can predict the likelihood of advanced fibrosis and is well validated in NAFLD, although readings may get less reliable with BMI over 40. Controlled Attenuation Parameter (CAP) is an ultrasound-based technique which can be performed simultaneously with TE to quantify steatosis non-invasively.

### Liver biopsy

Although it is frequently not required for either diagnosis or staging, liver biopsy remains the 'gold standard' investigation for diagnosis and assessment of degree of inflammation and extent of liver fibrosis. The histological changes seen in NAFLD are identical to those described in ALD (see previous section). The definition of NASH is based on a combination of three lesions (steatosis, hepatocellular injury and inflammation; see Fig. 24.31) with a mainly centrilobular, acinar zone 3 distribution. Perisinusoidal fibrosis is a characteristic feature of NAFLD. Histological scoring systems are widely used to assess both necroinflammation and fibrosis severity semi-quantitatively.

It is important to note that hepatic fat content tends to diminish as cirrhosis develops and so NAFLD is likely to be under-diagnosed in the setting of advanced liver disease, where it is thought to be the underlying cause of 30%–75% of cases in which no specific aetiology is readily identified (so-called 'cryptogenic cirrhosis').

24.50 Simple non-invasive scores for NAFLD/fibrosis <sup>1</sup>			
Test	Key variables	Thresholds	
		Age < 65 yr	Age > 65 yr

FIB-4: an inexpensive and accurate marker of fibrosis in HCV infection. comparison with liver biopsy and fibrotest. Hepatology 2007; 46(1):32–36.*

## Management

As it is a marker of the metabolic syndrome, identification of NAFLD should prompt screening for and treatment of cardiovascular risk factors in all patients. It is also necessary to assess whether patients have advanced fibrosis so that liver-targeted treatment can be focused particularly on those patients. An example of an algorithm for the assessment and risk stratification of patients with NAFLD is provided in Fig. 24.32.

### Non-pharmacological treatment

Current treatment comprises lifestyle interventions to promote weight loss and improve insulin sensitivity through dietary changes and physical exercise. Sustained weight reduction of 7%–10% is associated with significant improvement in histological and biochemical NASH severity. However, this is only achieved by a small proportion of patients, focusing attention on other strategies. A Mediterranean diet pattern and reduced fructose consumption may also be helpful.

### Pharmacological treatment

No pharmacological agents are currently licensed specifically for NAFLD therapy. Treatment directed at coexisting metabolic disorders, such as dyslipidaemia and hypertension, should be given. Although HMG-CoA reductase inhibitors (statins) do not ameliorate NAFLD, there does not appear to be any increased risk of hepatotoxicity or other side-effects, and so they may be used safely to treat dyslipidaemia. Specific insulin-sensitising agents, in particular glitazones, may help selected patients. Positive results with high-dose vitamin E (800 U/day) have been tempered by evidence that high doses may be associated with an increased risk of prostate cancer and all-cause mortality, which has limited its use. Obeticholic acid, a farnesoid X receptor agonist, appears to improve fibrosis in non-cirrhotic NASH in an interim analysis but the trial is ongoing. Several other new medicines are currently in late-phase clinical trials and so liver-targeted pharmacological treatments are likely to be available within the next few years.

## Autoimmune liver and biliary disease

The liver is an important target for autoimmune injury. The clinical picture is dictated by the nature of the autoimmune process and, in particular, the target cell for immune injury. The disease patterns are quite distinctive for primary hepatocellular injury (autoimmune hepatitis) and biliary epithelial cell injury (primary biliary cholangitis and primary sclerosing cholangitis).

### Autoimmune hepatitis

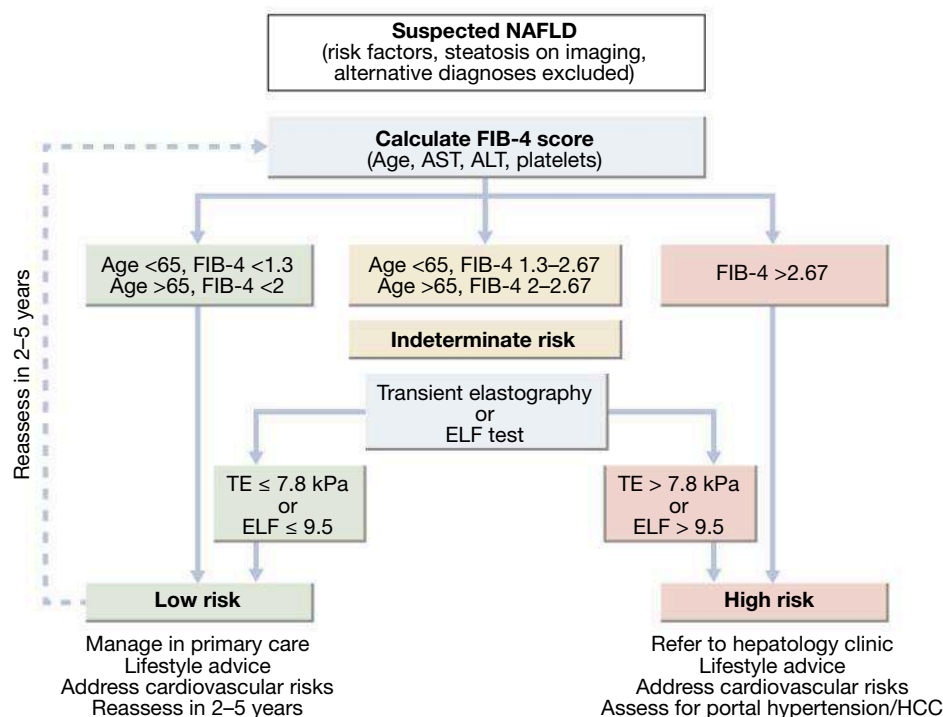

Autoimmune hepatitis (AIH) is a disease of immune-mediated injury targeting hepatocytes, which can present either as an acute severe hepatitis or chronic hepatitis leading to cirrhosis. It is a lifelong disease which often runs a relapsing and remitting course. It can develop at any age, with peaks around the second and sixth decades. It is more common in women with a 5:1 predominance. It has a strong association with other autoimmune diseases (Box 24.51).

### Pathophysiology

It is characterised by the presence of serum antibodies and peripheral blood T lymphocytes reactive with self-proteins, and high levels of serum immunoglobulins – in particular, IgG. The reasons for the breakdown in immune tolerance in autoimmune hepatitis remain unclear. There are strong HLA associations (typically DR3 and DR4), indicating an underlying genetic predisposition, with a presumed environmental trigger. Exposure to the antibiotic nitrofurantoin can induce autoimmune hepatitis in a small number of cases, and cross-reactivity to viruses such as HAV and EBV has been proposed as an alternative trigger.

### Clinical features

Some patients may be asymptomatic, with a raised ALT detected on blood tests. The onset of symptoms is usually insidious, with fatigue, anorexia and arthralgia. The non-specific nature of the early features can lead to the diagnosis being missed in the early disease stages. In about one-quarter of patients the onset is acute, resembling viral hepatitis, but

**Fig. 24.32** Assessment and risk stratification of patients with non-alcoholic fatty liver disease (NAFLD). (ALT = alanine aminotransferase; AST = aspartate aminotransferase; ELF = enhanced liver fibrosis; FIB-4 = fibrosis-4; HCC = hepatocellular carcinoma; TE = transient elastography)

### 24.51 Conditions associated with autoimmune hepatitis

- Autoimmune thyroiditis
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Primary sclerosing cholangitis
- Coeliac disease
- Type 1 diabetes
- Dermatomyositis
- Coombs-positive haemolytic anaemia
- Ulcerative colitis

### 24.52 Frequency of autoantibodies in chronic non-viral liver diseases and in healthy people

Disease	Antinuclear antibody (%)	Anti-smooth muscle antibody (%)	Antimitochondrial antibody*
Healthy controls	5	1.5	0.01
Autoimmune hepatitis	80	70	15
Primary biliary cholangitis	25	35	95
Cryptogenic cirrhosis	40	30	15

\*Patients with antimitochondrial antibody frequently have cholestatic liver function tests and may have primary biliary cholangitis (see text).

resolution does not occur. This acute presentation can lead to extensive liver necrosis and liver failure. Signs of chronic liver disease, especially spider naevi and hepatosplenomegaly, can be present. Approximately 25% of patients will have cirrhosis at diagnosis, and some will progress to cirrhosis despite treatment.

#### Investigations

There is no single diagnostic test for autoimmune hepatitis. Liver enzymes typically show raised ALT and AST, although these fluctuate. Serological tests for autoantibodies are often positive (Box 24.52). The most frequently seen autoantibody pattern is high titre of antinuclear and/or anti-smooth muscle antibodies, typically associated with raised IgG levels, frequently seen in young adult females. Disease characterised by the presence of anti-liver-kidney microsomal (LKM) antibodies, recognising cytochrome P450-IID6 expressed on the hepatocyte membrane, is typically seen in paediatric populations and can be more resistant to treatment than ANA-positive disease. More recently, a pattern of antibody reactivity with anti-soluble liver antigen (anti-SLA) has been described typically in adult patients, often with aggressive disease and lacking autoantibodies of other specificities.

It should be noted that low titres of these antibodies occur in some healthy people and in patients with other inflammatory liver diseases. ANA also occur in connective tissue diseases and other autoimmune diseases (with an identical pattern of homogenous nuclear staining) while anti-smooth muscle antibody has been reported in infectious mononucleosis, chronic hepatitis C infection and a variety of malignant diseases.

Elevated serum IgG levels are an important diagnostic and treatment response feature if present, but the diagnosis is still possible in the presence of normal IgG levels. If the diagnosis of autoimmune hepatitis is suspected, liver biopsy should be performed both to confirm the diagnosis before commencing long-term immunosuppression and to stage any liver fibrosis. It typically shows an abundance of lymphocytes and plasma cells around the portal tracts (portal lymphoplasmacytic hepatitis) with inflammation extending out from the edge of the portal tracts into the lobule (interface hepatitis). Scoring systems, such as the International Autoimmune Hepatitis Group (IAIHG) criteria, are useful for epidemiological study and for assessing trial eligibility but are complex for normal clinical practice.

#### Management

Treatment with glucocorticoids is life-saving in autoimmune hepatitis, particularly during exacerbations of active and symptomatic disease. Initially, prednisolone (30–40 mg/day) is given orally; the dose is then gradually reduced as the patient and LFTs improve. Budesonide may be used in non-cirrhotic patients if steroid side-effects are problematic. Maintenance therapy is usually with azathioprine (1–2 mg/kg daily), although introduction of this is often delayed by around a month to allow the liver enzymes to settle in case it causes drug-induced hepatotoxicity. Maintenance azathioprine can be used as monotherapy, or may be combined with low-dose prednisolone (ideally, below 5 mg/day). Second-line therapies are unlicensed with little long-term outcome data. However, in case series, mycophenolate mofetil (MMF) appears effective in patients who are azathioprine-intolerant, but less so in azathioprine non-responders. Similarly, tacrolimus appears helpful in refractory disease.

The aims of treatment are to achieve resolution of symptoms and to completely control inflammatory activity to prevent progressive fibrosis, especially in younger patients or those with cirrhosis. As flares may be asymptomatic but increase the risk of cirrhosis or decompensation, disease activity (indicated by rising ALT and IgG levels) should be monitored regularly. Maintenance treatment is required for at least 3 years and is often continued long term, as relapse rates are high if immunosuppression is withdrawn.

#### Primary biliary cholangitis

Primary biliary cholangitis (PBC, formerly known as primary biliary cirrhosis until 2015, when the name was changed to reflect the large proportion of non-cirrhotic patients) is a chronic, progressive cholestatic liver disease that predominantly affects women aged 30 and over. It is strongly associated with the presence of antimitochondrial antibodies (AMA), which in combination with cholestatic liver enzymes are diagnostic of PBC. It is characterised by granulomatous inflammation of the portal tracts, leading to progressive damage and eventually loss of the small and middle-sized bile ducts. This, in turn, leads to fibrosis and cirrhosis of the liver.

#### Epidemiology

The prevalence of PBC varies across the world. It is relatively common in northern Europe and North America but is rare in Africa and Asia. There is a strong female-to-male predominance of 9:1; it is also more common among cigarette smokers. Clustering of cases has been reported, suggesting an environmental trigger in susceptible individuals.

#### Pathophysiology

Immune mechanisms are clearly involved. The condition is closely associated with other autoimmune non-hepatic diseases, such as thyroid disease, and there is a genetic association with HLA-DR8, together with polymorphisms in a number of other genes regulating the nature of the immune response (e.g. IL-12 and its receptor). AMA is directed at pyruvate dehydrogenase complex, a mitochondrial enzyme complex that plays a key role in cellular energy generation. PBC-specific ANAs (such as those directed at the nuclear pore antigen gp210) have a characteristic staining pattern in immunofluorescence assays (selectively binding to the nuclear rim or nuclear dots), which means that they should not be mistaken for the homogeneously staining ANA seen in autoimmune hepatitis. Increases in serum immunoglobulin levels are frequent but, unlike in autoimmune hepatitis, it is typically IgM that is elevated.

Pathologically, chronic granulomatous inflammation destroys the interlobular bile ducts; progressive lymphocyte-mediated inflammatory damage causes fibrosis, which spreads from the portal tracts to the liver parenchyma and eventually leads to cirrhosis.

#### Clinical features

PBC may be detected incidentally on routine blood tests, but systemic symptoms such as fatigue and generalised itch are common. The severity of these symptoms does not correlate with the severity of the liver

disease. Although there may be right upper abdominal discomfort, the typical biliary-type pain, fever and rigors seen with bacterial cholangitis do not occur in PBC. Bone pain or fractures can rarely result from osteomalacia (fat-soluble vitamin malabsorption) or, more commonly, from osteoporosis. Xanthomatous deposits occur in a minority, especially around the eyes. Scratch marks may be found in patients with severe pruritus.

### Associated diseases

Autoimmune and connective tissue diseases occur with increased frequency in PBC, particularly the sicca syndrome, systemic sclerosis, coeliac disease and thyroid diseases. Hypothyroidism should always be considered in patients with fatigue.

### Diagnosis and investigations

The LFTs show a pattern of cholestasis (see [Box 24.2](#)). Hypercholesterolaemia is common and worsens as disease progresses but appears not to be associated with increased cardiovascular risk. AMA is present in over 95% of patients; when it is absent, the diagnosis should not be made without obtaining histological evidence and considering cholangiography (typically MRCP) to exclude other biliary disease. Due to the peripheral nature of the ducts affected by PBC, the biliary tree should appear normal on imaging. ANA and anti-smooth muscle antibodies are present in around 15% of patients (see [Box 24.52](#)); autoantibodies found in associated diseases may also be present. Fibrosis stage should be assessed, usually using transient elastography. Liver biopsy is necessary only if there is diagnostic uncertainty. The histological features of PBC correlate poorly with the clinical features; portal hypertension can develop before the histological onset of cirrhosis.

### Management

The hydrophilic bile acid ursodeoxycholic acid (UDCA), at a dose of 13–15 mg/kg daily, improves bile flow, replaces toxic hydrophobic bile acids in the bile acid pool and reduces apoptosis of the biliary epithelium. Clinically, UDCA improves LFTs, may slow down histological progression and has few side-effects; it is therefore widely used in the treatment of PBC and should be regarded as the optimal first-line treatment. Eighty percent of patients will have a good biochemical response to UDCA with a reduction in serum alkaline phosphatase to normal or near-normal levels, and this corresponds to very good long-term outcomes. However, a significant minority of patients, especially those presenting under the age of 50 years, show an inadequate response to UDCA, and have an increased risk of developing end-stage liver disease. Obeticholic acid (OCA) is a second-generation bile acid therapeutic that acts as an agonist for the nuclear farnesoid X receptor. It improves alkaline phosphatase in more than half of patients who did not respond to or tolerate UDCA, and is licensed for second-line therapy in PBC. Bezafibrate, a peroxisome proliferator-activated receptor- $\alpha$  (PPAR $\alpha$ ) agonist used predominantly to treat hyperlipidaemia, has also been shown to improve alkaline phosphatase in the majority of UDCA non-responders, although it is not licensed for this use. Due to the short-term nature of the studies, neither drug has yet been shown to alter clinically significant outcomes. Despite the autoimmune aetiology, immunosuppressants, such as glucocorticoids, azathioprine, penicillamine and ciclosporin, have all failed to show any overall benefit when given to unselected PBC patients.

Liver transplantation should be considered once liver failure has developed and may also be indicated in patients with intractable pruritus. Serum bilirubin remains the most reliable marker of declining liver function. Transplantation is associated with an excellent 5-year survival of over 80%, although the disease will recur in over one-third of patients at 10 years.

### Pruritus

This is the main symptom requiring treatment. The cause is unknown, but up-regulation of opioid receptors and increased levels of endogenous opioids may play a role. First-line treatment is with the anion-binding resin colestyramine, which probably acts by binding potential

pruritogens in the intestine and increasing their excretion in the stool. A dose of 4–16 g/day orally is used. The powder is mixed in orange juice and the main dose (8 g) taken before and after breakfast, when maximal duodenal bile acid concentrations occur. Colestyramine may bind other drugs in the gut (most obviously UDCA) and adequate spacing should be used between drugs. Colestyramine is sometimes ineffective and can be difficult for some patients to tolerate. Alternative treatments include rifampicin (150 mg/day, titrated up to a maximum of 600 mg/day as required with close monitoring of LFTs), naltrexone (an opioid antagonist; 25 mg/day initially, increasing up to 300 mg/day), plasmapheresis and a liver support device (e.g. a molecular adsorbent recirculating system, MARS).

### Fatigue

Fatigue affects about one-third of patients with PBC. The cause is unknown but it may reflect intracerebral changes due to cholestasis. Unfortunately, once depression, hypothyroidism and coeliac disease have been excluded, there is currently no specific treatment. The impact on patients' lives can be substantial.

### Malabsorption

Prolonged cholestasis is associated with steatorrhoea and malabsorption of fat-soluble vitamins, which should be replaced as necessary. Coeliac disease should be excluded since its incidence is increased in PBC.

### Bone disease

Osteopenia and osteoporosis are common and normal post-menopausal bone loss is accelerated. Baseline bone density should be measured and treatment started with replacement calcium and vitamin D<sub>3</sub>. Bisphosphonates should be used if there is evidence of osteoporosis. Osteomalacia is rare.

## Overlap syndromes

### AMA-negative PBC ('autoimmune cholangitis')

A few patients demonstrate the clinical, biochemical and histological features of PBC but do not have detectable AMA in the serum. Serum transaminases, serum immunoglobulin levels and titres of ANA tend to be higher than in AMA-positive PBC. The clinical course mirrors classical PBC, however, and these patients should be considered as having a variant of PBC.

### PBC/autoimmune hepatitis overlap

A few patients with AMA and cholestatic LFTs have elevated transaminases, high serum immunoglobulin IgG levels and interface hepatitis on liver histology. In such individuals, a trial of glucocorticoid therapy may be beneficial.

## Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is an immune-mediated cholestatic liver disease characterised by multifocal stricturing of the larger bile ducts of the extra- and/or intrahepatic biliary tree, often in association with inflammatory bowel disease. This is also associated with progressive hepatic fibrosis which can lead to cirrhosis and portal hypertension, along with an increased risk of various cancers (cholangiocarcinoma, gallbladder, colon).

The incidence is about 6.3/100 000 in people of European ancestry. Unlike most other autoimmune diseases, PSC is twice as common in men as women. Most patients present at age 25–40 years, although the condition may be diagnosed at any age and is an important cause of chronic liver disease in children. The generally accepted diagnostic criteria are:

- generalised beading and stenosis of the biliary system on cholangiography ([Fig. 24.33](#))
- absence of choledocholithiasis (or history of bile duct surgery)
- exclusion of bile duct cancer, by prolonged follow-up.

The term 'secondary sclerosing cholangitis' is used to describe the typical changes described above when a clear predisposing factor for duct fibrosis can be identified. The causes of secondary sclerosing cholangitis are shown in [Box 24.53](#).

### Pathophysiology

The cause of PSC is unknown but there is a close association with inflammatory bowel disease, particularly ulcerative colitis ([Box 24.54](#)). About 70%–80% of PSC patients have coexisting ulcerative colitis, and PSC is the most common form of chronic liver disease in ulcerative colitis. Between 3% and 10% of patients with ulcerative colitis develop PSC, particularly those with extensive colitis or pancolitis. The distribution of PSC-associated colitis is often predominantly right-sided with relative distal sparing, and may be less symptomatic than non-PSC IBD. The prevalence of PSC is lower in patients with Crohn's colitis (about 1%). Patients with PSC and ulcerative colitis are at greater risk of colorectal neoplasia than those with ulcerative colitis alone, and individuals who develop colorectal neoplasia are at greater risk of cholangiocarcinoma.

PSC is thought to be an immunologically mediated disease, triggered in genetically susceptible individuals by toxic or infectious agents, which may gain access to the biliary tract through a leaky, diseased colon. A close link has been identified with HLA haplotype A1-B8-DR3-DRW52A, which is commonly found in association with other organ-specific autoimmune diseases (e.g. autoimmune hepatitis).

**Fig. 24.33** Magnetic resonance cholangiopancreatogram showing typical changes of primary sclerosing cholangitis. There is intrahepatic bile duct beading, stricturing and dilatation. The extrahepatic bile duct is also diffusely strictured. Courtesy of Dr Dilip Patel, Royal Infirmary of Edinburgh.

### 24.53 Causes of secondary sclerosing cholangitis

- Previous bile duct surgery with stricturing and cholangitis
- Bile duct stones causing cholangitis
- Traumatic or ischaemic bile duct injury
- Critical illness ischaemic cholangiopathy
- Intrahepatic infusion of 5-fluorodeoxyuridine
- Insertion of formalin into hepatic hydatid cysts
- Insertion of alcohol into hepatic tumours
- Parasitic infections (e.g. *Clonorchis*)
- Autoimmune pancreatitis/immunoglobulin G4-associated cholangitis
- Acquired immunodeficiency syndrome (AIDS; probably infective as a result of cytomegalovirus or *Cryptosporidium*)

Perinuclear antineutrophil cytoplasmic antibodies (ANCA) have been detected in the sera of 60%–80% of patients with PSC with or without ulcerative colitis, and in 30%–40% of patients with ulcerative colitis alone. The antibody is not specific for PSC and is found in other chronic liver diseases (e.g. 50% of patients with autoimmune hepatitis), so is of little diagnostic use on its own.

### Clinical features

The diagnosis is often made incidentally when persistently raised serum ALP is discovered in an individual with ulcerative colitis. Patients may present with episodes of biliary obstruction, or with symptoms of cirrhosis or portal hypertension. Common symptoms include fatigue, intermittent jaundice, weight loss, right upper quadrant abdominal pain and pruritus. Attacks of acute cholangitis are uncommon and usually follow biliary instrumentation.

### Investigations

Biochemical screening usually reveals a cholestatic pattern of LFTs but ALP and bilirubin levels may vary widely in individual patients during the course of the disease. For example, ALP and bilirubin values increase during acute cholangitis, decrease after therapy and sometimes fluctuate for no apparent reason. Modest elevations in serum transaminases are usually seen, whereas hypoalbuminaemia and clotting abnormalities are found at a late stage only. In addition to ANCA, low titres of serum ANA and anti-smooth muscle antibodies may be found in PSC but have no diagnostic significance; serum AMA is absent.

The key investigation is MRCP, which is usually diagnostic and reveals multiple irregular stricturing and dilatation (see [Fig. 24.33](#)). ERCP should be reserved for therapeutic interventions.

On liver biopsy, the characteristic early features of PSC are periductal 'onion skin' fibrosis and inflammation, with portal oedema and bile ductular proliferation resulting in expansion of the portal tracts ([Fig. 24.34](#)). Later, fibrosis spreads, progressing inevitably to biliary cirrhosis; obliterative cholangitis leads to the so-called 'vanishing bile duct syndrome'.

The link with IBD and associated colon cancer risk is sufficiently strong that all patients diagnosed with PSC should undergo an initial colonoscopy, even in the absence of bowel symptoms.

### Management

There is no cure for PSC but management of cholestasis and its complications and specific treatment of the disease process are indicated. UDCA is widely used, although the evidence to support this is limited. UDCA may have benefit in terms of reducing colon carcinoma risk.

The course of PSC is variable. Overall, the median time from diagnosis to death or transplant is around 20 years. Prognosis is worse in

### 24.54 Comparison of primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC)

	PBC	PSC
Gender (F:M)	9:1	1:3
Age	Older: median age 50–55 years	Younger: median age 20–40 years
Disease associations	Non-organ-specific autoimmune disease (e.g. Sjögren syndrome) and autoimmune thyroid disease	Ulcerative colitis
Autoantibody profile	90% AMA +ve	65%–85% pANCA +ve (but this is non-specific and not diagnostic)
Predominant bile-duct injury	Intrahepatic	Extrahepatic > intrahepatic
(AMA = antimitochondrial antibody; pANCA = perinuclear antineutrophil cytoplasmic antibody)		

**Fig. 24.34 Primary sclerosing cholangitis.** Note onion skin scarring (arrows) surrounding a bile duct.

symptomatic patients, possibly reflecting a later disease stage at diagnosis. In recent series, the leading cause of death in PSC is cholangiocarcinoma (58% of deaths), with lower rates attributable to liver failure (30%) and variceal bleeding (9%). Immunosuppressive agents, including prednisolone, azathioprine, methotrexate and ciclosporin, have been tried; results have generally been disappointing.

Symptomatic patients often have pruritus. Management is as for PBC. Fatigue appears to be less prominent than in PBC, although it is still present in some patients.

#### Cancer screening

Patients with PSC should have annual ultrasound scans to assess for gallbladder polyps, to aid early detection of gallbladder cancer. Patients with PSC and colitis should undergo annual colonoscopy to screen for colorectal cancer. There is not an established role for routine screening for cholangiocarcinoma with either imaging or serum CA19-9 levels, due to both the low specificity and the low likelihood of successful intervention, even with earlier diagnosis.

#### Management of complications

Broad-spectrum antibiotics (e.g. ciprofloxacin) should be given for acute attacks of cholangitis. If new symptoms or worsening liver tests, non-invasive imaging such as MRCP and/or contrast CT should be performed to assess for a dominant stricture (which may be either inflammatory or malignant). If a dominant stricture is associated with either jaundice or infection, ERCP may be performed for sampling (via brush cytology) to exclude cholangiocarcinoma and to relieve the obstruction, usually through balloon dilatation rather than stenting. Fat-soluble vitamin replacement is necessary in jaundiced patients. Metabolic bone disease (usually osteoporosis) is a common complication that requires treatment.

#### Surgical treatment

Surgical resection of the extrahepatic bile duct and biliary reconstruction have a limited role in the management of non-cirrhotic patients with dominant extrahepatic disease. Orthotopic transplantation is the only surgical option in patients with advanced liver disease; 5-year survival is 80%–90% in most centres. Unfortunately, the condition may recur in the graft in around 20% of patients and there are no identified therapies able to prevent this. Cholangiocarcinoma is a contraindication to transplantation. Colon carcinoma risk persists following transplantation (and may be increased because of immunosuppression) so colonoscopic surveillance should continue.

A comparison of PBC and PSC is shown in [Box 24.53](#).

### IgG4-associated cholangitis

This disease (as well as its nomenclature) is closely related to autoimmune pancreatitis (which is present in more than 90% of the patients).

### 24.55 Manifestations of IgG4-related disease

- Autoimmune pancreatitis
- Sialadenitis (especially submandibular gland)
- Dacryoadenitis (lacrimal gland)
- Retroperitoneal fibrosis
- Riedel's thyroiditis
- Retro-orbital tumours
- Periaortitis and periarteritis

IgG4-associated cholangitis (IAC) often presents in middle-aged to older men with obstructive jaundice (due to either hilar stricturing/intrahepatic sclerosing cholangitis or a low bile duct stricture). Cholangiographic appearances can resemble PSC or hilar cholangiocarcinoma. Patients may have past or concurrent evidence of IgG4 disease in other organs ([Box 24.55](#)). The serum IgG4 is often raised and liver biopsy shows a lymphoplasmacytic infiltrate, with IgG4-positive plasma cells. It is important not to miss the diagnosis as it responds well to glucocorticoid therapy, often with complete normalisation of liver enzymes and resolution of strictures on serial imaging.

### Liver tumours and other focal liver lesions

Identification of a hepatic mass lesion is common, both in patients with known pre-existing liver disease and as a primary presentation. Although primary and secondary malignant tumours are important potential diagnoses, benign disease is frequent. The critical steps to be taken in diagnosing hepatic mass lesions are:

- determining the presence, nature and severity of any underlying chronic liver disease, as the differential diagnosis is very different in patients with and those without chronic liver disease
- using optimal (usually multiple) imaging modalities.

### Primary malignant tumours

#### Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the most common primary liver tumour, and the sixth most frequent cause of cancer worldwide. Cirrhosis is present in 75%–90% of individuals with HCC and is an important risk factor for the disease. The risk is between 1% and 5% in cirrhosis caused by hepatitis B and C. There is also an increased risk in cirrhosis due to haemochromatosis, alcohol, NAFLD and alpha-1-antitrypsin deficiency. In northern Europe, 90% of those with HCC have underlying cirrhosis, compared with 30% in Taiwan, where hepatitis B is the main risk factor. The age-adjusted incidence rates vary from 28 per 100 000 in South-east Asia (reflecting the prevalence of hepatitis B) to 10 per 100 000 in southern Europe and 5 per 100 000 in northern Europe. Chronic hepatitis B infection increases the risk of HCC 100-fold and is the major risk factor worldwide. The risk of HCC is 0.4% per year in the absence of cirrhosis and 2%–6% in cirrhosis. The risk is four times higher in HBeAg-positive individuals than in those who are HBeAg-negative. Hepatitis B vaccination has led to a fall in HCC in countries with a high prevalence of hepatitis B. The incidence in Europe and North America has risen recently, probably related to the increased prevalence of hepatitis C and NAFLD cirrhosis. The risk is higher in men and rises with age.

Macroscopically, the tumour usually appears as a single mass in the absence of cirrhosis, or as a single nodule or multiple nodules in the presence of cirrhosis. It takes its blood supply from the hepatic artery and tends to spread by invasion into the portal vein and its radicals. Lymph node metastases are common, while lung and bone metastases are rare. Well-differentiated tumours can resemble normal hepatocytes and can be difficult to distinguish from normal liver.

### Clinical features

HCC may present with symptoms or through screening of high-risk patients. Commonly, liver function deteriorates in those with underlying cirrhosis, with worsening ascites, jaundice or variceal haemorrhage. Other symptoms can include weight loss, anorexia and abdominal pain. This often rapid deterioration may be the first presentation of previously undiagnosed cirrhosis. Examination may reveal hepatomegaly or a right hypochondrial mass. Tumour vascularity can lead to an abdominal bruit, and hepatic rupture with intra-abdominal bleeding may occur. The advanced nature of disease that presents in this way makes curative therapy unlikely.

HCC found through screening is typically detected much earlier in its natural history, significantly increasing the treatment options.

### Investigations

#### Serum markers

Alpha-fetoprotein (AFP) is produced by 60% of HCCs. Levels increase with the size of the tumour and are often normal or only minimally elevated in small tumours detected by ultrasound screening. Serum AFP can also rise in the presence of active hepatitis B and C viral replication; very high levels are seen following acute hepatic necrosis, such as that following paracetamol toxicity. AFP is used in conjunction with ultrasound in screening but, in view of low sensitivity and specificity, levels need to be interpreted with caution. Nevertheless, in the absence of active liver inflammation, a significantly elevated or progressively rising AFP warrants an aggressive search for HCC (normal range is  $<10\text{ ng/ml}$  [8 IU/ml]). In HCC patients with elevated AFP levels, serial measurements can be a useful biomarker of disease progression or response to treatment.

#### Imaging

Ultrasound will detect focal liver lesions as small as 1 cm. The use of ultrasound contrast agents has increased sensitivity and specificity but is highly user-dependent. Ultrasound may also show evidence of portal vein involvement and features of coexistent cirrhosis. The diagnosis is usually confirmed on either multi-phase contrast-enhanced CT or MRI, which demonstrate the typical hallmarks of HCC: arterial enhancement with washout on the portal venous phase (Fig. 24.35). Small lesions of less than 2 cm can be difficult to differentiate from hyperplastic nodules in cirrhosis. A combination of imaging modalities (CT and MRI) may be required for indeterminate or probable HCC when the typical radiological features are absent (Fig. 24.36).

#### Liver biopsy

Histological confirmation is advisable in patients with large tumours who do not have cirrhosis or hepatitis B, in order to confirm the diagnosis and exclude metastatic tumour. Biopsy should be avoided in patients who

may be eligible for transplantation or surgical resection because there is a small (1.8%–4%) risk of tumour seeding along the needle tract. In all cases of potential HCC where biopsy is being considered, the impact that a confirmed diagnosis will have on therapy must be weighed against the risks of bleeding.

#### Role of screening

Screening for HCC, by ultrasound scanning, with or without AFP measurements, every 6 months is indicated in high-risk patients who would be suitable for therapy if diagnosed with HCC. The risk is highest in patients with chronic hepatitis B and cirrhosis due to viral hepatitis and haemochromatosis, and lower in patients with cirrhosis due to Wilson's disease and autoimmune hepatitis. Cost-effectiveness studies suggest that HCC surveillance is warranted in cirrhotic patients where there is an annual incidence of HCC of  $\geq 1.5\%$  per year. Screening may also be indicated in those with chronic hepatitis B (who carry an increased risk of HCC, even in the absence of cirrhosis). Although many studies investigating the efficacy of HCC surveillance are affected by lead-time and length-time bias, the current evidence base supports the continued use of HCC surveillance. Screening identifies smaller tumours, often less than 3 cm in size, which are more likely to be cured by surgical resection, local ablative therapy or transplantation.

#### Management

This is different for patients with cirrhosis and those without. In the presence of cirrhosis, treatment options depend on tumour size and number, severity of liver disease (Child–Pugh score) and performance status. An algorithm for managing those with cirrhosis is shown in Fig. 24.36.

#### Hepatic resection

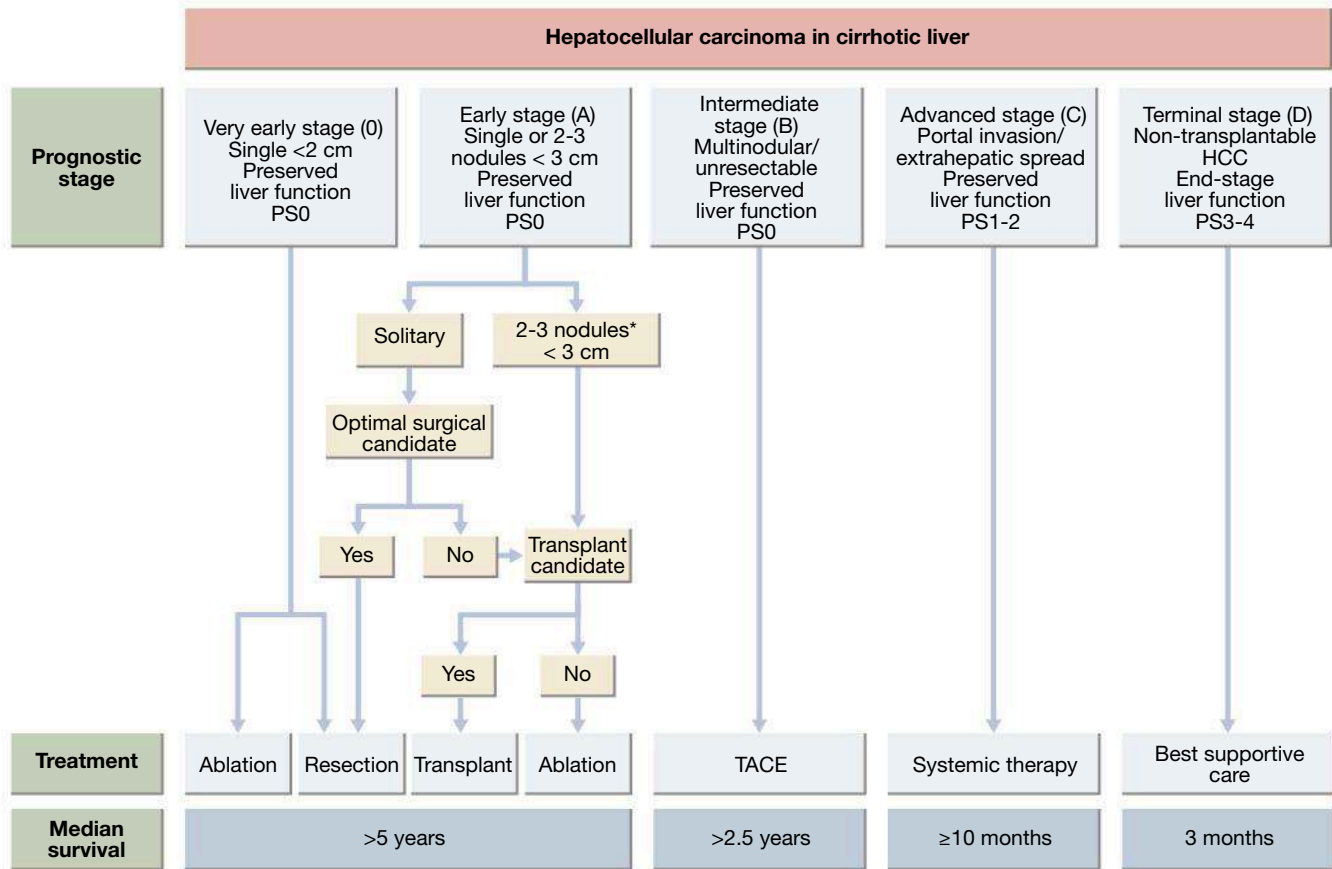

This is the treatment of choice for non-cirrhotic patients. The 5-year survival in this group is about 50%. There is a 50% recurrence rate at 5 years, however, which may be due to a second de novo tumour or recurrence of the original tumour. Few patients with cirrhosis are suitable for hepatic resection because of the high risk of hepatic failure. Nevertheless, surgery can be safely performed in cirrhotic patients with small tumours, good liver function (Child–Pugh A) and the absence of clinically relevant portal hypertension (HVPG  $\leq 10\text{ mmHg}$ ). In experienced centres, advances in surgical technique and pre-operative assessment have permitted liver resection to be performed safely in selected patients with more advanced liver disease and tumour burden.

#### Liver transplantation

Transplantation has the benefit of curing underlying cirrhosis and removing the risk of a second, de novo tumour in an at-risk patient. The requirement for immunosuppression creates its own risks of reactivation,

**Fig. 24.35** Contrast-enhanced MRI liver showing a large hepatocellular carcinoma. The tumour (marked by the arrows) demonstrates contrast uptake (enhancement) in the arterial phase (A) and washout in the portal venous phase (B). Courtesy of Dr Hamish Ireland, Royal Infirmary of Edinburgh.

**Fig. 24.36 Management of hepatocellular carcinoma complicating cirrhosis.** Modified Barcelona Clinic Liver Cancer (BCLC) staging system. Patient management is determined by the size and number of tumours, evidence of portal invasion or extrahepatic spread, severity of underlying liver cirrhosis and performance status. Preserved liver function refers to Childs–Pugh A cirrhosis without ascites. Performance status (PS): 0 = fully active, no symptoms, >2 = limited self-care, confined to bed or chair for more than 50% of waking hours. Optimal surgical candidate refers to a global assessment of a patient's suitability based on compensated liver disease (Child–Pugh A), acceptable grade of portal hypertension, acceptable amount of remaining parenchyma and possibility of using a laparoscopic or minimally invasive approach.

\*In some countries, including the United Kingdom, transplant may be considered in patients with up to five tumours, each less than 3 cm. (HCC = hepatocellular carcinoma; TACE = transarterial chemoembolisation) Adapted from European Association for the Study of the Liver (EASL) Clinical Practice Guidelines: Management of Hepatocellular Carcinoma. *Journal of Hepatology*. 2018; 69:182–236.

however, if residual or metastatic disease is present, and assessment of patients for suitability for liver transplantation focuses on the exclusion of extrahepatic disease and vascular invasion. The 5-year survival following liver transplantation is 75% for patients with single tumours of less than 5 cm in size or three tumours smaller than 3 cm (the Milan criteria). Extended criteria have been developed in a number of countries, including the UK, allowing patients to be transplanted with a greater number of small tumours ( $\leq 5$ ) or larger single tumours (5–7 cm) that have demonstrated stability after a period of observation (6 months), either with or without locoregional therapy.

#### Ablative therapy

Ablative therapies use a number of different techniques to achieve localised destruction of tumour tissue. US or CT-guided thermal ablative techniques, including radiofrequency ablation (RFA) and microwave ablation, have largely replaced percutaneous ethanol injection in the treatment of HCC. Alternative techniques include cryoablation and irreversible electroporation. Loco-regional ablative therapies may be curative for patients with early HCC. Thermal ablation in single tumours <3 cm in size is an alternative to surgery based on technical factors (position of the tumour), severity of underlying liver disease and comorbidity.

#### Transarterial chemoembolisation

Transarterial chemoembolisation (TACE) is the most widely used palliative treatment for patients with HCC not amenable to surgery or

potentially curative ablative techniques. TACE involves the selective intra-arterial infusion of chemotherapeutic agents followed by embolisation of the tumour feeding vessels with absorbable gelatin powder (Gelfoam) to achieve localised tumour necrosis and devascularisation. Conventional TACE achieves response rates of 52% with 1-year and 3-year survival rates of 70% and 40%, respectively. Modifications of this technique include the use of drug-eluting beads. TACE should not be used in patients with advanced liver or renal dysfunction, vascular invasion or extra-hepatic spread. TACE is widely used as a bridging therapy for patients awaiting liver transplant and increasingly has found a role in down-staging therapy in patients being considered for liver transplant. Selective internal radiation therapy (SIRT) involves intra-arterial infusion of radioactive substances or microspheres into the hepatic artery. Its use is being investigated as an alternative to TACE or systemic therapy and as a bridging therapy to liver transplant.

#### Systemic therapy

Sorafenib improves survival from 8 to 11 months in cirrhotic patients, but often with significant side-effects. The drug is a multikinase inhibitor with activity against Raf, vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) signalling, and is the first systemic therapy to prolong survival in HCC. Levatinib is an alternative oral multi-kinase inhibitor that has demonstrated non-inferiority to sorafenib but with a different side-effect profile. Second-line therapies include regorafenib and cabozantinib. Trials of immune therapy are

ongoing. Pre-treatment with sorafenib 2–3 weeks before TACE appears to improve progression-free survival, as reported in the TACTICS trial.

### Fibrolamellar hepatocellular carcinoma

This rare variant differs from HCC in that it occurs in young adults, equally in males and females, in the absence of hepatitis B infection and cirrhosis. The tumours are often large at presentation and the AFP is usually normal. Histology of the tumour reveals malignant hepatocytes surrounded by a dense fibrous stroma. The treatment of choice is surgical resection. This variant of HCC has a better prognosis following surgery than an equivalent-sized HCC, two-thirds of patients surviving beyond 5 years.

### Other primary malignant tumours

These are rare but include haemangio-endothelial sarcomas. Cholangiocarcinoma (bile duct cancer) typically presents with bile duct obstruction rather than as a hepatic mass lesion, although intra-hepatic cholangiocarcinoma can present as a focal liver tumour.

### Secondary malignant tumours

These are common and usually originate from carcinomas in the lung, breast, abdomen or pelvis. They may be single or multiple. Peritoneal dissemination frequently results in ascites.

#### Clinical features

The primary neoplasm is asymptomatic in 50% of patients, being detected on either radiological, endoscopic or blood biochemistry screening. There is liver enlargement and weight loss; jaundice may be present.

#### Investigations

A raised ALP activity is the most common biochemical abnormality but LFTs may be normal. Ascitic fluid, if present, has a high protein content and may be blood-stained; cytology sometimes reveals malignant cells. Imaging shows filling defects (Fig. 24.37); laparoscopy may reveal the tumour and facilitates liver biopsy.

#### Management

Hepatic resection can improve survival for slow-growing colonic carcinoma metastases, and is an approach that should be actively explored in patients who are fit for liver resection and have had the primary tumour resected, once extrahepatic disease has been excluded. Patients with neuro-endocrine tumours (NETs), such as gastrinomas, insulinomas and

**Fig. 24.37** CT liver showing multiple hypo-attenuating liver metastases (arrows). Courtesy of Dr Hamish Ireland, Royal Infirmary of Edinburgh.

glucagonomas, and those with lymphomas may benefit from surgery, hormonal treatment or chemotherapy. Unfortunately, palliative treatment to relieve pain is all that is available for most patients.

### Benign tumours

The increasing use of ultrasound scanning has led to more frequent identification of incidental benign focal liver lesions.

#### Hepatic adenomas

These are rare benign hepatocellular tumours that may present as an abdominal mass or with abdominal pain but now more typically present as an incidental finding on imaging.

They are more common in women (female: male ratio 10:1) and are associated with oral contraceptive, androgen and anabolic steroid use. Hepatic adenomas can increase in size during pregnancy. Large or rapidly growing adenomas can rarely rupture, causing intraperitoneal bleeding. In women, resection is indicated for hepatic adenomas  $\geq 5$  cm in diameter or with exophytic protrusion, as this is associated with higher rates of bleeding. Hepatic adenomas  $< 5$  cm rarely bleed and there is a low rate of malignant transformation. Management involves avoidance of the oral contraceptive pill and weight loss. Resection is recommended for hepatic adenoma in men, irrespective of size because of a higher rate of malignant transformation.

#### Haemangiomas

These are the most common benign liver tumours and are present in 1%–20% of the population. Most are smaller than 3 cm and rarely cause symptoms. The diagnosis is usually made by ultrasound but CT/MRI may show a low-density lesion with delayed arterial filling. Surgery is needed only for very large symptomatic lesions or where the diagnosis is in doubt.

#### Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is a benign polyclonal hepatocellular proliferation resulting from an arterial malformation. FNH is more common in women (female: male ratio 9:1) and typically present between 35 and 50 years. Most are solitary and  $< 5$  cm but 20%–30% are multiple. The lesions are usually asymptomatic. They can be differentiated from adenoma by a focal central scar seen on CT or MRI (Fig. 24.38). Histologically, they consist of nodular regeneration of hepatocytes without fibrosis. In the absence of symptoms, surgical resection is not required. If a confident diagnosis of FNH can be made then follow-up imaging is not required. There is no need to discontinue the oral contraceptive pill or monitor in pregnancy.

#### Cystic liver disease and liver abscess

Isolated or multiple simple cysts are common in the liver and are a relatively frequent finding on ultrasound screening. They can be associated with polycystic renal disease (Fig. 24.39). They are intrinsically benign and require no therapy, other than in rare cases where the mass effect of very large or multiple cysts causes abdominal discomfort. In such cases, percutaneous or surgical debulking can be attempted but recurrence is typical. Liver transplant may rarely be required in severe cases. Liver abscesses are discussed on page 891.

### Drugs and the liver

The liver is the primary site of drug metabolism and an important target for drug-induced injury. Pre-existing liver disease may affect the capacity of the liver to metabolise drugs and unexpected toxicity may occur when patients with liver disease are given drugs in normal doses. Box 24.56

**Fig. 24.38** MRI liver showing a large focal nodular hyperplasia with central scar (arrow). Courtesy of Dr Hamish Ireland, Royal Infirmary of Edinburgh.

**Fig. 24.39** CT abdomen from a patient with polycystic liver and kidney disease. Multiple low attenuation cysts are seen within the liver (highlighted in blue) and left kidney (red). Courtesy of Dr Hamish Ireland, Royal Infirmary of Edinburgh.

also shows drugs that should be avoided in patients with cirrhosis, as they can exacerbate known complications of cirrhosis. The possibility of undiagnosed underlying liver injury should always be considered in patients exhibiting unexpected effects following drug exposure.

### Drug-induced liver injury

Drug toxicity should always be considered in the differential diagnosis of patients presenting with acute liver failure, jaundice or abnormal liver biochemistry. Drug-induced liver injury (DILI) can be classified as either intrinsic (predictable dose-related toxicity occurring in a large proportion of individuals exposed to a drug) or idiosyncratic (occurring unpredictably in a small proportion of patients exposed to a drug). Typical patterns of drug toxicity are listed in [Box 24.57](#); the most common picture is a mixed cholestatic hepatitis. The presence of jaundice indicates more severe liver damage. Although acute liver failure can occur, most drug reactions are self-limiting and chronic liver damage is rare. Abnormal LFTs often take weeks to normalise following a drug-induced hepatitis, and it may be months before they normalise after a cholestatic hepatitis. Occasionally, permanent bile duct loss (ductopenia) follows a cholestatic drug reaction, such as that due to co-amoxiclav, resulting in chronic cholestasis with persistent symptoms such as itching.

The key to diagnosis is a detailed drug history ([Box 24.58](#)), looking for temporal relationships between drug exposure and onset of liver abnormality (bearing in mind the fact that liver injury can frequently take weeks

24.56 Drugs to be avoided in cirrhosis		
Drug	Problem	Toxicity
Non-steroidal anti-inflammatory drugs	Reduced renal blood flow Mucosal ulceration	Hepatorenal failure Bleeding varices
Angiotensin-converting enzyme inhibitors	Reduced renal blood flow	Hepatorenal failure
Codeine	Constipation	Hepatic encephalopathy
Narcotics	Constipation, drug accumulation	Hepatic encephalopathy
Anxiolytics	Drug accumulation	Hepatic encephalopathy

24.57 Examples of common causes of drug-induced hepatotoxicity	
Pattern	Drug
Cholestasis	Chlorpromazine High-dose oestrogens
Cholestatic hepatitis	Non-steroidal anti-inflammatory drugs Co-amoxiclav Statins
Acute hepatitis	Rifampicin Isoniazid
Non-alcoholic steatohepatitis	Amiodarone
Venous outflow obstruction	Busulfan Azathioprine
Fibrosis	Methotrexate
Autoimmune hepatitis-like	Nitrofurantoin Checkpoint inhibitors (nivolumab/ pembrolizumab)

24.58 Diagnosing acute drug-induced liver disease	
<ul style="list-style-type: none"> <li>• Tabulate the drugs taken: Prescribed and self-administered</li> <li>• Establish whether hepatotoxicity is reported in the literature</li> <li>• Relate the time the drugs were taken to the onset of illness: 4 days to 8 weeks (usual)</li> <li>• Establish the effect of stopping the drugs on normalisation of liver biochemistry: Hepatic liver function tests (2 months) Cholestatic/mixed liver function tests (6 months)</li> </ul>	
<b>N.B.</b> Challenge tests with drugs should be avoided	
<ul style="list-style-type: none"> <li>• Exclude other causes: Viral hepatitis Biliary disease</li> <li>• Consider liver biopsy</li> </ul>	

or even months to develop following exposure). A liver biopsy should be considered if there is suspicion of pre-existing liver disease or if blood tests fail to improve when the suspect drug is withdrawn.

Where drug-induced liver injury is suspected or cannot be excluded, the potential culprit drug should be discontinued unless it is impossible to do so safely.

### Types of liver injury

Different histological patterns of liver injury may occur with drug injury.

## Cholestasis

Pure cholestasis (selective interference with bile flow in the absence of liver injury) can occur with oestrogens; this was common when high concentrations of oestrogens (50 µg/day) were used as contraceptives. Both the current oral contraceptive pill and hormone replacement therapy can be safely used in chronic liver disease.

Chlorpromazine and antibiotics such as flucloxacillin are examples of drugs that cause cholestatic hepatitis, which is characterised by inflammation and canalicular injury. Co-amoxiclav is the most common antibiotic to cause abnormal LFTs but, unlike other antibiotics, it may not produce symptoms until 10–42 days after it is stopped. Anabolic steroids used by body-builders may also cause a cholestatic hepatitis. In some cases (e.g. NSAIDs and cyclo-oxygenase 2 (COX-2) inhibitors), there is overlap with acute hepatocellular injury.

## Hepatocyte necrosis

Many drugs cause an acute hepatocellular necrosis with high serum transaminase concentrations; paracetamol is the best known. Inflammation is not always present but does accompany necrosis in liver injury due to diclofenac (an NSAID) and isoniazid (an anti-tuberculous drug). Granulomas may be seen in liver injury following the use of allopurinol. Acute hepatocellular necrosis has also been described following the use of several herbal remedies, including germander, comfrey and jin bu huan. Recreational drugs, including cocaine and ecstasy, can also cause severe acute hepatitis.

## Steatosis

Microvesicular hepatocyte fat deposition, due to direct effects on mitochondrial beta-oxidation, can follow exposure to tetracyclines and sodium valproate. Macrovesicular hepatocyte fat deposition has been described with tamoxifen, and amiodarone toxicity can produce a similar histological picture to NASH.

## Vascular/sinusoidal lesions

Drugs such as the alkylating agents used in oncology can damage the vascular endothelium and lead to hepatic venous outflow obstruction. Chronic overdose of vitamin A can damage the sinusoids and trigger local fibrosis that can result in portal hypertension.

## Hepatic fibrosis

Most drugs cause reversible liver injury and hepatic fibrosis is very uncommon. Methotrexate, however, as well as causing acute liver injury when it is started, can lead to cirrhosis when used in high doses over a long period of time. Risk factors for drug-induced hepatic fibrosis include pre-existing liver disease and a high alcohol intake.

## Autoimmune hepatitis-like

Nitrofurantoin is a commonly used antibiotic for urinary tract infections which can cause a liver injury with the features of autoimmune hepatitis, with raised ALT and IgG levels and anti-nuclear or anti-smooth muscle antibodies. Immune checkpoint inhibitors (such as nivolumab and pembrolizumab) are increasingly used as immunotherapy in cancer treatments. A well-recognised side-effect is the development of florid organ-specific autoimmune disease, including an autoimmune hepatitis which can require high-dose steroids to control it.

## Inherited liver diseases

The inherited diseases are an important and probably under-diagnosed group of liver diseases. In addition to the 'classical' conditions, such as haemochromatosis and Wilson's disease, the important role played by the liver in the expression of the inborn errors of metabolism should be remembered, as should the potential for genetic underpinning for intra-hepatic cholestasis.

## i

### 24.59 Causes of haemochromatosis

#### Primary haemochromatosis

- HFE-associated haemochromatosis (AR)
- Juvenile haemochromatosis (hemojuvelin/hepcidin mutation, AR)
- Transferrin receptor 2 deficiency (*TFR2* mutation, AR)
- Ferroportin disease (*SLC40A1* mutation, AD)

#### Secondary iron overload

- Transfusional or dietary iron overload
- Iron-loading anaemia (thalassaemia, sideroblastic anaemia, chronic haemolytic anaemias)
- Liver disease (ALD, NAFLD, hepatitis C)

(AD = autosomal dominant, AR = autosomal recessive)

## Haemochromatosis

Haemochromatosis is a condition in which the amount of total body iron is increased; the excess iron is deposited in, and causes damage to, several organs, including the liver. It may be primary or secondary to other diseases (Box 24.59).

### Genetic haemochromatosis

In genetic haemochromatosis (GH), iron is deposited throughout the body and total body iron may reach 20–60g (normally 4g). The important organs involved are the liver, pancreatic islets, endocrine glands, joints and heart. In the liver, iron deposition occurs first in the periportal hepatocytes, extending later to all hepatocytes, with associated fibrosis and eventually cirrhosis.

### Pathophysiology

Body iron content is controlled by regulation of iron absorption from diet and its storage in the reticuloendothelial system. The hormone hepcidin inhibits iron transport by binding to ferroportin on enterocytes and macrophages (see Fig. 25.20). Approximately 90% of GH patients are homozygous for a single point mutation resulting in a cysteine to tyrosine substitution at position 282 (C282Y) in the HFE protein, which leads to reduced hepcidin levels and ultimately, uncontrolled increased iron absorption. This is one of the most frequent genetic disorders in Northern European populations. However, penetrance is variable and fewer than 50% of C282Y homozygotes will develop clinical features of haemochromatosis. Iron loss in menstruation and pregnancy can delay the onset of GH in females. A single copy of the C282Y mutation can also cause GH if also accompanied by a histidine-to-aspartic acid mutation at position 63 (H63D), referred to as compound heterozygosity. This genotype has a lower risk of iron overload and typically causes a less severe form of haemochromatosis. A number of other rare autosomal recessive mutations leading to GH are described. The second most common form of inherited iron disorder is *ferroportin disease*, an autosomal dominant disorder which typically has a milder clinical phenotype than HFE-associated haemochromatosis.

### Clinical features

Symptomatic disease usually presents in men over 40 years of age with features of liver disease (often with hepatomegaly), diabetes or heart failure. Fatigue and arthropathy are early symptoms but are frequently absent. Leaden-grey skin pigmentation can sometimes occur due to excess melanin, especially in exposed parts, axillae, groins and genitalia: hence the term 'bronzed diabetes'. Impotence, loss of libido and testicular atrophy are recognised complications, as are early-onset osteoarthritis targeting unusual sites such as the metacarpophalangeal joints, chondrocalcinosis and pseudogout. Cardiac failure or cardiac dysrhythmia may occur due to iron deposition in the heart.

**Fig. 24.40 Liver histology: haemochromatosis.** This Perls stain shows accumulating iron within hepatocytes, which is stained blue. There is also accumulation of large fat globules in some hepatocytes (macrovesicular steatosis). Iron also accumulates in Kupffer cells and biliary epithelial cells.

### Investigations

In the absence of inflammation, serum ferritin is proportional to iron stores and is used as a screening test for iron overload. Patients with GH have raised ferritin and raised transferrin saturations (> 40% in women, > 50% in men), and this pattern should prompt molecular testing for HFE mutations. If HFE-associated GH is confirmed, those with raised transaminases or a ferritin over 1000 µg/L (100 µg/dL) are at highest risk for liver disease and should also undergo fibrosis assessment (usually with transient elastography). If GH is suspected but HFE genotyping is normal, MRI liver or liver biopsy can be used to assess for significant iron overload to identify patients requiring extended genetic testing. Liver biopsy allows assessment of the distribution of iron, with deposition predominantly within hepatocytes being characteristic of haemochromatosis, while accumulation within reticuloendothelial cells is more suggestive of secondary iron overload. The Hepatic Iron Index (HII) provides quantification of liver iron (µmol of iron per gram dry weight of liver/age in years). An HII of more than 1.9 suggests genetic haemochromatosis (Fig. 24.40). The differential diagnoses for elevated ferritin are systemic inflammatory diseases, alcohol-related liver disease and NAFLD. Very significant ferritin elevation can be seen in adult Still's disease.

### Management

Treatment consists of weekly venesection of 500 mL blood (250 mg iron) to reduce ferritin to under 50 µg/L (5 µg/dL) and transferrin saturations to under 50%. Thereafter, venesection is continued as required to maintain these parameters. Liver and cardiac problems improve after iron removal, but joint pain is less predictable and can improve or worsen after iron removal. Diabetes does not resolve. First-degree family members should be investigated, preferably by genetic screening, to identify and treat other cases early.

Pre-cirrhotic patients with GH have a normal life expectancy, and even cirrhotic patients have a good prognosis compared with other forms of cirrhosis (three-quarters of patients are alive 5 years after diagnosis). This is probably because liver function is often well preserved at diagnosis and improves with therapy. Screening for hepatocellular carcinoma (p. 901) is mandatory because this is the main cause of death, affecting one-third of patients with cirrhosis. Venesection reduces but does not abolish the risk of hepatocellular carcinoma in the presence of cirrhosis.

## Secondary haemochromatosis

Many conditions, including chronic haemolytic disorders, sideroblastic anaemia, other conditions requiring multiple blood transfusion (generally over 50 L), porphyria cutanea tarda, dietary iron overload and occasionally

alcohol-related cirrhosis, are associated with widespread secondary iron overload. The features are similar to those of primary haemochromatosis but the history and clinical findings point to the true diagnosis. Some patients are heterozygotes for *HFE* mutations and this may contribute to the development of iron overload.

## Wilson's disease

Wilson's disease (hepatolenticular degeneration) is a rare but important autosomal recessive disorder of copper metabolism caused by a variety of mutations in the *ATP7B* gene. Pathological copper accumulation leads to damage to liver, brain and other organs.

### Pathophysiology

Copper acts as a cofactor for a number of essential enzymes. Dietary absorption is usually balanced by excretion into bile. The *ATP7B* gene encodes a transmembrane copper-transporting ATPase which excretes copper into bile, and loss of function causes excessive copper accumulation. This transporter is also required for synthesis of functional caeruloplasmin, the circulating copper-binding protein. The amount of copper in the body at birth is normal but thereafter it increases steadily; the organs most affected are the liver, basal ganglia of the brain, eyes, kidneys and skeleton.

At least 700 different mutations have been described. Most cases are compound heterozygotes with two different mutations in *ATP7B*. Attempts to correlate the genotype with the mode of presentation and clinical course have not shown any consistent patterns. The large number of culprit mutations means that, in contrast to haemochromatosis, genetic diagnosis is not routine in Wilson's disease, although it may have a role in screening families following identification of the genotype in an index patient.

### Clinical features

Symptoms usually arise between the ages of 5 and 45 years. Hepatic disease occurs predominantly in childhood and early adolescence. Neurological damage causes movement disorders and dementia, which tends to present in later adolescence. These features can occur alone or simultaneously. Other manifestations include renal tubular damage and osteoporosis, but these are rarely presenting features.

### Liver disease

There is a wide spectrum of acute and chronic presentations of liver disease, including asymptomatic elevated liver enzymes, acute hepatitis, recurrent jaundice and silent progression to cirrhosis. Fulminant liver failure can occur, especially in young women. This causes the liberation of free copper into the blood stream, causing massive haemolysis and renal tubulopathy. The possibility of Wilson's disease should be considered in any patient under the age of 40 presenting with recurrent acute hepatitis or chronic liver disease of unknown cause, especially when this is accompanied by haemolytic anaemia.

### Neurological disease

Clinical features include a variety of extrapyramidal features, particularly tremor, choreoathetosis, dystonia, parkinsonism and dementia. Neurological disease typically develops after the onset of liver disease and can be prevented by effective treatment. This increases the importance of diagnosis in the liver phase beyond just allowing effective management of liver disease.

### Kayser–Fleischer rings

These constitute the most important single clinical clue to the diagnosis and can be seen in 60% of adults with Wilson's disease (less often in children but almost always in neurological Wilson's disease), but require slit-lamp examination for correct identification. Kayser–Fleischer rings are characterised by greenish-brown discoloration of the corneal margin appearing first at the upper periphery. They disappear with treatment.

## Investigations

Diagnosis of Wilson's disease is based on algorithms incorporating symptoms and signs, measures of copper metabolism and DNA analysis. A low serum caeruloplasmin is the best single laboratory clue to the diagnosis. However, advanced liver failure from any cause can also reduce the serum caeruloplasmin, and conversely a normal value does not exclude the diagnosis if there is a high index of suspicion. Other features of disordered copper metabolism should therefore be sought; these include a high free serum copper concentration, a high urine copper excretion of greater than  $0.6\mu\text{mol}/24\text{ hrs}$  ( $38\mu\text{g}/24\text{ hrs}$ ) and a very high hepatic copper content. Measuring 24-hour urinary copper excretion while giving D-penicillamine is a useful confirmatory test; more than  $25\mu\text{mol}/24\text{ hrs}$  is considered diagnostic of Wilson's disease.

## Management

Pharmacological treatment is with either chelating-agents (D-penicillamine or trientine) that increase urinary copper excretion, or zinc salts, which reduce absorption of dietary copper. The copper-binding agent penicillamine is the drug of choice. The dose given must be sufficient to produce cupriuresis and most patients require  $1.5\mu\text{g}/\text{day}$  (range  $1\text{--}4\mu\text{g}$ ). The dose can be reduced once the disease is in remission but treatment must continue for life, even through pregnancy. Care must be taken to ensure that re-accumulation of copper does not occur. Abrupt discontinuation of treatment must be avoided because this may precipitate acute liver failure. Toxic effects occur in one-third of patients and include rashes, protein-losing nephropathy, lupus-like syndrome and bone marrow depression. If these arise, trientine dihydrochloride ( $1.2\text{--}2.4\mu\text{g}/\text{day}$ ) and zinc ( $50\text{ mg}$  3 times daily) are potential alternatives.

Prognosis is excellent with early treatment, and presymptomatic patients compliant with treatment have comparable survival to the general population. Liver transplantation is indicated for fulminant liver failure or for advanced cirrhosis with liver failure. The value of liver transplantation in severe neurological Wilson's disease is unclear. Siblings and children must be investigated and treatment should be given to all affected individuals, even if they are asymptomatic.

## Alpha-1-antitrypsin deficiency

Alpha-1-antitrypsin ( $\alpha_1\text{-AT}$ ) is a serine protease inhibitor (Serpin, or Pi) produced by the liver and secreted into the circulation. One of its main functions is the breakdown of neutrophil elastase. Circulating levels of  $\alpha_1\text{-AT}$  can double during the acute phase response and play a key anti-inflammatory role, preventing damage to normal tissue. Numerous variants of the *SERPINA1* gene have been described but there are two common mutations. The wild type is known as the M allele. Ninety-five percent of cases of severe deficiency are due to homozygosity of the Z allele. Mild deficiency can result from the less-severe S allele. The mutated  $\alpha_1\text{-AT}$  forms polymers within the endoplasmic reticulum of hepatocytes, with reduced secretion into the blood. The accumulation of polymers within hepatocytes causes the liver toxicity, whereas the unopposed neutrophil elastase activity causes damage to structural proteins in the lungs. Homozygous individuals (PiZZ) have low plasma  $\alpha_1\text{-AT}$  concentrations, although globules containing  $\alpha_1\text{-AT}$  are found in the liver, and these people may develop hepatic and pulmonary disease. Liver manifestations include cholestatic jaundice in the neonatal period (neonatal hepatitis), which can resolve spontaneously; and chronic hepatitis leading to cirrhosis in adults. Alpha<sub>1</sub>-AT deficiency is an exacerbating factor for liver disease of other aetiologies, and the possibility of dual pathology should be considered when severity of disease, such as ALD, appears disproportionate to the level of underlying insult.

There are no clinical features that distinguish liver disease due to  $\alpha_1\text{-AT}$  deficiency from liver disease due to other causes, and the diagnosis is made from the low plasma  $\alpha_1\text{-AT}$  concentration and genotyping for the presence of the mutation. Alpha<sub>1</sub>-AT-containing globules can be demonstrated in the liver (Fig. 24.41) but this is not necessary to make the diagnosis.

**Fig. 24.41** Liver histology in alpha-1-antitrypsin deficiency. Accumulation of periodic acid–Schiff-positive granules (arrows) within individual hepatocytes is shown in this section from a patient with  $\alpha_1\text{-AT}$  deficiency.

There is no specific treatment. The risk of severe and early-onset emphysema means that all patients should be advised to stop smoking.

## Gilbert syndrome

Gilbert syndrome is by far the most common inherited disorder of bilirubin metabolism (see Box 24.12). It is an autosomal recessive trait when caused by a mutation in the promoter region of the gene for UDP-glucuronyl transferase enzyme (*UGT1A1*), which leads to reduced enzyme expression. It can be inherited in a dominant fashion when there is a missense mutation in the gene. This results in decreased conjugation of bilirubin, which accumulates as unconjugated bilirubin in the blood. The levels of unconjugated bilirubin increase during fasting, as fasting reduces levels of UDP-glucuronyl transferase.

## Clinical features

The typical presentation is with isolated elevation of bilirubin, typically, although not exclusively, in the setting of physical stress or illness. There are no stigmata of chronic liver disease other than jaundice. Increased excretion of bilirubin and hence stercobilinogen leads to normal-coloured or dark stools, and increased urobilinogen excretion causes the urine to turn dark on standing as urobilin is formed. In the presence of haemolysis, pallor due to anaemia and splenomegaly due to excessive reticulo-endothelial activity are usually present.

## Investigations

The plasma bilirubin is usually less than  $100\mu\text{mol/L}$  ( $\sim 6\text{ mg/dL}$ ) and the LFTs are otherwise normal. There is no bilirubinuria because the hyperbilirubinaemia is predominantly unconjugated. Hepatic histology is normal and liver biopsy is not recommended for the investigation of patients with possible Gilbert syndrome. The condition is not associated with liver injury and thus has an excellent prognosis, needs no treatment, and is clinically important only because it may be mistaken for more serious liver disease.

## Vascular liver disease

Metabolically, the liver is highly active and has large oxygen requirements. This places it at risk of ischaemic injury in settings of impaired perfusion. The risk is mitigated, however, by the dual perfusion of the liver (via the portal vein as well as hepatic artery), with the former representing a low-pressure perfusion system that offers protection against the potential effects of arterial hypotension. The single outflow through the hepatic vein and the low-pressure perfusion system of the portal vein make the liver vulnerable to venous thrombotic ischaemia in the context of Budd–Chiari syndrome and portal vein thrombosis, respectively.

## Hepatic arterial disease

### Liver ischaemia

Liver ischaemic injury (ischaemic hepatitis) is relatively common during hypotensive or hypoxic events and is under-diagnosed. The characteristic pattern is one of rising transaminase values in the days following such an event (e.g. prolonged seizures). Ischaemic hepatitis is more common in patients with pre-existing hepatic congestion (e.g. congestive cardiac failure) or underlying liver disease. Liver synthetic dysfunction and encephalopathy are uncommon but can occur. Liver failure is very rare. Diagnosis typically rests on clinical suspicion and exclusion of other potential aetiologies. Treatment is aimed at optimising liver perfusion and oxygen delivery. Outcome is dictated by the morbidity and mortality associated with the underlying disease, given that liver ischaemia frequently occurs in the context of other organ ischaemia in high-risk patients.

### Liver arterial disease

Hepatic arterial disease is rare outside the setting of liver transplantation and is difficult to diagnose. It can cause significant liver damage. Hepatic artery occlusion may result from inadvertent injury during biliary surgery or may be caused by emboli, neoplasms, polyarteritis nodosa, blunt trauma or radiation. It usually causes severe upper abdominal pain with or without signs of circulatory shock. LFTs show raised transaminases (AST or ALT usually >1000 U/L), as in other causes of acute liver damage. Patients usually survive if the liver and portal blood supply are otherwise normal.

Hepatic artery aneurysms are extrahepatic in three-quarters of cases and intrahepatic in one-quarter. Atheroma, vasculitis, bacterial endocarditis and surgical or biopsy trauma are the main causes. They usually lead to bleeding into the biliary tree, peritoneum or intestine. CT scans are helpful in identifying the location of the aneurysm, adjacent structures and evidence of rupture. Angiography remains the gold standard for diagnosis. Treatment is radiological or surgical. Any of the vasculitides can affect the hepatic artery but this rarely causes symptoms.

Hepatic artery thrombosis (HAT) is a recognised complication of liver transplantation and typically occurs in the early post-transplant period. Clinical features are often related to bile duct rather than liver ischaemia because of the dominant role of the hepatic artery in extrahepatic bile duct perfusion. Manifestations can include bile duct anastomotic failure with bile leak or the development of late bile duct strictures (ischaemic cholangiopathy). Diagnosis and initial intervention are radiological in the first instance, with ERCP and biliary stenting being the principal approaches to the treatment of biliary strictures causing significant cholestasis.

## Portal venous disease

### Portal hypertension

See page 881.

### Portal vein thrombosis

Portal venous thrombosis as a primary event is rare but can occur in any condition predisposing to thrombosis. It may also complicate intra-abdominal inflammatory or neoplastic disease and is a recognised cause of portal hypertension. Acute portal venous thrombosis causes abdominal pain and diarrhoea, and may rarely lead to bowel infarction, requiring surgery. Underlying thrombophilia needs to be excluded. Treatment is based on anticoagulation, which is associated with increased recanalisation rates following acute portal vein thrombosis. Subacute thrombosis can be asymptomatic but may subsequently lead to extrahepatic portal hypertension. Ascites is unusual in non-cirrhotic portal hypertension, unless the albumin is particularly low.

Portal vein thrombosis can arise as a secondary event in patients with cirrhosis and portal hypertension, and is a recognised cause of decompensation in patients with previously stable cirrhosis. In individuals showing such decompensation, portal vein patency should be assessed by ultrasound with Doppler flow studies. The role of anticoagulation in patients with chronic portal vein thrombosis is unclear, but it is recommended in potential transplant candidates to reduce the risk of clot propagation. Chronic portal vein thrombosis can be a cause of portal hypertension.

### Hepatopulmonary syndrome

This condition is characterised by resistant hypoxaemia ( $PaO_2 < 9.3$  kPa (70 mmHg)), intrapulmonary vascular dilatation in patients with cirrhosis, and portal hypertension. Clinical features include finger clubbing, cyanosis and a characteristic reduction in arterial oxygen saturation on standing (orthodeoxia). The hypoxia is due to intrapulmonary shunting through direct arteriovenous communications. Nitric oxide (NO) over-production may be important in pathogenesis. The hepatopulmonary syndrome can be treated by liver transplantation but, if severe ( $PaO_2 < 6.7$  kPa (50 mmHg)), is associated with an increased operative risk.

### Portopulmonary hypertension

This unusual complication of portal hypertension is similar to 'primary pulmonary hypertension' (p. 549). It is defined as pulmonary hypertension with increased pulmonary vascular resistance and a normal pulmonary artery wedge pressure in a patient with portal hypertension. The condition is caused by vasoconstriction and obliteration of the pulmonary arterial system and leads to breathlessness and fatigue.

## Hepatic venous disease

Obstruction to hepatic venous blood flow can occur in the small central hepatic veins, the large hepatic veins, the inferior vena cava or the heart. The clinical features depend on the cause and on the speed with which obstruction develops, and can mimic many other forms of chronic liver disease, sometimes leading to delayed diagnosis. Congestive hepatomegaly and ascites are the most consistent features. The possibility of hepatic venous obstruction should always be considered in patients with an atypical liver presentation.

### Budd–Chiari syndrome

This uncommon condition is caused by thrombosis of the larger hepatic veins and sometimes the inferior vena cava. Many patients have haematological disorders such as myelofibrosis, primary proliferative polycythaemia, paroxysmal nocturnal haemoglobinuria, or antithrombin III, protein C or protein S deficiencies (Ch. 25). Pregnancy and oral contraceptive use, obstruction due to tumours (particularly carcinomas of the liver, kidneys or adrenals), congenital venous webs and occasionally inferior vena caval stenosis are the other main causes. The underlying cause cannot be found in about 30% of patients, although this percentage is falling as molecular diagnostic tools (e.g. for the *JAK2* mutation in myelofibrosis) increase the capacity to diagnose underlying haematological disorders. Hepatic congestion affecting the centrilobular areas is followed by centrilobular fibrosis, and eventually cirrhosis supervenes in those who survive long enough.

#### Clinical features

Acute venous occlusion causes rapid development of upper abdominal pain, marked ascites and occasionally acute liver failure. More gradual occlusion causes gross ascites and, often, upper abdominal discomfort. Hepatomegaly, frequently with tenderness over the liver, is almost always present. Peripheral oedema occurs only when there is inferior vena cava obstruction. Features of cirrhosis and portal hypertension develop in those who survive the acute event.

## Investigations

The LFTs vary considerably, depending on the presentation, and can show the features of acute hepatitis. Ascitic fluid analysis shows a protein concentration above 25 g/L (2.5 g/dL) (exudate) in the early stages; however, this often falls later in the disease. Doppler ultrasound may reveal obliteration of the hepatic veins and reversed flow or associated thrombosis in the portal vein. CT may show enlargement of the caudate lobe, as this often has a separate venous drainage system that is not involved in the disease. CT and MRI may also demonstrate occlusion of the hepatic veins and inferior vena cava. Liver biopsy demonstrates centrilobular congestion with fibrosis, depending on the duration of the illness. Venography is needed only if CT and MRI are unable to demonstrate the hepatic venous anatomy clearly.

## Management

Predisposing causes should be treated as far as possible; where recent thrombosis is suspected, thrombolysis with recombinant tissue plasminogen activator or streptokinase, followed by heparin and oral anticoagulation, should be considered. Long-term anticoagulation is required. Ascites is initially treated medically but often with only limited success. Short hepatic venous strictures can be treated with angioplasty. In the case of more extensive hepatic vein occlusion, many patients can be managed successfully by insertion of a covered TIPSS, followed by anticoagulation. Surgical shunts, such as portacaval shunts, are rarely performed now that TIPSS is available. Approximately 40% of patients will require TIPSS following failure of medical management. Survival at 1 year and 5 years following TIPSS is 88% and 78%, respectively. Occasionally, a web can be resected or an inferior vena caval stenosis dilated. Progressive liver failure is an indication for liver transplantation and life-long anticoagulation.

## Sinusoidal obstruction syndrome (veno-occlusive disease)

Sinusoidal obstruction syndrome (SOS; previously known as veno-occlusive disease) is a rare condition characterised by widespread occlusion of the small central hepatic veins. Pyrrolizidine alkaloids in *Senecio* and *Heliotropium* plants used to make teas, as well as cytotoxic drugs and hepatic irradiation, are all recognised causes. SOS may develop in 10%–20% of patients following haematopoietic stem cell transplantation (usually within the first 20 days) and carries a 90% mortality in severe cases. Pathogenesis involves obliteration and fibrosis of terminal hepatic venules due to deposition of red cells, haemosiderin-laden macrophages and coagulation factors. In this setting, SOS is thought to relate to pre-conditioning therapy with irradiation and cytotoxic chemotherapy. The clinical features are similar to those of the Budd–Chiari syndrome (see above). Investigations show evidence of venous out-flow obstruction histologically but, in contrast to Budd–Chiari, the large hepatic veins appear patent radiologically. Transjugular liver biopsy (with portal pressure measurements) may facilitate the diagnosis. Treatment involves close supportive care/fluid management to maintain intravascular filling, and in severe cases, defibrotide, a drug that binds to vascular endothelial cells, promoting fibrinolysis and suppressing coagulation, is recommended.

## Cardiac disease

Hepatic damage, due primarily to congestion, may develop in all forms of right heart failure; usually, the clinical features are predominantly cardiac. Very rarely, long-standing cardiac failure and hepatic congestion give rise to cardiac cirrhosis. Liver cirrhosis is a recognised complication of some forms of congenital heart disease. Fontan-associated liver disease develops in patients with diverse forms of congenital cardiac disease resulting in a single functioning ventricle, treated with the Fontan procedure. Chronic hepatic congestion resulting from passive filling of the pulmonary arterial circulation results in progressive liver fibrosis and cirrhosis. Severe

left ventricular dysfunction is a cause of ischaemic hepatitis. Cardiac causes of acute and chronic liver disease are typically under-diagnosed. Treatment is principally that of the underlying heart disease with supportive treatment for the liver component.

## Nodular regenerative hyperplasia of the liver

This is the most common cause of non-cirrhotic portal hypertension in developed countries; it is characterised by small hepatocyte nodules throughout the liver without fibrosis, which can result in sinusoidal compression. It is believed to be due to damage to small hepatic arterioles and portal venules. It occurs in older people and is associated with many conditions, including connective tissue disease, haematological diseases and immunosuppressive drugs, such as azathioprine. The condition is usually asymptomatic but occasionally presents with portal hypertension or with an abdominal mass. The diagnosis is made by liver biopsy, which, in contrast to cirrhosis, shows nodule formation in the absence of fibrous septa. Liver function is good and the prognosis is very favourable. Management is based on treatment of the portal hypertension.

## Pregnancy and the liver

The inter-relationship between liver disease and pregnancy can be a complex one and a source of real anxiety for both patient and clinician. Three possibilities need to be borne in mind when treating a pregnant woman with a liver abnormality:

- This represents a worsening of pre-existing chronic liver or biliary disease (although pregnancy may be the first time a woman's liver biochemistry has been tested, so this may not have previously been diagnosed).
- This represents a genuine first presentation of liver disease that is not intrinsically related to pregnancy.
- This represents a genuine pregnancy-associated liver injury process.

It is critical to obtain information relating to liver disease risk factors and pre-pregnancy liver status to establish whether any abnormality was present before pregnancy. In general, the earlier in pregnancy that liver abnormality presents, the more likely it is to represent either pre-existing liver disease or non-pregnancy-related acute liver disease. Equally, the best outcome for both mother and baby results from optimising the physical condition of the mother, and in situations of deteriorating liver function (which can be steep in late pregnancy) consideration should always be given to early delivery if the fetus is viable. Joint management between hepatologists and obstetricians is essential.

## Intercurrent and pre-existing liver disease

Acute hepatitis A can occur during pregnancy but has no effect on the fetus. Chronic hepatitis B requires identification in pregnancy because of long-term health implications for the mother and the effectiveness of perinatal vaccination (with or without pre-delivery maternal antiviral therapy) in reducing neonatal acquisition of chronic hepatitis B. Maternal transmission of hepatitis C occurs in 1% of cases and there is no convincing evidence that the mode of delivery affects this. Hepatitis E (genotypes 1 and 2) is reported to progress to acute liver failure much more commonly in pregnancy, with a 20% maternal mortality. Pregnancy may be associated with either worsening or improvement of autoimmune hepatitis, although improvement during pregnancy and rebound post-partum is the most common pattern seen. Complications of portal hypertension may be a particular issue in the second and third trimesters.

Gallstones are more common during pregnancy and may present with cholecystitis or biliary obstruction. The diagnosis can usually be made

### Box 24.60 Abnormal liver function tests in pregnancy

- **Liver function tests:** alkaline phosphatase (ALP) levels and albumin normally fall in pregnancy. ALP levels can rise due to the contribution of placental ALP.
- **Pre-existing liver disease:** pregnancy is uncommon in cirrhosis because cirrhosis causes relative infertility. Varices can enlarge in pregnancy, and ascites should be treated with amiloride rather than spironolactone. Penicillamine for Wilson's disease and azathioprine for autoimmune liver disease should be continued during pregnancy. Autoimmune liver disease can flare up post partum.
- **Incidental:** viral, autoimmune and drug-induced hepatitis must be excluded in the presence of an elevated alanine aminotransferase (ALT). Immunoglobulin/vaccination given to the fetus at birth prevents transmission of hepatitis B to the fetus if the mother is infected. Gallstones are more common in pregnancy and post partum, and are a cause of a raised ALP level. Biliary imaging with ultrasound and magnetic resonance cholangiopancreatography is safe. Endoscopic retrograde cholangiopancreatography to remove stones can be performed safely with shielding of the fetus from radiation.
- **Pregnancy-related liver diseases:** occur predominantly in the third trimester and resolve post partum. Maternal and fetal mortality and morbidity are reduced by expediting delivery.

with ultrasound. In biliary obstruction due to gallstones, therapeutic ERCP can be safely performed but lead protection for the fetus is essential and X-ray screening must be kept to a minimum.

### Pregnancy-associated liver disease

Several conditions occur only during pregnancy, may recur in subsequent pregnancies and resolve after delivery of the baby, and these are discussed in Chapter 32. The causes of abnormal LFTs in pregnancy, which include pregnancy-associated liver disease, are shown in Box 24.60.

## Liver transplantation

Liver transplantation is an effective treatment for end-stage liver disease. However, the number of procedures is limited by cadaveric donor availability and 5%–15% of those listed for liver transplantation will die while awaiting a donor liver. The main complications of liver transplantation relate to long-term immunosuppression, rejection or disease recurrence in the liver graft.

### Indications and contraindications

More than 30 000 liver transplants are performed worldwide each year. The main indications vary between regions. In Europe, the majority of liver transplants are for decompensated cirrhosis (56%), most frequently due to alcohol, hepatitis C or NAFLD, followed by hepatocellular carcinoma (17%), with 8% for acute liver failure. Fig. 24.42 shows indications for transplantation in the UK. In Asia, the most common indication is hepatocellular carcinoma related to hepatitis B. Patterns are changing over time, with reducing need for transplant in hepatitis C as a result of improved antiviral therapy, but increasing prevalence of NAFLD. Liver transplantation is increasingly being undertaken in older patients, with 30% of liver transplants in Europe now in patients aged over 60 years, but only a very small number aged over 70 years.

Transplant may be undertaken to improve survival in advanced liver disease or to alleviate symptoms. Common indications for elective transplant assessment are listed in Box 24.61. There are various criteria for HCC based on the size and number of lesions and level of serum alpha-fetoprotein (as these factors predict risk of recurrence post-transplant). Current UK guidelines allow transplant for a single lesion below

Fig. 24.42 Indications for elective adult liver transplantation in the UK, 2019–2020.

24.61 Indications for liver transplant assessment for cirrhosis	
<b>Complications</b>	
<ul style="list-style-type: none"> <li>• First episode of bacterial peritonitis</li> <li>• Diuretic-resistant ascites</li> <li>• Recurrent variceal haemorrhage</li> <li>• Hepatocellular carcinoma</li> <li>• Persistent hepatic encephalopathy</li> </ul>	
<b>Poor liver function</b>	
<ul style="list-style-type: none"> <li>• Bilirubin &gt; 100 µmol/L (5.8 mg/dL) in primary biliary cholangitis</li> <li>• MELD score &gt; 12 (Box 24.32)</li> <li>• UKELD score ≥ 49</li> <li>• Child–Pugh grade C (Box 24.31)</li> </ul>	
(MELD = Model for End-stage Liver Disease; UKELD United Kingdom Model for End-stage Liver Disease)	

5 cm, or up to five lesions all below 3 cm, provided there is no macrovascular invasion or extrahepatic spread. Larger lesions may be suitable if stable following treatment. Specific criteria exist for patients with acute liver failure, depending on aetiology.

The main contraindications to transplantation are extrahepatic sepsis or malignancy, active alcohol or other substance misuse, and significant cardiorespiratory disease.

Patients are matched for ABO blood group and size but do not require HLA matching with donors, as the liver is a relatively immune-privileged organ compared with the heart or kidneys.

Organ allocation is often based on greatest need, estimating short-term mortality using the MELD or UKELD scores (see Box 24.32). The United Kingdom has recently moved to a national allocation system based on Transplant Benefit Score, which uses donor and recipient variables to calculate the difference between the mortality without transplant (need) and the predicted 5-year survival with transplant (utility), to identify those with the greatest net benefit.

Approaches to increase the availability of donor organs include:

- **Split liver transplantation.** Due to the liver's regenerative capacity, a cadaveric donor liver can be split into two, with the larger right lobe used in an adult and the smaller left lobe used in a child.

- *Living donor transplantation.* This is normally performed using the left lateral segment or the right lobe from a healthy donor. The donor mortality is significant, at 0.5%–1%. Pre-operative assessment includes looking at donor liver size and psychological status.
- *Use of marginal grafts.* Higher-risk livers (older donors, steatotic livers, non-heart-beating donors) are being used in selected patients. Novel organ perfusion technologies may help to improve graft selection and outcomes in this group.
- *Increased donation.* Improved infrastructure to support organ donation, increased public awareness of transplantation and changes to consent process ('opt-out', or presumed consent) may all increase donation rates.

## Complications

### Early complications

#### Primary graft non-function

This is due to a severe ischaemia—reperfusion injury, resulting in irreversible graft failure and requiring early re-transplantation in around 4%–6% of recipients. Factors that increase the likelihood of primary non-function include increasing donor age, degree of steatosis in the liver and the length of ischaemia.

#### Technical complications

These include hepatic artery thrombosis, which may necessitate re-transplantation. Anastomotic biliary strictures can also occur; these may respond to endoscopic stenting, or require surgical reconstruction. Portal vein thrombosis following transplant is rare.

#### Rejection

Lifelong immunosuppression is required in most liver transplant recipients, although at lower levels than with kidney or heart/lung transplants. Immunosuppression is maximal in the early post-operative period, with reducing levels over time. A number of different regimens are used but the majority include a calcineurin inhibitor (usually tacrolimus) with or without an antimetabolite (azathioprine or mycophenolate) or tapering steroids. Some patients can eventually be maintained on a single agent. Acute cellular rejection occurs in 15%–25% of patients, commonly presenting as raised liver enzymes at 5–30 days post-transplant, but can arise later. This normally responds to 3 days of high-dose intravenous methylprednisolone.

#### Infections

Bacterial infections, such as pneumonia and wound infections, can occur in the first few weeks after transplantation. Opportunistic infections are also seen, and prophylaxis against fungal infections and *Pneumocystis jirovecii* may be given during the first few months. Cytomegalovirus (primary infection or reactivation) is common in the 3 months after transplantation and can cause fevers, bone marrow suppression and hepatitis. Patients who have never had cytomegalovirus infection but who receive a liver from a donor who has been exposed are at greatest risk and are usually given prophylactic antiviral therapy, such as valganciclovir. Patients with latent tuberculosis should receive prophylaxis against reactivation.

### Late complications

Late complications are mostly consequences of long-term immunosuppression. These include malignancy (especially skin cancers and lymphoma), renal failure and cardiovascular disease. Weight gain is common following liver transplantation, leading to obesity and diabetes. Chronic rejection is rare, occurring in only 5% of cases. Recurrence of the initial

disease can occur, especially with autoimmune liver diseases or hepatocellular carcinoma.

## Prognosis

Current UK data show 1-year survival for patients transplanted for cirrhosis of 94%, with 5-year survival of 84%. Outcomes are worse in patients transplanted for acute liver failure as they often have multi-organ failure at the time of transplantation, and in patients transplanted for hepatocellular carcinoma, due to disease recurrence.

## Cholestatic and biliary disease

The concepts of biliary and cholestatic disease, and the important distinctions between them, can be a source of confusion. 'Cholestasis' relates to impaired bile flow, usually detected as a biochemical abnormality (typically, elevation of ALP and elevation in serum bile acid levels and bilirubin). This can be due to failure of bile acid transport across the hepatocyte membrane, or physical obstruction of the bile duct. 'Biliary disease' relates to pathology at any level from the small intrahepatic bile ducts to the sphincter of Oddi. Although there is very significant overlap between cholestatic and biliary disease, there are scenarios where cholestasis can exist without biliary disease (transporter disease or pure drug-induced cholestasis) and where biliary disease can exist without cholestasis (when disease of the bile duct does not impact on bile flow).

## Chemical cholestasis

Pure cholestasis can occur as an inherited condition (p. 906), as a consequence of cholestatic drug reactions (p. 906) or as acute cholestasis of pregnancy. A more frequent, but less recognised, acquired biochemical cholestasis occurs in sepsis ('cholangitis lenta'). This biochemical phenomenon is one of the causes of LFT abnormality in sepsis. Also termed subacute non-suppurative cholangitis, it is characterised by inspissated bile plugs in dilated bile ductules in the absence of mechanical obstruction. It does not require specific treatment and has a prognostic significance conferred by the underlying septic process.

Mutations in the biliary transporter proteins on the hepatocyte canalicular membrane (familial intrahepatic cholestasis 1, FIC1), illustrated in Fig. 24.7, have been shown to cause an inherited intrahepatic biliary disease in childhood, characterised by raised ALP levels and progression to a biliary cirrhosis. It is also becoming increasingly clear that these proteins contribute to intrahepatic biliary disease in adulthood.

## Benign recurrent intrahepatic cholestasis

Benign recurrent intrahepatic cholestasis (BRIC) is a rare autosomal recessive genetic disorder characterised by recurrent episodes of cholestatic jaundice lasting weeks to months. It usually presents in adolescence. Prodromal symptoms include pruritus, nausea, vomiting and weight loss. Patients are asymptomatic between episodes. Blood tests typically show conjugated hyperbilirubinaemia with elevated alkaline phosphatase. Cholangiography shows no evidence of biliary obstruction. Liver biopsy shows cholestasis during episodes but is normal between episodes.

BRIC is associated with mutations in the genes for two bile acid transporters: ATP8B1 (BRIC1) encoding FIC1 and ABCB11 (BRIC2) encoding the bile salt export pump (BSEP). Treatment is required to relieve symptoms and the long-term prognosis is good.

## Intrahepatic biliary disease

### Inflammatory and immune disease

The small intrahepatic bile ducts appear to be specifically vulnerable to immune injury, and ductopenic injury ('vanishing bile duct syndrome') can be a feature of a number of chronic conditions, including graft-versus-host disease (GVHD), sarcoidosis and, in the setting of liver transplantation, ductopenic rejection. Intrahepatic small bile duct injury occurs most frequently in primary biliary cholangitis, an autoimmune cholestatic disease, and less frequently in primary sclerosing cholangitis (see Box 24.54).

### Caroli's disease

Caroli's disease and Caroli's syndrome are rare congenital disorders characterised by multifocal saccular dilatation of the intrahepatic bile ducts. Bile duct ectasia may involve the entire liver, a lobe or a single segment. In Caroli's disease, biliary ectasia occurs in isolation. However, in the more common variant, Caroli's syndrome, the bile duct dilatation is associated with congenital hepatic fibrosis. The molecular pathogenesis is incompletely understood. Most cases are transmitted in an autosomal recessive manner and are associated with autosomal recessive polycystic kidney disease (ARPKD). In both conditions, focal dilatation of bile ducts leads to cholestasis with formation of biliary sludge and intraductal calculi. Recurrent attacks of cholangitis require antibiotic therapy and predispose to hepatic abscess formation. There is an increased risk of cholangiocarcinoma affecting 2.5%–16% of patients. Prognosis is generally poor. Localised disease may be treated by segmental liver resection. Patients with diffuse disease complicated by recurrent biliary sepsis or portal hypertension may require liver transplantation.

### Congenital hepatic fibrosis

Congenital hepatic fibrosis (CHF) is a rare developmental disorder characterised by broad bands of fibrous tissue linking portal tracts and irregular-shaped proliferating bile ducts, resulting from ductal plate malformation. CHF may be inherited in an autosomal recessive manner and is associated with a range of disorders with multi-system involvement, including: Caroli's syndrome, polycystic kidney disease, Joubert syndrome and Bardet-Biedl syndrome. The renal tubules may show cystic dilatation (medullary sponge kidney) and renal cysts/renal failure may develop. The condition typically present in childhood or early adulthood, although late presentation is described. Patients may present with symptoms of portal hypertension, including painful splenomegaly and variceal bleeding with preserved hepatic function, or with symptoms of cholestasis and recurrent cholangitis (Caroli's syndrome). However, patients frequently present with symptoms related to other organ systems (e.g. kidney, central nervous system).

### Cystic fibrosis

The term cystic fibrosis-associated liver disease (CFLD) encompasses the range of liver disease seen in patients with cystic fibrosis. Liver function test abnormalities are common, with persistent abnormalities affecting 40% of patients with cystic fibrosis. Biliary cirrhosis develops in 5%–10% of individuals by adolescence/early adulthood when complications such as variceal haemorrhage may occur. Non-cirrhotic portal hypertension may develop as a consequence of pre-sinusoidal obliterative portal venopathy. UDCA improves liver biochemistry but it is unclear whether the drug can prevent progression of liver disease. Deficiency of fat-soluble vitamins (A, D, E and K) may need to be treated in view of biliary and pancreatic disease.

## Extrahepatic biliary disease

Diseases of the extrahepatic biliary tree typically present with the clinical features of impaired bile flow (jaundice, itch and fat malabsorption). Obstructive disease is frequently a consequence of ductal gallstones, sometimes with associated infection or inflammatory strictures, or post-surgical strictures. Malignant diseases (cholangiocarcinoma or carcinoma of the head of pancreas) should be considered in all patients with extrahepatic biliary obstruction. PSC frequently involves the extrahepatic biliary tree and its differential, IgG4 disease, is an important and potentially treatable cause of disease.

### Choledochal cysts

Choledochal cysts are uncommon congenital cysts of the biliary tree (Fig. 24.43). They are usually diagnosed in the first decade of life. The majority cause diffuse dilatation of the common bile duct (type I). Others represent true diverticulae of the common bile duct (type II), dilatation of the intra-duodenal bile duct at the pancreatico-biliary junction (type III) or dilatation of the intrahepatic and/or the extrahepatic biliary ducts (type IV). Type IV choledochal cysts are subdivided into those affecting the intrahepatic and extrahepatic ducts (type IVA) or multiple cysts affecting extrahepatic ducts with normal intrahepatic ducts (type IVB). Type V choledochal cysts refer to one or more cystic dilatations of intrahepatic ducts with normal extrahepatic ducts, with multiple cystic dilatations of intrahepatic ducts referred to as Caroli's disease. Children may present with abdominal mass, jaundice or biliary peritonitis from cyst rupture. Adults more commonly present with jaundice, abdominal pain and cholangitis. Liver abscess and biliary cirrhosis may develop. There is an increased incidence of cholangiocarcinoma. Cyst excision with hepaticojejunostomy is the treatment of choice.

## Secondary biliary cirrhosis

Secondary biliary cirrhosis develops after prolonged large duct biliary obstruction due to gallstones, benign bile duct strictures or sclerosing cholangitis (see below). Carcinomas rarely cause secondary biliary cirrhosis because few patients survive long enough. The clinical features are those of chronic cholestasis with episodes of ascending cholangitis or even liver abscess. Cirrhosis, ascites and portal hypertension are late features. Relief of biliary obstruction may require endoscopic or surgical intervention. Cholangitis dictates treatment with antibiotics, which can be given continuously if attacks recur frequently.

## Gallstones

Gallstone formation is the most common disorder of the biliary tree and it is unusual for the gallbladder to be diseased in the absence of gallstones. In high-income countries, gallstones occur in 7% of males and 15% of females aged 18–65 years, with an overall prevalence of 11%. In individuals under 40 years there is a 3:1 female preponderance, whereas in older people the sex ratio is about equal. Gallstones are less frequent in Asia and Africa. There has been much debate over the role of diet

Fig. 24.43 Classification and frequency of choledochal cysts. Adapted from the Todani Classification of Choledochal Cysts (1977).

in cholesterol gallstone disease; an increase in dietary cholesterol, fat, total calories and refined carbohydrate or lack of dietary fibre has been implicated.

### Pathophysiology

Gallstones are conventionally classified into cholesterol or pigment stones, although the majority are of mixed composition. Gallstones contain varying quantities of calcium salts, including calcium bilirubinate, carbonate, phosphate and palmitate, which are radio-opaque. Gallstone formation is multifactorial and the factors involved are related to the type of gallstone (Boxes 24.62 and 24.63).

### Cholesterol gallstones

Cholesterol is held in solution in bile by its association with bile acids and phospholipids in the form of micelles and vesicles. Biliary lipoproteins may also have a role in solubilising cholesterol. In gallstone disease, the liver produces bile that contains an excess of cholesterol because there is either a relative deficiency of bile salts or a relative excess of cholesterol ('lithogenic' bile). Abnormalities of bile salt synthesis and circulation, cholesterol secretion and gallbladder function may make production of lithogenic bile more likely.

### Pigment stones

Brown, crumbly pigment stones are almost always the consequence of bacterial or parasitic biliary infection. They are common in the Far East, where infection allows bacterial  $\beta$ -glucuronidase to hydrolyse conjugated bilirubin to its free form, which then precipitates as calcium bilirubinate. The mechanism of black pigment gallstone formation in high-income countries is not satisfactorily explained. Haemolysis is important as a contributing factor for the development of black pigment stones that occur in chronic haemolytic disease.

### Biliary sludge

This describes gelatinous bile that contains numerous microspherulites of calcium bilirubinate granules and cholesterol crystals, as well as glycoproteins; it is an important precursor to the formation of gallstones in the majority of patients. Biliary sludge is frequently formed under normal conditions but then either dissolves or is cleared by the gallbladder; only in about 15% of patients does it persist to form cholesterol stones. Fasting, parenteral nutrition and pregnancy are also associated with sludge formation.

### Clinical features

Only 10% of individuals with gallstones develop clinical evidence of gallstone disease. However, once symptoms occur they are likely to recur. Symptomatic stones within the gallbladder (Box 24.64) manifest as either biliary pain ('biliary colic') or cholecystitis (see below). If a gallstone becomes acutely impacted in the cystic duct, the patient will experience pain. The term 'biliary colic' is a misnomer because the pain does not rhythmically increase and decrease in intensity like other forms of colic. Typically, the pain occurs suddenly and persists for several hours; if it continues for more than 6 hours, a complication such as cholecystitis or pancreatitis may be present. Pain is usually felt in the epigastrium (70% of patients) or right upper quadrant (20%) and radiates to the interscapular region or the tip of the right scapula, but other sites include the left upper quadrant and the lower chest. The pain can mimic intrathoracic disease, oesophagitis, myocardial infarction or aortic dissection.

Combinations of fatty food intolerance, dyspepsia and flatulence not attributable to other causes have been referred to as 'gallstone dyspepsia'. These symptoms are not now recognised as being caused by gallstones and are best regarded as functional dyspepsia. Acute and chronic cholecystitis is described below.

A mucocele may develop if there is slow distension of the gallbladder from continuous secretion of mucus; if this material becomes infected, an empyema supervenes. Calcium may be secreted into the lumen of the hydropic gallbladder, causing 'limey' bile, and if calcium salts are precipitated in the gallbladder wall, the radiological appearance of 'porcelain' gallbladder results.

Gallstones in the gallbladder (cholecystolithiasis) migrate to the common bile duct (choledocholithiasis; p. 916) in approximately 10%–20% of patients and can cause biliary colic. Rarely, stones can fistulate between the gallbladder and the gastric outlet or duodenum (causing obstruction, known as Bouveret syndrome) or colon. If this occurs, air will be seen in the biliary tree on plain abdominal X-rays. If a stone larger than 2.5 cm in diameter has migrated into the gut, it may then impact either at the terminal ileum or sigmoid colon. The resultant intestinal obstruction may be followed by 'gallstone ileus'. Gallstones impacted in the cystic duct may cause obstruction to the common hepatic duct and the clinical picture of extrahepatic biliary diseases ('Mirizzi syndrome', with its important differential of malignant bile duct stricture). The more common cause of jaundice due to gallstones is a stone passing from the cystic duct into the common bile duct (choledocholithiasis), which may also result in cholangitis or acute pancreatitis. It is usually very small stones that precipitate acute pancreatitis, due to oedema at the ampulla as the stone

### 24.65 Gallbladder disease in old age

- **Gallstones:** by the age of 70 years, prevalence is around 30% in women and 19% in men.
- **Acute cholecystitis:** tends to be severe, may have few localising signs and is associated with a high frequency of empyema and perforation. If such complications supervene, mortality may reach 20%.
- **Cholecystectomy:** mortality after urgent cholecystectomy for acute uncomplicated cholecystitis is not significantly higher than in younger patients.
- **Endoscopic sphincterotomy and removal of common duct stones:** well tolerated by older patients, with lower mortality than surgical common bile duct exploration.
- **Cancer of the gallbladder:** a disease of old age, with a 1-year survival of 10%.

**Fig. 24.44** Magnetic resonance cholangiopancreatogram showing multiple small stones in the gallbladder (large arrow), two larger stones in the distal common bile duct (smaller arrows) and also a cystic lesion in the head of pancreas (C).

passes into the duodenum. No stone is seen within the bile duct in 80% of cases of presumed gallstone pancreatitis, suggesting stone passage. Previous stone passage is also the likely cause of most cases of benign papillary fibrosis, which is most commonly seen in patients with previous or present gallstone disease. It presents with biliary pain (often following cholecystectomy) with cholestatic LFTs and biliary dilatation, or acute pancreatitis, and is treated by ERCP and sphincterotomy.

Cancer of the gallbladder is increasing in frequency but in over 85% of cases is associated with the presence of gallstones. Previously, the diagnosis was typically made as an incidental histological finding following cholecystectomy for gallstone disease. Increasing awareness of the risk of gallbladder carcinoma and of the role played by polyps in the natural history has led to an increase in screening activity and prospective diagnosis. Biliary disease is common in the elderly and can be challenging to manage in frail patients (Box 24.65).

### Investigations

Ultrasound is the investigation of choice for diagnosing gallstones. Most stones are diagnosed by transabdominal ultrasound, which has more than 84% sensitivity and 99% specificity for gallbladder stones (see Fig. 24.8). CT, MRCP (Fig. 24.44) and, increasingly, EUS are excellent modalities for detecting complications of gallstones (distal bile duct stone or gallbladder empyema) but are inferior to ultrasound in defining their presence in the gallbladder. When recurrent attacks of otherwise unexplained acute pancreatitis occur, they may result from 'microlithiasis' in the gallbladder or common bile duct and are best assessed by EUS.

### Management

Asymptomatic gallstones found incidentally in the gallbladder should not be treated because the majority will never cause symptoms.

### 24.66 Treatment of gallstones

#### Gallbladder stones

- Cholecystectomy: laparoscopic or open
- Oral bile acids: chenodeoxycholic or ursodeoxycholic (low rate of stone dissolution)

#### Bile duct stones

- Endoscopic sphincterotomy and stone extraction
- Surgical bile duct exploration
- Lithotripsy (endoscopic or extracorporeal shock wave, ESWL)

Symptomatic gallstones are best treated surgically by laparoscopic cholecystectomy; the severity of symptoms should be balanced against the individual patient surgical risk in order to decide whether surgery is warranted. Asymptomatic common bile duct stones should also be removed due to the high risk of complications (Box 24.66).

## Cholecystitis

### Acute cholecystitis

#### Pathophysiology

Acute cholecystitis is almost always associated with obstruction of the gallbladder neck or cystic duct by a gallstone. Occasionally, obstruction may be by mucus, parasitic worms or a biliary tumour, or may follow endoscopic bile duct stenting. The pathogenesis is unclear but the initial inflammation is possibly chemically induced. This leads to gallbladder mucosal damage, which releases phospholipase, converting biliary lecithin to lysolecithin, a recognised mucosal toxin. At the time of surgery, approximately 50% of cultures of the gallbladder contents are sterile. Infection occurs eventually, and in older patients or those with diabetes mellitus a severe infection with gas-forming organisms can cause emphysematous cholecystitis. Acalculous cholecystitis can occur in the intensive care setting and in association with parenteral nutrition, sickle cell disease and diabetes mellitus.

#### Clinical features

The cardinal feature is pain in the right upper quadrant but also in the epigastrium, the right shoulder tip or the interscapular region. Differentiation between biliary colic and acute cholecystitis may be difficult; features suggesting cholecystitis include severe and prolonged pain, fever and leucocytosis.

Examination shows right hypochondrial tenderness with guarding, worse on inspiration (Murphy's sign) and occasionally a gallbladder mass (30% of cases). Fever is present but rigors are unusual and suggest cholangitis. Jaundice occurs in less than 10% of patients and is usually due to passage of stones into the common bile duct, or to compression or even stricturing of the common bile duct following stone impaction in the cystic duct (Mirizzi syndrome). Gallbladder perforation occurs in 10%–15% of cases and gallbladder empyema may arise.

#### Investigations

Peripheral blood leucocytosis is common, except in older patients, in whom the signs of inflammation may be minimal. Minor increases of transaminases and amylase may be encountered. Amylase should be measured to detect acute pancreatitis, which may be a potentially serious complication of gallstones. Only when the amylase is higher than 1000 U/L can pain be confidently attributed to acute pancreatitis, since moderately elevated levels of amylase can occur with many other causes of abdominal pain. Plain X-rays of the abdomen and chest may show radio-opaque gallstones, and rarely intrabiliary gas due to fistulation of a gallstone into the intestine; they are important in excluding lower lobe pneumonia and a perforated viscus. Ultrasonography detects gallstones and gallbladder thickening due to cholecystitis but gallbladder empyema or perforation is best assessed by CT.

## Management

### Medical

Medical management consists of bed rest, pain relief, antibiotics and intravenous fluids. Moderate pain can be treated with NSAIDs but more severe pain should be managed with opiates. A cephalosporin (such as cefuroxime) or piperacillin/tazobactam is the usual antibiotic of choice, but metronidazole is normally added in severely ill patients and local prescribing practice may vary. Cholecystitis usually resolves with medical treatment but the inflammation may progress to an empyema or perforation and peritonitis.

### Surgical

Urgent surgery is the optimal treatment when cholecystitis progresses in spite of medical therapy and when complications such as empyema or perforation develop. The operation should be carried out within 5 days of the onset of symptoms. Delayed surgery after 2–3 months is no longer favoured. When cholecystectomy may be difficult due to extensive inflammatory change, percutaneous gallbladder drainage can be performed, with subsequent cholecystectomy 4–6 weeks later. Recurrent biliary colic or cholecystitis is frequent if the gallbladder is not removed.

## Chronic cholecystitis

Chronic inflammation of the gallbladder is almost invariably associated with gallstones. The usual symptoms are those of recurrent attacks of upper abdominal pain, often at night and following a heavy meal. The clinical features are similar to those of acute calculous cholecystitis but milder. Patients may recover spontaneously or following analgesia and antibiotics. They are usually advised to undergo elective laparoscopic cholecystectomy.

## Acute cholangitis

Acute cholangitis is caused by bacterial infection of bile ducts and occurs in patients with other biliary problems, such as choledocholithiasis (see below), biliary strictures or tumours, or after ERCP. Jaundice, fever (with or without rigors) and right upper quadrant pain are the main presenting features ('Charcot's triad'). Treatment is with antibiotics, relief of biliary obstruction and removal (if possible) of the underlying cause.

## Choledocholithiasis

Stones in the common bile duct (choledocholithiasis) occur in 10%–15% of patients with gallstones (Fig. 24.45), which have usually migrated from the gallbladder. Primary bile duct stones are rare but can develop within the common bile duct many years after a cholecystectomy, and are sometimes related to biliary sludge arising from dysfunction of the sphincter of Oddi. In Far Eastern countries, primary common bile duct stones are thought to follow bacterial infection secondary to parasitic infections with *Clonorchis sinensis*, *Ascaris lumbricoides* or *Fasciola hepatica*. Common bile duct stones can cause bile duct obstruction and may be complicated by cholangitis due to secondary bacterial infection, sepsis, liver abscess and biliary stricture.

### Clinical features

Choledocholithiasis may be asymptomatic, may be found incidentally by operative cholangiography at cholecystectomy or on abdominal imaging, or may manifest as biliary colic, jaundice, cholangitis or pancreatitis. If the gallbladder is still present, it is usually small, fibrotic and impalpable.

### Investigations

The LFTs show a cholestatic pattern. If cholangitis is present, the patient usually has a leucocytosis. Initial imaging is with transabdominal ultrasound which often show dilated extrahepatic and intrahepatic bile ducts, together with gallbladder stones (Fig. 24.46), but does not always reveal the cause of the obstruction in the common bile duct; 50% of bile duct stones are missed on ultrasound, particularly those in the distal common bile duct. MRCP and EUS both have a high sensitivity for ductal stones,

Fig. 24.45 Endoscopic retrograde cholangiopancreatogram showing common duct stones (arrows).

Fig. 24.46 Endoscopic ultrasonography (EUS) image showing a prominent common bile duct (CBD) containing a small stone (arrow) causing acoustic shadowing.

and can also help to define biliary anatomy prior to intervention. MRCP is often preferred as it is non-invasive.

### Management

Cholangitis should be treated with analgesia, intravenous fluids and broad-spectrum antibiotics, such as cefuroxime and metronidazole (local prescribing practice may vary). Blood cultures should be taken before the antibiotics are administered. Patients also require urgent decompression of the biliary tree and stone removal. ERCP with biliary sphincterotomy and stone extraction is the treatment of choice and is successful in about 90% of patients. In some complex cases cholangioscopy ('SpyGlass™') with electrohydraulic lithotripsy may be required. If ERCP fails, other approaches include percutaneous transhepatic drainage and combined ('rendezvous') endoscopic procedures, extracorporeal shock wave lithotripsy (ESWL) and surgery.

Surgical treatment of choledocholithiasis is performed less frequently than ERCP. The CBD may be explored laparoscopically, either trans-cystic (via the gallbladder) or trans-ductal, or at laparotomy.

## Recurrent pyogenic cholangitis

This disease occurs predominantly in South-east Asia. Biliary sludge, calcium bilirubinate concretions and stones accumulate in the intrahepatic bile ducts, with secondary bacterial infection. Patients present with recurrent attacks of upper abdominal pain, fever and cholestatic jaundice. Investigation of the biliary tree demonstrates that both the intrahepatic and the extrahepatic portions are filled with soft biliary mud. Eventually, the liver becomes scarred and liver abscesses and secondary biliary cirrhosis develop. The condition is difficult to manage and requires drainage of the biliary tract with extraction of stones, antibiotics and, in certain patients, partial resection of damaged areas of the liver.

## Tumours of the gallbladder and bile duct

### Carcinoma of the gallbladder

This is an uncommon tumour, occurring more often in females and usually in those over the age of 70 years. More than 90% are adenocarcinomas; the remainder are anaplastic or, rarely, squamous tumours. Gallstones are present in 70%–80% of cases and are thought to be important in the aetiology of the tumour. Individuals with a calcified gallbladder ('porcelain gallbladder') are at high risk of malignant change, and gallbladder polyps greater than 1 cm in size are associated with increased risk of malignancy; preventative cholecystectomy should be considered in such patients. Chronic infection with *Salmonella*, especially in areas where typhoid is endemic, is also a risk factor.

Carcinoma of the gallbladder may be diagnosed incidentally and is found in 0.2%–3% of gallbladders removed at cholecystectomy for gallstone disease. It may manifest as repeated attacks of biliary pain and, later, persistent jaundice and weight loss. A gallbladder mass may be palpable in the right hypochondrium. LFTs show cholestasis, and calcification of the gallbladder wall ('porcelain gallbladder') may be found on X-ray. The tumour can be diagnosed by ultrasonography and staged by CT. The treatment is surgical excision but local extension of the tumour beyond the wall of the gallbladder into the liver, lymph nodes and surrounding tissues is common at diagnosis. Only a minority of pre-operatively diagnosed gallbladder cancers are suitable for resection. Palliative management is usually all that can be offered. Survival is generally short, death typically occurring within 1 year in patients presenting with symptoms.

### Cholangiocarcinoma

Cholangiocarcinoma (CCA) is an uncommon tumour that can arise anywhere in the biliary tree, from the intrahepatic bile ducts (20%–25% of cases) and the confluence of the right and left hepatic ducts at the liver hilum (50%–60%) to the distal common bile duct (20%). It accounts for only 1.5% of all cancers but the incidence is increasing. The cause is unknown but the tumour is associated with gallstones, primary and secondary sclerosing cholangitis, Caroli's disease and choledochal cysts (see Fig. 24.43). In the Far East, particularly northern Thailand, chronic liver fluke infection (*Clonorchis sinensis*) is a major risk factor for the development of CCA in men. Primary sclerosing cholangitis carries a lifetime risk of CCA of 5%–20%, although only 5% of CCAs relate to primary sclerosing cholangitis. Cirrhosis is a risk factor for intrahepatic cholangiocarcinoma. Chronic biliary inflammation appears to be a common factor in the development of biliary dysplasia and cancer that is shared by all the predisposing causes.

Tumours typically invade the lymphatics and adjacent vessels, with a predilection for spread within perineural sheaths. The presentation is usually with obstructive jaundice. About 50% of patients also have upper abdominal pain and weight loss. The diagnosis is made using a combination of CT and MRI (see Fig. 24.10) but can be difficult to confirm in patients with sclerosing cholangitis. Serum levels of the tumour marker CA19-9 are elevated in up to 80% of cases, although this may occur in biliary obstruction of any cause. In the setting of biliary obstruction, ERCP may result in positive biliary cytology. The sensitivity of biliary brushing cytology is low (20%–43%) but can be improved with analysis for chromosomal aneuploidy using fluorescent in situ hybridisation (FISH). Endoscopic ultrasound–fine needle aspiration (EUS–FNA) of bile duct masses or lymph nodes is sometimes possible, and in specialist centres cholangioscopy with biopsy is now established. CCAs can be treated surgically in about 20% of patients, which improves 5-year survival from less than 5% to 20%–40%. Surgery involves excision of the extrahepatic biliary tree with or without a liver resection and a Roux loop reconstruction. Liver transplant is generally not recommended as a treatment for CCA due to high recurrence rate and poor long-term survival. Neoadjuvant chemotherapy followed by liver transplant is effective in highly selected patients with perihilar CCA, but is not a widely accepted or available treatment.

Most patients with CCA are treated with stent insertion across the malignant biliary stricture, using endoscopic or percutaneous transhepatic techniques to achieve relief of jaundice (Fig. 24.47). Patients with unresectable disease may receive chemotherapy and selected

**Fig. 24.47 Cholangiocarcinoma.** **A** Endoscopic retrograde cholangiopancreatogram showing a malignant distal biliary stricture (arrow) and dilated duct above this. **B** A self-expanding metallic stent (SEMS) has been placed across the stricture to relieve jaundice (arrow).

patients may benefit from combined chemotherapy and radiotherapy. Loco-regional therapies with chemotherapy may be effective for locally advanced unresectable tumours, but particularly intrahepatic CCA. Palliation with endoscopic photodynamic therapy has provided encouraging results for extrahepatic CCA.

### Carcinoma at the ampulla of Vater

Nearly 40% of all adenocarcinomas of the small intestine arise in relationship to the ampulla of Vater and present with pain, anaemia, vomiting and weight loss. Jaundice may be intermittent or persistent. The diagnosis is made by duodenal endoscopy and biopsy of the tumour but staging by CT/MRI and EUS is essential. Ampullary carcinoma must be differentiated from carcinoma of the head of the pancreas and a CCA because these last two conditions both have a worse prognosis. Imaging may show a 'double duct sign' with dilatation of both the common bile duct and pancreatic duct due to obstruction at the ampulla. EUS is the most sensitive method of assessing and staging ampullary or periampullary tumours.

Curative surgical treatment can be undertaken by pancreaticoduodenectomy and the 5-year survival may be as high as 50%. If resection is impossible, palliative surgical bypass or stenting may be necessary.

### Benign gallbladder tumours

These are uncommon, often asymptomatic and usually found incidentally at operation or postmortem. Cholesterol polyps, sometimes associated with cholesterosis, papillomas and adenomas, are the main types.

### Miscellaneous biliary disorders

#### Functional gallbladder disorder

Functional gallbladder disorder refers to symptoms of biliary-type pain in the absence of gallstones, sludge or microlithiasis. Gallstone disease needs to be excluded by means of abdominal US ± EUS to exclude microlithiasis. Other diagnostic tests may be required to exclude peptic ulcer disease, pancreatitis or musculoskeletal syndromes. Cholecystokinin-stimulated hepatobiliary scintigraphy can be used to evaluate gallbladder ejection fraction.

Symptoms suggestive of functional gallbladder disorder often improve spontaneously so urgent surgical intervention is not required. Management involves patient education and reassurance. Pharmacological therapy with analgesia, neuromodulators and antispasmodics may be beneficial. Cholecystectomy can improve symptoms in many patients with recurrent functional biliary pain. It is suggested that a low gallbladder ejection fraction (<40%) may identify a subset of patients likely to benefit from surgery but evidence is contradictory.

#### Post-cholecystectomy syndrome

Post-cholecystectomy syndrome refers to a complex of heterogeneous symptoms including abdominal pain and dyspepsia that recur and/or persist following cholecystectomy. It occurs in 10%–30% of patients depending on how the condition is defined, how actively symptoms are sought and what the original indication for cholecystectomy was. The syndrome occurs most frequently in women, in patients who have had symptoms for more than 5 years before cholecystectomy, and in cases when the operation was undertaken for non-calculous gallbladder disease. An increase in bowel frequency resulting from bile acid diarrhoea occurs in about 5%–10% of patients after cholecystectomy and often responds to colestyramine (4–8g daily). Severe post-cholecystectomy syndrome occurs in only 2%–5% of patients. The main causes are listed in [Box 24.67](#).

The usual symptoms include right upper quadrant pain, flatulence, fatty food intolerance and occasionally jaundice and cholangitis. The LFTs may be abnormal and sometimes show cholestasis. Ultrasonography is used to detect biliary obstruction, and EUS or MRCP to seek common

### 24.67 Causes of post-cholecystectomy symptoms

#### Immediate post-surgical

- Bleeding
- Biliary peritonitis
- Abscess
- Bile duct trauma/transection
- Fistula

#### Biliary

- Common bile duct stones
- Benign stricture
- Tumour
- Cystic duct stump syndrome
- Disorders of the ampulla of Vater (e.g. benign papillary fibrosis; sphincter of Oddi dysfunction)

#### Extrabiliary

- Functional dyspepsia
- Peptic ulcer
- Pancreatic disease
- Gastro-oesophageal reflux
- Irritable bowel syndrome
- Functional abdominal pain

bile duct stones. If retained bile duct stones are excluded, sphincter of Oddi dysfunction should be considered (see below). Other investigations that may be required include upper gastrointestinal endoscopy, small bowel radiology and pancreatic function tests. The possibility of a functional illness should also be considered.

### Functional biliary sphincter disorders ('sphincter of Oddi dysfunction')

The sphincter of Oddi is a small smooth-muscle sphincter situated at the junction of the bile duct and pancreatic duct in the duodenum. It has been believed that sphincter of Oddi dysfunction (SOD) was characterised by an increase in contractility that produces a benign non-calculous obstruction to the flow of bile or pancreatic juice. This may cause pancreaticobiliary pain, deranged LFTs or recurrent pancreatitis. Classification systems, based on clinical history, laboratory results, findings on investigation and response to interventions, are difficult because of the fluctuating nature of symptoms and the well-recognised placebo effect of interventions. SOD was previously classified into types I–III but these have been replaced by newer terminology ([Boxes 24.68](#) and [24.69](#)).

#### Clinical features

Patients with functional biliary sphincter disorders, who are predominantly female, present with symptoms and signs suggestive of either biliary or pancreatic disease:

- *Patients with biliary sphincter disorders* experience recurrent, episodic biliary-type pain. They have often had a cholecystectomy but the gallbladder may be intact.
- *Patients with pancreatic sphincter disorders* usually present with unexplained recurrent attacks of pancreatitis.

#### Investigations

The diagnosis is established by excluding gallstones, including microlithiasis, and by demonstrating a dilated or slowly draining bile duct. The gold standard for diagnosis is sphincter of Oddi manometry. This is not widely available, however, and is associated with a high rate of procedure-related pancreatitis. Hepatobiliary scintigraphy may have value in the second-line investigation of post-cholecystectomy syndrome.

#### Management

All patients with organic stenosis are treated with endoscopic sphincterotomy. The results are good but patients should be warned that there is a high risk of complications, particularly acute pancreatitis (10%–15%). Manometry should ideally be performed in all suspected functional sphincter of Oddi disorder patients, and results of sphincterotomy in those with high pressures are good, but this should be avoided in

### 24.68 Classification of biliary sphincter of Oddi dysfunction (SOD)

#### Organic stenosis (formerly SOD type I)

- Biliary-type pain
- Abnormal liver enzymes (ALP or ALT/AST > twice normal on two or more occasions)
- Dilated common bile duct (> 12 mm diameter on US or > 10 mm on cholangiography)
- Delayed drainage of ERCP contrast beyond 45 mins

#### Functional sphincter of Oddi disorder (formerly SOD type II)

- Biliary-type pain
- Absence of bile duct stones or other structural abnormalities
- Elevated liver enzymes or dilated bile duct (but not both)

#### Functional biliary-type pain (formerly SOD type III)

- Biliary-type pain with no other abnormalities

(ALT = alanine aminotransferase; ALP = alkaline phosphatase; AST = aspartate aminotransferase; ERCP = endoscopic retrograde cholangiopancreatography; US = ultrasound)

### 24.69 Criteria for pancreatic sphincter of Oddi dysfunction

- Recurrent attacks of acute pancreatitis – pancreatic-type pain with amylase or lipase 3 times normal and/or imaging evidence of acute pancreatitis
- Other aetiologies of acute pancreatitis excluded
- Normal pancreas at endoscopic ultrasound
- Abnormal sphincter manometry

patients with functional biliary-type pain as it is of no benefit. Medical therapy with nifedipine and/or low-dose amitriptyline may be tried. Pancreatic SOD can be treated with biliary sphincterotomy, carried out in specialist centres, but this should be undertaken with caution and careful consideration.

Routine prophylactic pancreatic duct stenting in patients undergoing ERCP for sphincter of Oddi disorders is no longer encouraged. Prophylactic administration of rectal NSAIDs (e.g. diclofenac 100mg) is recommended instead because this significantly reduces the risk of procedure-related acute pancreatitis.

### Cholesterosis of the gallbladder

In this condition, lipid deposits in the submucosa and epithelium appear as multiple yellow spots on the pink mucosa, giving rise to the description 'strawberry gallbladder'. Cholesterosis of the gallbladder is usually asymptomatic. Larger polypoid deposits occur in a third of cases leading to the formation of cholesterol polyps that can detach resulting in complications similar to small gallstones, including right upper quadrant pain. Small,

fixed filling defects may be visible on ultrasonography; the radiologist can usually differentiate between gallstones and cholesterosis. The condition is usually diagnosed at cholecystectomy; if the diagnosis is made radiologically, cholecystectomy may be indicated, depending on symptoms.

### Adenomyomatosis of the gallbladder

In this condition, there is hyperplasia of the muscle and mucosa of the gallbladder. The projection of pouches of mucous membrane through weak points in the muscle coat produces Rokitansky–Aschoff sinuses. There is much disagreement over whether adenomyomatosis is a cause of right upper quadrant pain or other gastrointestinal symptoms. It may be diagnosed by oral cholecystography, when a halo or ring of opacified diverticula can be seen around the gallbladder. Other appearances include deformity of the body of the gallbladder or marked irregularity of the outline. Localised adenomyomatosis in the region of the gallbladder fundus causes the appearance of a 'Phrygian cap'. Most patients are treated by cholecystectomy but only after other diseases in the upper gastrointestinal tract have been excluded.

### IgG4-associated cholangitis

This often presents with obstructive jaundice and is described on page 901.

## Multiple Choice Questions

- 24.1 A 52-year-old homeless man with a history of alcohol dependency is admitted to hospital with a 2-month history of weight loss, fever, cough and abdominal distension. Liver ultrasound scan shows moderate ascites with normal liver appearance with patent portal/hepatic veins and no focal lesions. A diagnostic ascitic tap is performed:
- Microscopy: WCC 350 cell/mm<sup>3</sup>, polymorphs 100 cells/mm<sup>3</sup>, lymphocytes 250 cells/mm<sup>3</sup>. No organisms seen.  
Ascitic protein: 28 g/L  
Ascitic albumin: 19 g/L  
Serum albumin: 26 g/L  
Cytology: inflammatory cells only.
- What is the most likely cause of this patient's ascites?
- A. Spontaneous bacterial peritonitis  
B. Tuberculosis  
C. Budd–Chiari syndrome  
D. Pancreatic cancer  
E. Alcohol-related liver disease with cirrhosis

Answer: B.

Tuberculosis is a cause of high-protein ascites with a low serum–ascites albumin gradient (SAAG) (< 11 g/L). Elevated lymphocytes are typically seen on ascites microscopy. Acid-fast bacilli (AFB) may be seen but prolonged TB culture may be required for definitive diagnosis. Budd–Chiari syndrome is a cause of ascites with high SAAG (> 11 g/L). Disseminated malignancy with peritoneal involvement is a cause of exudative ascites with low SAAG (< 11 g/L) but normal CT imaging and ascites cytology makes this diagnosis less likely. Ascites due to liver cirrhosis has a high SAAG (> 11 g/L). Spontaneous bacterial peritonitis is diagnosed by the finding of elevated polymorphs (> 250 cells/mm<sup>3</sup>) in ascitic fluid.

- 24.2 A 56-year-old woman with autoimmune hepatitis and cirrhosis is admitted with agitation and confusion. Examination reveals a flapping tremor and a diagnosis of hepatic encephalopathy is made. Which of the following would be suitable first-line therapy?
- A. Dietary protein restriction  
B. Oral lactulose  
C. Rifaximin  
D. L-ornithine L-aspartate (LOLA)  
E. Benzodiazepines

Answer: B.

Hepatic encephalopathy is caused by disturbed brain function provoked by gut-derived neurotoxins that are normally metabolised by the liver and excluded from the systemic circulation. Treatment aims to reduce toxin production in the bowel. First-line therapy is with lactulose (15–30 mL three times daily) to promote regular bowel motions. Rifaximin is a non-absorbable antibiotic that reduces bacterial load in the gut and is helpful in treating recurrent episodes of encephalopathy. L-ornithine L-aspartate (LOLA) is an amino acid supplement that may be useful in

reducing ammonia levels and improving encephalopathy in patients with refractory disease. Dietary protein restriction is no longer recommended in the treatment of encephalopathy and may worsen nutritional state. Sedative drugs including opiates and benzodiazepines may precipitate/worsen encephalopathy in cirrhotic patients and should be avoided in these patients.

- 24.3 An 18-year-old man presents to his family doctors having noticed mild jaundice having been treated with a course of oral amoxicillin for lower respiratory tract infection. Abdominal ultrasound is normal. His liver biochemistry reveals:
- Bilirubin 60 µmol/L  
Direct bilirubin 9 µmol/L  
ALT 23 U/L  
ALP 82 U/L  
GGT 35 U/L  
Albumin 40 g/L
- What is the most likely diagnosis?
- A. Drug-induced liver injury  
B. Primary sclerosing cholangitis  
C. Gilbert syndrome  
D. Dubin–Johnston syndrome  
E. Hepatitis E infection

Answer: C.

Gilbert syndrome is an inherited disorder of bilirubin metabolism characterised by isolated elevation of bilirubin, usually in the context of physical stress or illness. It presents with isolated elevation of unconjugated bilirubin (indirect bilirubin) and otherwise normal liver enzymes. Drug-induced liver injury may present with jaundice but there would be additional liver enzyme disturbance following either a hepatitic, cholestatic or mixed pattern. Dubin–Johnston syndrome is an inherited disorder of bilirubin metabolism associated with conjugated (direct) hyperbilirubinaemia. Hepatitis E infection may present with jaundice in associated with an acute hepatitis with elevated transaminase levels (ALT/AST).

- 24.4 A 42-year-old man presents with abnormal liver enzymes, on a background of early onset emphysema. His serum  $\alpha_1$ -AT level is 0.03 g/L (normal range 1.1–2.1 g/L). Which of the following statements about alpha-1-antitrypsin deficiency is true?
- A. Most liver disease is due to the PiMM genotype  
B. Lung disease occurs due to the accumulation of abnormally folded protein in alveolar cells  
C. Inheritance is autosomal dominant  
D. It can present as neonatal jaundice  
E. A liver biopsy is required for diagnosis

Answer: D.

Alpha-1-antitrypsin deficiency can present in a range of ways, from neonatal cholestatic jaundice through to adult-onset cirrhosis. Inheritance is autosomal recessive. The normal genotype is PiMM and most disease is due to PiZZ. Liver disease occurs due to accumulation of abnormally folded protein in hepatocytes, whereas lung disease is a result of unopposed neutrophil elastase activity. Diagnosis is usually based on serum  $\alpha_1$ -AT levels and genotyping.

24.5 A 56-year-old man with alcohol-related cirrhosis is admitted with ascites and hepatic encephalopathy, and is noted to have loss of muscle mass. The Na is 131 mmol/L (normal range 135–145). Which of the following would you advise the patient?

- A. Salt intake should be increased in view of hyponatraemia
- B. Fluid intake should be restricted
- C. Protein intake should be restricted in view of encephalopathy
- D. Calorie intake should be 15–20 kCal/kg per day
- E. A bedtime snack is recommended

Answer: E.

Malnutrition is common in cirrhosis. A bedtime snack will avoid prolonged fasting which can trigger catabolism. Calorie intake should be at least 35 kCal/kg per day, with a protein intake of 1.2–1.5 g/kg. A no-added-salt diet is recommended in ascites, and fluid restriction is rarely needed (and may exacerbate renal impairment in this case).

- Breathlessness

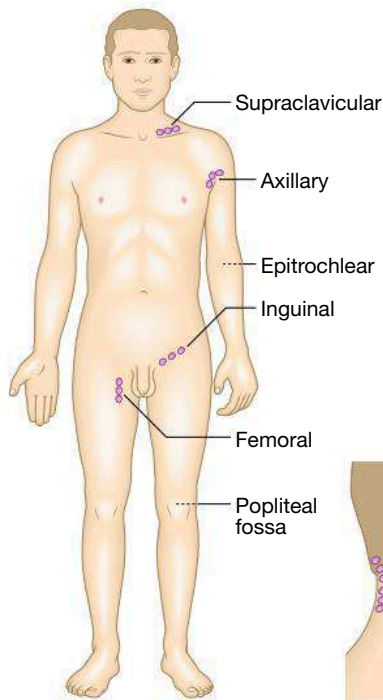

*Insets (Glossitis) From Hoffbrand VA, John E, Pettit JE, Vyas P. Color atlas of clinical hematology, 4th edn. Philadelphia: Mosby, Elsevier Inc.; 2010; (Petechiae) From Young NS, Gerson SL, High KA (eds). Clinical hematology. St Louis: Mosby, Elsevier Inc.; 2006.*

Abnormalities detected in the blood are caused not only by primary diseases of the blood and lymphoreticular systems, but also by diseases affecting other systems of the body. The clinical assessment of patients with haematological abnormalities must include

a general history and examination, as well as a search for symptoms and signs of specific primary haematological and other disorders that result in abnormalities of red cells, white cells, platelets, coagulation, lymph nodes and lymphoreticular tissues.

## 6 Lymphadenopathy

Lymphadenopathy can be caused by benign or malignant disease. The clinical points to clarify are shown in the box.

### Lymphadenopathy

#### History

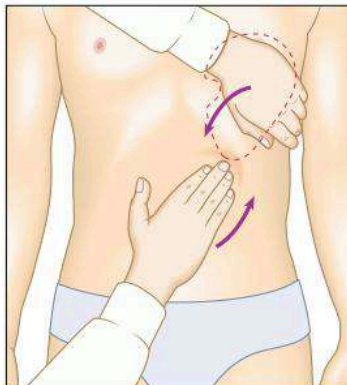

- Speed of onset, rate of enlargement
- Painful or painless
- Associated symptoms: weight loss, night sweats, itch

#### Examination

- Sites: localised, generalised
- Size (cm)
- Character: hard, soft, rubbery
- Fixed, mobile
- Search area that node drains for abnormalities (e.g. dental abscess)
- Other general examination (e.g. joints, rashes, finger clubbing)

## 8 Examination of the spleen

- Move your hand up from the right iliac fossa, towards the left upper quadrant on expiration.
- Keep your hand still and ask the patient to take a deep breath through the mouth to feel the spleen edge being displaced downwards.
- Place your left hand around the patient's lower ribs and approach the costal margin to pull the spleen forwards.
- To help palpate a spleen that is only slightly enlarged, roll the patient on to the right side and examine as before.

### Characteristics of the spleen

- Notch
- Superficial
- Dull to percussion
- Cannot get examining hand between ribs and spleen
- Moves well with respiration

## Anaemia

Symptoms and signs help to indicate the clinical severity of anaemia. A full history and examination is needed to identify the underlying cause.

### Anaemia

#### Non-specific symptoms

- Tiredness
- Lightheadedness
- Breathlessness
- Development/worsening of ischaemic symptoms, e.g. angina or claudication

#### Non-specific signs

- Mucous membrane pallor
- Tachypnoea
- Raised jugular venous pressure
- Tachycardia
- Flow murmurs
- Ankle oedema
- Postural hypotension

## Bleeding

Bleeding can be due to congenital or acquired abnormalities in the coagulation system. History and examination help to clarify the severity and the underlying cause of the bleeding problem.

### Bleeding

#### History

- Site of bleed
- Duration of bleed
- Precipitating causes, including previous surgery or trauma
- Family history
- Drug history
- Age at presentation
- Other medical conditions, e.g. liver disease

#### Examination

There are two main patterns of bleeding:

1. Mucosal bleeding
  - Reduced number or function of platelets (e.g. bone marrow failure or aspirin) or von Willebrand factor (e.g. von Willebrand disease)
  - Skin: petechiae, bruises
  - Gum and mucous membrane bleeding
  - Fundal haemorrhage
  - Post-surgical bleeding
2. Coagulation factor deficiency (e.g. haemophilia or warfarin/anticoagulant)
  - Bleeding into joints (haemarthrosis) or muscles
  - Bleeding into soft tissues
  - Retroperitoneal haemorrhage
  - Intracranial haemorrhage
  - Post-surgical bleeding

Disorders of the blood cover a wide spectrum of illnesses, ranging from some of the most common disorders affecting humans (anaemias) to relatively rare conditions such as leukaemias and congenital coagulation disorders. Although the latter are uncommon, advances in cellular and molecular biology have had major impacts on their diagnosis, treatment and prognosis. Haematological changes occur as a consequence of diseases affecting any system and give important information in the diagnosis and monitoring of many conditions.

## Functional anatomy and physiology

Blood flows throughout the body in the vascular system, and consists of:

- red cells, which transport oxygen from the lungs to the tissues
- white cells, which defend against infection
- platelets, which interact with blood vessels and clotting factors to maintain vascular integrity and prevent bleeding
- plasma, which contains proteins with many functions, including antibodies and coagulation factors.

## Haematopoiesis

Haematopoiesis describes the formation of blood cells, an active process that must maintain normal numbers of circulating cells and be able to respond rapidly to increased demands such as bleeding or infection. During development, haematopoiesis occurs in the yolk sac, liver and spleen, and subsequently in red bone marrow in the medullary cavity of all bones. In childhood, red marrow is progressively replaced by fat (yellow marrow) so that, in adults, normal haematopoiesis is restricted to the vertebrae, pelvis, sternum, ribs, clavicles, skull, upper humeri and proximal femora. However, red marrow can expand in response to increased demands for blood cells.

Bone marrow contains a range of immature haematopoietic precursor cells and a storage pool of mature cells for release at times of increased demand. Haematopoietic cells interact closely with surrounding connective tissue stroma, made up of reticular cells, macrophages, fat cells, blood vessels and nerve fibres (Fig. 25.1). In normal marrow, nests of red cell precursors cluster around a central macrophage, which provides iron and also phagocytoses nuclei from red cells prior to their release into the circulation. Megakaryocytes are large cells that produce and release platelets into vascular sinuses. White cell precursors are clustered next to the bone trabeculae; maturing cells migrate into the marrow

spaces towards the vascular sinuses. Plasma cells are antibody-secreting mature B cells that normally represent less than 5% of the marrow population and are scattered throughout the intertrabecular spaces.

## Stem cells

All blood cells are derived from pluripotent haematopoietic stem cells. These comprise only 0.01% of the total marrow cells, but they can self-renew (i.e. make more stem cells) or differentiate to produce a hierarchy of lineage-committed progenitor cells. The resulting primitive progenitor cells cannot be identified morphologically, so they are named according to the types of cell (or colony) they form during cell culture experiments. CFU-GM (colony-forming unit – granulocyte, monocyte) is a progenitor cell that produces granulocytic and monocytic lines, CFU-E produce erythroid cells, and CFU-Meg produce megakaryocytes and ultimately platelets (Fig. 25.2).

Growth factors, produced in bone marrow stromal cells and elsewhere, control the survival, proliferation, differentiation and function of stem cells and their progeny. Some, such as interleukin-3 (IL-3), stem cell factor (SCF) and granulocyte, macrophage-colony-stimulating factor (GM-CSF), act on a wide number of cell types at various stages of differentiation. Others, such as erythropoietin, granulocyte-colony-stimulating factor (G-CSF) and thrombopoietin (Tpo), are lineage-specific. Many of these growth factors are now synthesised by recombinant DNA technology and used as treatments: for example, erythropoietin to correct renal anaemia and G-CSF to hasten neutrophil recovery after chemotherapy.

The bone marrow also contains stem cells that can differentiate into non-haematological cells. Mesenchymal stem cells differentiate into skeletal muscle, cartilage, cardiac muscle and fat cells while others differentiate into nerves, liver and blood vessel endothelium. This is termed stem cell plasticity and may have exciting clinical applications in the future (Ch. 3).

## Blood cells and their functions

### Red cells

Red cell precursors formed in the bone marrow from the erythroid (CFU-E) progenitor cells are called erythroblasts or normoblasts (Fig. 25.3). These divide and acquire haemoglobin, which turns the cytoplasm pink; the nucleus condenses and is extruded from the cell. The first non-nucleated red cell is a reticulocyte, which still contains ribosomal material in the cytoplasm, giving these large cells a faint blue tinge ('polychromasia').

Fig. 25.1 Structural organisation of normal bone marrow.

**Fig. 25.2** Stem cells and growth factors in haematopoietic cell development. (BFU-E = burst-forming unit – erythroid; CFU-E = colony-forming unit – erythroid; CFU-GM = colony-forming unit – granulocyte, monocyte; CFU-Meg = colony-forming unit – megakaryocyte; Epo = erythropoietin; G-CSF = granulocyte–colony-stimulating factor; GM-CSF = granulocyte, macrophage – colony-stimulating factor; IL = interleukin; M-CSF = macrophage–colony-stimulating factor; SCF = stem cell factor; Tpo = thrombopoietin)

**Fig. 25.3** Maturation pathway of red cells, granulocytes and platelets. The image on the right is a normal blood film.

Reticulocytes lose their ribosomal material and mature over 3 days, during which time they are released into the circulation. Increased numbers of circulating reticulocytes (reticulocytosis) reflect increased erythropoiesis. Proliferation and differentiation of red cell precursors is stimulated by erythropoietin, a polypeptide hormone produced by renal interstitial peritubular cells in response to hypoxia. Failure of erythropoietin production in patients with renal failure causes anaemia, which can be treated

with exogenous recombinant erythropoietin or similar pharmacological agents called erythropoiesis-stimulating agents, e.g. darbepoetin.

Normal mature red cells circulate for about 120 days. They are  $8\mu\text{m}$  biconcave discs lacking a nucleus, but filled with haemoglobin, which delivers oxygen to the tissues. In order to pass through the smallest capillaries, the red cell membrane is deformable, with a lipid bilayer to which a 'skeleton' of filamentous proteins is attached via special linkage

**Fig. 25.4 Normal structure of red cell membrane.** Red cell membrane flexibility is conferred by attachment of cytoskeletal proteins. Important transmembrane proteins include band 3 (an ion transport channel) and glycophorin C (involved in cytoskeletal attachment and gas exchange, and a receptor for *Plasmodium falciparum* in malaria). Antigens on the red blood cell determine an individual's blood group. There are currently 39 blood group systems (groups of carbohydrate or protein antigens controlled by a single gene or by multiple closely linked loci); the most important clinically are the ABO and Rhesus (Rh) systems (p. 940). The ABO genetic locus has three main allelic forms: A, B and O. The A and B alleles encode glycosyltransferases that introduce *N*-acetylgalactosamine (open circle) and *D*-galactose (blue circle), respectively, on to antigenic carbohydrate molecules on the membrane surface. People with the O allele produce an O antigen, which lacks either of these added sugar groups. Rh antigens are transmembrane proteins.

proteins (Fig. 25.4). Inherited abnormalities of any of these proteins result in loss of membrane as cells pass through the spleen, and the formation of abnormally shaped red cells called spherocytes or elliptocytes (see Fig. 25.8D). Red cells are exposed to osmotic stress in the pulmonary and renal circulation; in order to maintain homeostasis, the membrane contains ion pumps, which control intracellular levels of sodium, potassium, chloride and bicarbonate. In the absence of mitochondria, the energy for these functions is provided by anaerobic glycolysis and the pentose phosphate pathway in the cytosol. Membrane glycoproteins inserted into the lipid bilayer also form the antigens recognised by blood grouping (see Fig. 25.4). The ABO and Rhesus systems are the most commonly recognised, but over 400 blood group antigens have been described.

### Haemoglobin

Haemoglobin is a protein specially adapted for oxygen transport. It is composed of four globin chains, each surrounding an iron-containing porphyrin pigment molecule termed haem. Globin chains are a combination of two alpha and two non-alpha chains; haemoglobin A ( $\alpha\alpha/\beta\beta$ ) represents over 90% of adult haemoglobin, whereas haemoglobin F ( $\alpha\alpha/\gamma\gamma$ ) is the predominant type in the fetus. Each haem molecule contains a ferrous ion ( $\text{Fe}^{2+}$ ), to which oxygen reversibly binds; the affinity for oxygen increases as successive oxygen molecules bind. When oxygen is bound, the beta chains 'swing' closer together; they move apart as oxygen is lost. In the 'open' deoxygenated state, 2,3-bisphosphoglycerate (2,3-BPG), a product of red cell metabolism, binds to the haemoglobin molecule and lowers its oxygen affinity. These complex interactions produce the sigmoid shape of the oxygen dissociation curve (Fig. 25.5). The position of this curve depends on the concentrations of 2,3-BPG,  $\text{H}^+$  ions and  $\text{CO}_2$ ; increased levels shift the curve to the right and cause oxygen to be released more readily, e.g. when red cells reach hypoxic tissues. Haemoglobin F is unable to bind 2,3-BPG and has a left-shifted oxygen dissociation curve, which, together with the low pH of fetal blood, ensures fetal oxygenation. Strong oxidising agents, such as dapsone, can convert the ferrous iron in haemoglobin to its ferric state ( $\text{Fe}^{3+}$ ). The resultant methaemoglobin also has a left-shifted oxygen dissociation curve, which can result in tissue hypoxia (see Fig. 10.1).

Genetic mutations affecting the haem-binding pockets of globin chains or the 'hinge' interactions between globin chains result in

**Fig. 25.5 The haemoglobin–oxygen dissociation curve.** Factors are listed that shift the curve to the right (more oxygen released from blood) and to the left (less oxygen released) at given  $\text{PO}_2$ . To convert kPa to mmHg, multiply by 7.5. (2,3-BPG = 2,3-bisphosphoglycerate).

haemoglobinopathies or unstable haemoglobins. Alpha globin chains are produced by two genes on chromosome 16, and beta globin chains by a single gene on chromosome 11; imbalance in the production of globin chains results in the thalassaemias (p. 962). Defects in haem synthesis cause the porphyrias (Ch. 19).

### Destruction

Red cells at the end of their lifespan of approximately 120 days are phagocytosed by the reticulo-endothelial system. Amino acids from globin chains are recycled and iron is removed from haem for reuse in haemoglobin synthesis. The remnant haem structure is degraded to bilirubin and conjugated with glucuronic acid before being excreted in bile. In the small bowel, bilirubin is converted to stercobilin; most of this is excreted, but a small amount is reabsorbed and excreted by the kidney

as urobilinogen. Increased red cell destruction due to haemolysis or ineffective haematopoiesis results in jaundice and increased urinary urobilinogen. Free intravascular haemoglobin is toxic and is normally bound by haptoglobins, which are plasma proteins produced by the liver.

## White cells

White cells or leucocytes in the blood consist of granulocytes (neutrophils, eosinophils and basophils), monocytes and lymphocytes (see Fig. 25.12). Granulocytes and monocytes are formed from bone marrow CFU–GM progenitor cells during myelopoiesis. The first recognisable granulocyte in the marrow is the myeloblast, a large cell with a small amount of basophilic cytoplasm and a primitive nucleus with open chromatin and nucleoli. As the cells divide and mature, the nucleus segments and the cytoplasm acquires specific neutrophilic, eosinophilic or basophilic granules (see Fig. 25.3). This takes about 14 days. The cytokines G–CSF, GM–CSF and M–CSF are involved in the production of myeloid cells, and recombinant G–CSF can be used clinically to hasten recovery of blood neutrophil counts after chemotherapy.

Myelocytes or metamyelocytes are normally found only in the marrow, but may appear in the circulation in response to infection or toxic states. The appearance of more primitive myeloid precursors in the blood is often associated with the presence of nucleated red cells and is termed a 'leucoerythroblastic' picture; this indicates a serious disturbance of marrow function.

### Neutrophils

Neutrophils, the most common white blood cells in the blood of adults, are 10–14 µm in diameter, with a multilobular nucleus containing 2–5 segments and granules in their cytoplasm. Their main function is to recognise, ingest and destroy foreign particles and microorganisms (see Ch. 4). A large storage pool of mature neutrophils exists in the bone marrow. Every day, some  $10^{11}$  neutrophils enter the circulation, where cells may be circulating freely or attached to endothelium in the marginating pool. These two pools are equal in size; factors such as exercise or catecholamines increase the number of cells flowing in the blood. Neutrophils spend 6–10 hours in the circulation before being removed, principally by the spleen. Alternatively, they pass into the tissues and either are consumed in the inflammatory process or undergo apoptotic cell death and phagocytosis by macrophages.

### Eosinophils

Eosinophils represent 1%–6% of the circulating white cells. They are a similar size to neutrophils, but have a bilobed nucleus and prominent orange granules on Romanowsky staining. Eosinophils are phagocytic and their granules contain a peroxidase capable of generating reactive oxygen species and proteins involved in the intracellular killing of protozoa and helminths (Ch. 13). They are also involved in allergic reactions (e.g. atopic asthma, Ch. 17; see also Ch. 4).

### Basophils

These cells are less common than eosinophils, representing less than 1% of circulating white cells. They contain dense black granules that obscure the nucleus. Mast cells resemble basophils, but are found only in the tissues. These cells are involved in hypersensitivity reactions (Ch. 4).

### Monocytes

Monocytes are the largest of the white cells, with a diameter of 12–20 µm and an irregular nucleus in abundant pale blue cytoplasm containing occasional cytoplasmic vacuoles. These cells circulate for a few hours and then migrate into tissue, where they become macrophages, Kupffer cells or antigen-presenting dendritic cells. The former phagocytose debris, apoptotic cells and microorganisms (see Box 4.1).

### Lymphocytes

Lymphocytes are derived from pluripotent haematopoietic stem cells in the bone marrow. There are two main types: T cells (which mediate

cellular immunity) and B cells (which mediate humoral immunity) (Ch. 4). Lymphoid cells that migrate to the thymus develop into T cells, whereas B cells develop in the bone marrow.

The majority (about 80%) of lymphocytes in the circulation are T cells. Lymphocytes are heterogeneous, the smallest being the size of red cells and the largest the size of neutrophils. Small lymphocytes are circular with scanty cytoplasm but the larger cells are more irregular with abundant blue cytoplasm. Lymphocyte subpopulations have specific functions and lifespan can vary from a few days to many years. Cell surface antigens ('cluster of differentiation' (CD) antigens), which appear at different points of lymphocyte maturation and indicate the lineage and maturity of the cell, are used to classify lymphomas and lymphoid leukaemias.

## Haemostasis

Blood must be maintained in a fluid state in order to function as a transport system, but must be able to solidify to form a clot following vascular injury in order to prevent excessive bleeding, a process known as haemostasis. Successful haemostasis is localised to the area of tissue damage and is followed by removal of the clot and tissue repair. This is achieved by complex interactions between the vascular endothelium, platelets, von Willebrand factor, coagulation factors, natural anticoagulants and fibrinolytic enzymes (Fig. 25.6 and see Fig. 25.18). Dysfunction of any of these components may result in haemorrhage or thrombosis.

### Platelets

Platelets are formed in the bone marrow from megakaryocytes. Megakaryocytic progenitor cells (CFU–Meg) divide to form megakaryoblasts, which undergo a process called 'endomitotic reduplication', in which there is division of the nucleus but not the cell. This creates mature megakaryocytes, large cells with several nuclei and cytoplasm containing platelet granules. Large numbers of platelets then fragment off from each megakaryocyte into the circulation. The formation and maturation of megakaryocytes is stimulated by thrombopoietin produced in the liver. Platelets circulate for 8–10 days before they are destroyed in the reticulo-endothelial system. Some 30% of peripheral platelets are normally pooled in the spleen and do not circulate.

Under normal conditions, platelets are discoid, with a diameter of 2–4 µm (Fig. 25.7). The surface membrane invaginates to form a tubular network, the canalicular system, which provides a conduit for the discharge of the granule content following platelet activation. Drugs that inhibit platelet function and thrombosis include aspirin (cyclo-oxygenase inhibitor), clopidogrel, prasugrel and ticagrelor (adenosine diphosphate (ADP)-mediated activation inhibitors), dipyridamole (phosphodiesterase inhibitor), and abciximab, tirofiban and eptifibatid (which prevent fibrinogen binding to glycoprotein IIb/IIIa (α<sub>IIb</sub>β<sub>3</sub> integrin); see Fig. 25.18).

### Clotting factors

The coagulation system consists of a cascade of soluble inactive zymogen proteins designated by Roman numerals. When proteolytically cleaved and activated, each is capable of activating one or more components of the cascade. Activated factors are designated by the suffix 'a'. Some of these reactions require phospholipid and calcium. Coagulation occurs by two pathways: it is initiated by the extrinsic (or tissue factor) pathway and amplified by the 'intrinsic pathway' (see Fig. 25.6D).

Clotting factors are synthesised by the liver, although factor V is also produced by platelets and endothelial cells. Factors II, VII, IX and X require post-translational carboxylation to allow them to participate in coagulation. The carboxylase enzyme responsible for this in the liver is vitamin K-dependent. Vitamin K is converted to an epoxide in this reaction and must be reduced to its active form by a reductase enzyme. This reductase is inhibited by warfarin, and this is the basis of the anticoagulant effect of coumarins (p. 947). Inherited (e.g. haemophilia) and acquired (e.g. liver failure) causes of coagulation factor deficiency are associated with bleeding.

**Fig. 25.6** The stages of normal haemostasis. **A** Stage 1. Pre-injury conditions encourage flow. The vascular endothelium produces substances (including nitric oxide, prostacyclin and heparans) to prevent adhesion of platelets and white cells to the vessel wall. Platelets and coagulation factors circulate in a non-activated state. **B** Stage 2. Early haemostatic response: platelets adhere; coagulation is activated. At the site of injury, the endothelium is breached, exposing subendothelial collagen. Small amounts of tissue factor (TF) are released. Platelets bind to collagen via a specific receptor, glycoprotein Ia (GPIa), causing a change in platelet shape and its adhesion to the area of damage by the binding of other receptors (GPIb and GPIIb/IIIa) to von Willebrand factor and fibrinogen, respectively. Coagulation is activated by the tissue factor (extrinsic) pathway, generating small amounts of thrombin. **C** and **D** Stage 3. Fibrin clot formation: platelets become activated and aggregate; fibrin formation is supported by the platelet membrane; stable fibrin clot forms. The adherent platelets are activated by many pathways, including binding of adenosine diphosphate (ADP), collagen, thrombin and adrenaline (epinephrine) to surface receptors. The cyclo-oxygenase pathway converts arachidonic acid from the platelet membrane into thromboxane A<sub>2</sub>, which causes aggregation of platelets. Activation of the platelets results in release of the platelet granule contents, enhancing coagulation further (see Fig. 25.7). Thrombin plays a key role in the control of coagulation: the small amount generated via the TF pathway massively amplifies its own production; the 'intrinsic' pathway becomes activated and large amounts of thrombin are generated. Thrombin directly causes clot formation by cleaving fibrinopeptides (FPs) from fibrinogen to produce fibrin. Fibrin monomers are cross-linked by factor XIII, which is also activated by thrombin. Having had a key role in clot formation and stabilisation, thrombin then starts to regulate clot formation in two main ways: (a) activation of the protein C (PC) pathway (a natural anticoagulant), which reduces further coagulation; (b) activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which inhibits fibrinolysis (see E and F). **E** Stage 4. Limiting clot formation: natural anticoagulants reverse activation of coagulation factors. Once haemostasis has been secured, the propagation of clot is curtailed by anticoagulants. Antithrombin is a serine protease inhibitor synthesised by the liver, which destroys activated factors such as XIa, Xa and thrombin (IIa). Its major activity against thrombin and Xa is enhanced by heparin and fondaparinux, explaining their anticoagulant effect. Tissue factor pathway inhibitor (TFPI) binds to and inactivates VIIa and Xa. Activation of PC occurs following binding of thrombin to membrane-bound thrombomodulin; activated protein C (aPC) binds to its co-factor, protein S (PS), and cleaves Va and VIIIa. PC and PS are vitamin K-dependent and are depleted by coumarin anticoagulants such as warfarin. **F** Stage 5. Fibrinolysis: plasmin degrades fibrin to allow vessel recanalisation and tissue repair. The insoluble clot needs to be broken down for vessel recanalisation. Plasmin, the main fibrinolytic enzyme, is produced when plasminogen is activated, e.g. by tissue plasminogen activator (t-PA) or urokinase in the clot. Plasmin hydrolyses the fibrin clot, producing fibrin degradation products, including the D-dimer. This process is highly regulated; the plasminogen activators are controlled by an inhibitor called plasminogen activator inhibitor (PAI), the activity of plasmin is inhibited by  $\alpha_2$ -antiplasmin and  $\alpha_2$ -macroglobulin, and fibrinolysis is further inhibited by the thrombin-activated TAFI.

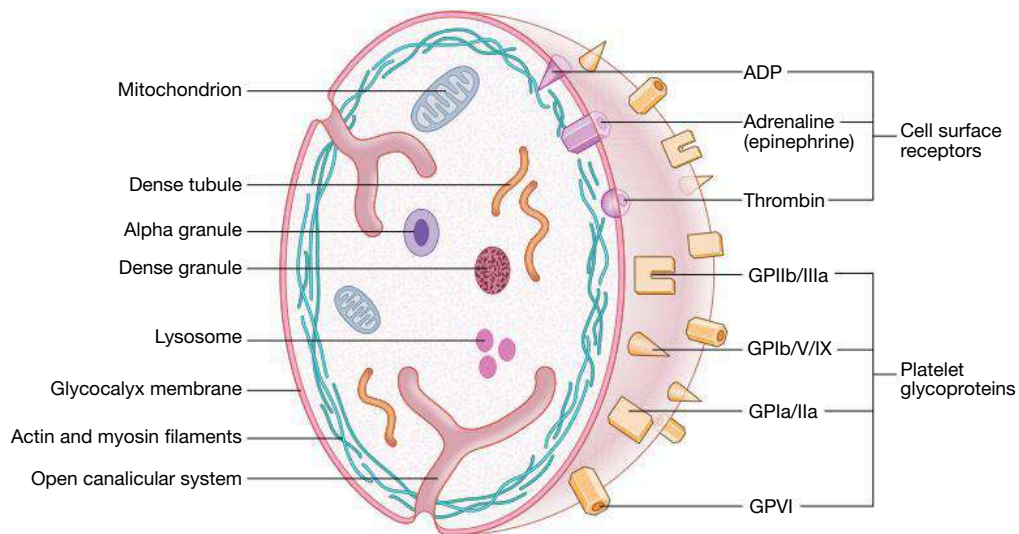

Fig. 25.6, cont'd

**Fig. 25.7 Normal platelet structure.** The platelet surface is populated by glycoproteins, which bind to key structures including fibrinogen, collagen and von Willebrand factor and cell surface receptors for thrombin, ADP and adrenaline (epinephrine). Through internal signalling pathways, platelet activation causes degranulation of alpha and dense granules, which ultimately results in platelet aggregation. Blockade of these pathways by drugs such as aspirin, clopidogrel, ticagrelor, tirofiban and abciximab forms the basis of antiplatelet therapy. (ADP = adenosine diphosphate; GP = glycoprotein)

## Investigation of diseases of the blood

### The full blood count

To obtain a full blood count (FBC), anticoagulated blood is processed through automated blood analysers that use a variety of technologies (particle-sizing, radiofrequency and laser instrumentation) to measure the haematological parameters. These include numbers of circulating cells, the proportion of whole blood volume occupied by red cells (the haematocrit, Hct), and the red cell indices that give information about the size of red cells (mean cell volume, MCV) and the amount of haemoglobin present in the red cells (mean cell haemoglobin, MCH). Blood analysers can differentiate types of white blood cell and give automated counts of neutrophils, lymphocytes, monocytes, eosinophils and basophils. It is important to appreciate, however, that a number of conditions can lead to spurious results (Box 25.1). The reference ranges for a number of common haematological parameters in adults are given in Chapter 35 and the effects of age are shown in Box 25.6.

### Blood film examination

Although technical advances in full blood count analysers have resulted in fewer blood samples requiring manual examination, scrutiny of blood components prepared on a microscope slide (the 'blood film') can often yield valuable information (Box 25.2 and Fig. 25.8). Analysers cannot identify abnormalities of red cell shape and content (e.g. Howell–Jolly bodies, basophilic stippling, malaria parasites) or fully define abnormal white cells such as blasts.

### Bone marrow examination

In adults, bone marrow for examination is usually obtained from the posterior iliac crest. After a local anaesthetic, marrow can be sucked out from the medullary space, stained and examined under the microscope (bone marrow aspirate). In addition, a core of bone may be removed (trephine biopsy), fixed and decalcified before sections are cut for staining (Fig. 25.9). A bone marrow aspirate is used to assess the composition and morphology of haematopoietic cells or abnormal infiltrates. Further investigations may be performed, such as cell surface marker analysis (immunophenotyping), chromosome (karyotyping) and molecular studies, including next generation sequencing (NGS) to identify mutated genes as part of the assessment of malignant diseases and bone marrow failure syndromes. Marrow can be cultured for suspected tuberculosis. A trephine biopsy is superior for assessing marrow cellularity, marrow fibrosis, and infiltration by abnormal cells such as metastatic carcinoma.

## Investigation of coagulation

### Bleeding disorders

In patients with clinical evidence of a bleeding disorder (p. 923), there are recommended screening tests (Box 25.3). Physiological activation

#### 25.1 Spurious full blood count results from autoanalysers

Result	Explanation
Increased haemoglobin	Lipaemia, jaundice, very high white cell count
Reduced haemoglobin	Improper sample mixing, blood taken from vein into which an infusion is flowing
Increased red cell volume (mean cell volume, MCV)	Cold agglutinins, non-ketotic hyperosmolarity
Increased white cell count	Nucleated red cells present
Reduced platelet count	Clot in sample, platelet clumping

of coagulation is predominantly by tissue factor, with amplification of the process by the small amounts of thrombin formed as a result. For ease of description, the terms extrinsic, intrinsic and common pathways are still used (see Fig. 25.6D).

Coagulation tests measure the time to clot formation in vitro in a platelet poor plasma sample after the clotting process is initiated by activators and calcium. The result of the test sample is compared with normal controls. The tissue factor ('extrinsic') pathway (see Fig. 25.6D) is assessed by the prothrombin time (PT), and the 'intrinsic' pathway by the activated partial thromboplastin time (APTT), sometimes known as the partial thromboplastin time with kaolin (PTTK). Coagulation is delayed by deficiencies of coagulation factors and by the presence of inhibitors of coagulation, such as heparin and lupus anticoagulants. The approximate reference ranges and causes of abnormalities are shown in Box 25.3. If both the PT and APTT are prolonged, this indicates either deficiency or inhibition of the final common pathway (which includes factors X, V, prothrombin and fibrinogen) or global coagulation factor deficiency involving more than one factor, as occurs in disseminated intravascular coagulation (DIC; pp. 199 and 988). Further specific tests may be performed based on interpretation of the clinical scenario and results of these screening tests. A mixing test with normal plasma allows differentiation between a coagulation factor deficiency (the prolonged time corrects) and the presence of an inhibitor of coagulation (the prolonged time does not correct); the latter may be a chemical (heparins) or an antibody (most often a lupus anticoagulant, but occasionally a specific inhibitor of one of the coagulation factors, typically factor VIII). Von Willebrand disease may present with a normal APTT; further investigation of suspected cases is detailed on page 984.

Platelet function has historically been assessed by the bleeding time, measured as the time to stop bleeding after a standardised incision. However, most centres have abandoned the use of this test. Platelet function can be assessed in vitro by measuring aggregation in response to various agonists, such as adrenaline (epinephrine), collagen, thrombin, arachidonic acid and ADP, agglutination in response to ristocetin or by measuring the constituents of the intracellular granules, e.g. adenosine triphosphate, adenosine diphosphate and their ratio to each other (ATP/ADP).

In disseminated intravascular coagulation (DIC), platelets and coagulation factors are consumed, resulting in thrombocytopenia and prolonged PT and APTT. In addition, there is evidence of active coagulation with consumption of fibrinogen and generation of fibrin degradation products (D-dimers). Note, however, that fibrinogen is an acute phase protein that may also be elevated in inflammatory disease (p. 67).

### Monitoring anticoagulant therapy

The International Normalised Ratio (INR) is validated only to assess the therapeutic effect of coumarin anticoagulants, including warfarin. INR is the ratio of the patient's PT to that of a normal control, raised to the power of the international sensitivity index of the thromboplastin used in the test (ISI, derived by comparison with an international reference standard material). Concentrations of the direct oral anticoagulants (DOACs) cannot be accurately assessed from the PT or the APTT, with which they have a variable and generally poor correlation, but can be measured using appropriately calibrated specific assays.

Monitoring of heparin therapy is, on the whole, required only with unfractionated heparins (UFH). Therapeutic anticoagulation prolongs the APTT relative to a control sample by a ratio of approximately 1.5–2.5. Many laboratories now prefer to measure UFH activity by an appropriately calibrated anti-Xa assay. Low-molecular-weight heparins have such a predictable dose response that monitoring of the anticoagulant effect is not required, except in patients with renal impairment (glomerular filtration rate less than 30 mL/min). When monitoring is indicated, an anti-Xa assay is used.

## 25.2 How to interpret red cell appearances

### Microcytosis (reduced average cell size, MCV < 76 fL) **A**

- Iron deficiency
- Sideroblastic anaemia
- Thalassaemia

### Macrocytosis (increased average cell size, MCV > 100 fL) **B**

- Vitamin B<sub>12</sub> or folate deficiency
- Liver disease, alcohol
- Hypothyroidism
- Myelodysplastic syndromes
- Drugs (e.g. zidovudine, trimethoprim, phenytoin, methotrexate, hydroxycarbamide)

### Target cells (central area of haemoglobinisation) **C**

- Liver disease
- Post-splenectomy
- Thalassaemia
- Haemoglobin C disease

### Spherocytes (dense cells, no area of central pallor) **D**

- Autoimmune haemolytic anaemia
- Post-splenectomy
- Hereditary spherocytosis

### Red cell fragments (intravascular haemolysis) **E**

- Microangiopathic haemolysis, e.g. haemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP)
- Disseminated intravascular coagulation (DIC)

### Nucleated red blood cells (normoblasts) **F**

- Marrow infiltration
- Severe haemolysis
- Myelofibrosis
- Acute haemorrhage

### Howell–Jolly bodies (small round nuclear remnants) **G**

- Hyposplenism
- Post-splenectomy
- Dyshaematopoiesis

### Basophilic stippling (abnormal ribosomal RNA appears as blue dots) **H**

- Dyshaematopoiesis
- Lead poisoning

**Fig. 25.8** Appearance of red blood cells. **A** Microcytosis. **B** Macrocytosis. **C** Target cells. **D** Spherocytes and polychromasia. **E** Red cell fragments. **F** Nucleated red blood cells. **G** Howell–Jolly bodies. **H** Basophilic stippling.

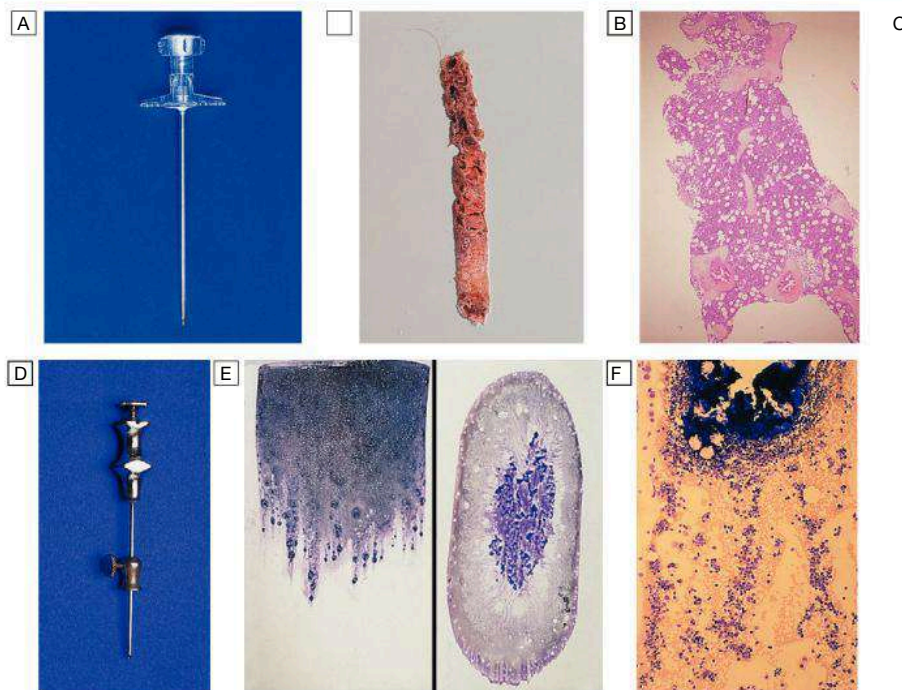

(MCV = mean cell volume)

## Thrombotic disorders

Measurement of plasma levels of D-dimers derived from fibrin degradation is useful in excluding the diagnosis of active venous thrombosis in some patients (see Fig. 9.6).

A variety of tests exist that may help to explain an underlying propensity to thrombosis, especially venous thromboembolism (thrombophilia) (Box 25.4). Examples of possible indications for testing are given in Box 25.5. In most patients, the results of these tests do not affect clinical

management (p. 984) but they may influence the duration of anticoagulation (e.g. antiphospholipid antibodies, p. XXX), justify family screening in inherited thrombophilias (p. 986), or suggest additional management strategies to reduce thrombosis risk (e.g. in myeloproliferative disease and paroxysmal nocturnal haemoglobinuria; p. 959). Anticoagulants can interfere with some of these assays. For example, warfarin reduces protein C and S levels and affects measurement of lupus anticoagulant. Heparin interferes with antithrombin and lupus anticoagulant assays and the DOACs all affect the measurement of lupus anticoagulant as well as other specific

**Fig. 25.9** Bone marrow aspirate and trephine. **A** Trephine biopsy needle. **B** Macroscopic appearance of a trephine biopsy. **C** Microscopic appearance of stained section of trephine. **D** Bone marrow aspirate needle. **E** Stained macroscopic appearance of marrow aspirate: smear (left) and squash (right). **F** Microscopic appearance of stained marrow particles and trails of haematopoietic cells.

25.3 Coagulation screening tests <sup>1</sup>		
Investigation	Reference range <sup>2</sup>	Situations in which tests may be abnormal
<b>Platelet count</b>	150–400 × 10 <sup>9</sup> /L	Thrombocytopenia
<b>Prothrombin time (PT)</b>	9–12 secs	Deficiencies of factors II, V, VII or X Severe fibrinogen deficiency, DIC
<b>Activated partial thromboplastin time (APTT)</b>	26–36 secs	Deficiencies of factors II, V, VIII, IX, X, XI, XII Severe fibrinogen deficiency Unfractionated heparin therapy Antibodies against clotting factors Lupus anticoagulant Multiple factor deficiency, e.g. DIC
<b>Fibrinogen concentration</b>	1.5–4.0 g/L	Hypofibrinogenaemia, e.g. liver failure, DIC

<sup>1</sup>N.B. International Normalised Ratio (INR) is used only to monitor coumarin therapy and is not a coagulation screening test. <sup>2</sup>Ranges are approximate and may vary between laboratories. (DIC = disseminated intravascular coagulation)

coagulation assays. Therefore these tests, when required, should be performed when the patient is not taking anticoagulants or, if required, during temporary discontinuation to facilitate accurate measurement

Box 25.6 lists some considerations specific to all haematological investigations in old age.

## Presenting problems in blood disease

### Anaemia

Anaemia refers to a state in which the level of haemoglobin in the blood is below the reference range appropriate for age and sex. Other factors, including pregnancy and altitude, also affect haemoglobin levels and must

25.5 Possible indications for thrombophilia testing*	
<ul style="list-style-type: none"> <li>• Venous thrombosis &lt;45 years</li> <li>• Recurrent venous thrombosis</li> <li>• Family history of unprovoked or recurrent thrombosis</li> <li>• Combined arterial and venous thrombosis</li> </ul>	<ul style="list-style-type: none"> <li>• Venous thrombosis at an unusual site:               <ul style="list-style-type: none"> <li>• Cerebral venous thrombosis</li> <li>• Hepatic vein (Budd–Chiari syndrome)</li> <li>• Portal vein, mesenteric vein, splenic vein</li> </ul> </li> </ul>
*Antiphospholipid antibodies should be sought where clinical criteria for antiphospholipid syndrome (APS) are fulfilled (p. 986). Thrombophilia testing may explain the diagnosis without necessarily affecting management and this limits the clinical value of such an approach.	

## 25.6 Haematological investigations in old age

- **Blood cell counts and film components:** not altered in general by ageing alone, although haemoglobin concentrations fall with increasing age.
- **Ratio of bone marrow cells to marrow fat:** falls.
- **Neutrophils:** maintained throughout life, although leucocytes may be less readily mobilised by bacterial invasion in old age.
- **Lymphocytes:** functionally compromised by age due to a T-cell-related defect in cell-mediated immunity.
- **Clotting factors:** no major changes, although mild congenital deficiencies may be first noticed in old age.
- **Erythrocyte sedimentation rate (ESR):** raised above the reference range, but usually in association with chronic or subacute disease. In truly healthy older people, the ESR range is very similar to that in younger people (see Ch. 4).
- **Clonal haematopoiesis.** Myeloid gene panels are more likely to demonstrate clonal haematopoiesis of indeterminate potential (CHIP) based on acquired gene mutations in the blood cells of older patients. This may occur as frequently as 20% of people aged over 80 years despite having normal blood counts.

## i

## 25.7 Causes of anaemia

### Decreased or ineffective marrow production

- Lack of iron, vitamin B<sub>12</sub> or folate
- Hypoplasia/myelodysplasia
- Invasion by malignant cells
- Renal failure
- Anaemia of chronic disease

### Normal marrow production but increased removal of cells

- Blood loss
- Haemolysis
- Hypersplenism

be taken into account when considering whether an individual is anaemic. The clinical features of anaemia reflect diminished oxygen supply to the tissues (p. 922). A rapid onset of anaemia (e.g. due to blood loss) causes more profound symptoms than a gradually developing anaemia. Individuals with cardiorespiratory disease are more susceptible to symptoms of anaemia.

The clinical assessment and investigation of anaemia should gauge its severity and define the underlying cause (Box 25.7).

### Clinical assessment

- *Iron deficiency anaemia* (p. 950) is the most common type of anaemia worldwide. A thorough gastrointestinal history is important, looking in particular for symptoms of blood loss. Menorrhagia is a common cause of anaemia in pre-menopausal females, so women should always be asked about menstrual periods.
- A *dietary history* should assess the intake of iron, B12 and folate, which may become deficient in comparison to needs (e.g. in pregnancy or during periods of rapid growth; see also Chs 22 and 33).
- *Past medical history* may reveal a disease that is known to be associated with anaemia, such as rheumatoid arthritis (anaemia of inflammation (AI)), or previous surgery (e.g. resection of the stomach or small bowel, which may lead to malabsorption of iron and/or vitamin B<sub>12</sub>).
- *Family history and ethnic background* may raise suspicion of haemolytic anaemias, such as the haemoglobinopathies, oxidative enzymopathies and membranopathies. Pernicious anaemia, an autoimmune disorder, may also run in families, but is not associated with a clear Mendelian pattern of inheritance.
- A *drug history* may reveal the ingestion of drugs that cause or worsen blood loss (e.g. anticoagulants, anti-platelet drugs and anti-inflammatory drugs), haemolysis (e.g. sulphonamides and anti-malarial drugs) or aplasia (e.g. chloramphenicol, mercaptopurine).

On examination, as well as the general physical findings of anaemia shown on page, there may be specific findings related to the aetiology of the anaemia; for example, a right iliac fossa mass due to an underlying

caecal carcinoma. Haemolytic anaemias can cause jaundice. Vitamin B<sub>12</sub> deficiency may be associated with neurological signs, including peripheral neuropathy, dementia and signs of subacute combined degeneration of the cord (Box 28.82). Sick-cell anaemia (p. 960) may result in leg ulcers, stroke or features of pulmonary hypertension. Anaemia may be multifactorial and the lack of specific symptoms and signs does not rule out silent pathology.

### Investigations

Schemes for the investigation of anaemias are often based on the size of the red cells, which is most accurately indicated by the MCV in the FBC. Commonly, in the presence of anaemia:

- A normal MCV (normocytic anaemia) suggests either acute blood loss or the anaemia of chronic disease, also known as the anaemia of inflammation (ACD/AI) (Fig. 25.10).
- A low MCV (microcytic anaemia) suggests iron deficiency or thalassaemia or sometimes ACD/AI (Fig. 25.10).
- A high MCV (macrocytic anaemia) suggests vitamin B<sub>12</sub> or folate deficiency or myelodysplasia (Fig. 25.11).

Specific types of anaemia and their management are described later in this chapter.

## High haemoglobin

Patients with a persistently raised haematocrit (Hct) (>0.52 males, >0.48 females) for more than 2 months should be investigated. 'True' polycythaemia (or absolute erythrocytosis) indicates an excess of red cells, while 'relative', 'apparent' or 'low-volume' polycythaemia is due to a decreased plasma volume. Causes of polycythaemia are shown in Box 25.8. These involve increased erythropoiesis in the bone marrow, either due to a primary increase in marrow activity, or in response to increased erythropoietin (Epo) levels in chronic hypoxaemia, or due to inappropriate secretion of Epo. Some athletes improperly use Epo to increase oxygen-carrying capacity and thus enhance their physical performance.

Apparent erythrocytosis with a raised Hct, normal red cell mass (RCM) and reduced plasma volume may be associated with hypertension, smoking, alcohol and diuretic use (Gaisböck syndrome).

### Clinical assessment and investigations

Males and females with Hct values of over 0.60 and over 0.56, respectively, can be assumed to have an absolute erythrocytosis. A clinical history and examination including measurement of oxygen saturation will identify most patients with polycythaemia secondary to hypoxia. The presence of hypertension, smoking, excess alcohol consumption and/or diuretic use is consistent with low-volume polycythaemia (Gaisböck syndrome). In polycythaemia rubra vera (PRV), the acquired V617F mutation is found in the JAK-2 gene (a kinase) in over 90% of cases; in the remainder, mutations in exon 12 of the same gene may be identified. Patients with PRV have an increased risk of arterial thromboses, particularly stroke, and venous thromboembolism. They may also have aquagenic pruritus (itching after exposure to water), hepatosplenomegaly and gout (due to high red cell turnover).

If JAK-2 mutations are absent and there is no obvious secondary cause, a measurement of red cell mass is required to confirm an absolute erythrocytosis, followed by further investigations to exclude hypoxia, and causes of inappropriate erythropoietin secretion.

## Leucopenia (low white cell count)

A reduction in the total numbers of circulating white cells is called leucopenia. This may be due to a reduction in all types of white cell or in individual cell types (usually neutrophils or lymphocytes). Leucopenia may occur in isolation or as part of a reduction in all three haematological lineages (pancytopenia; p. 939).

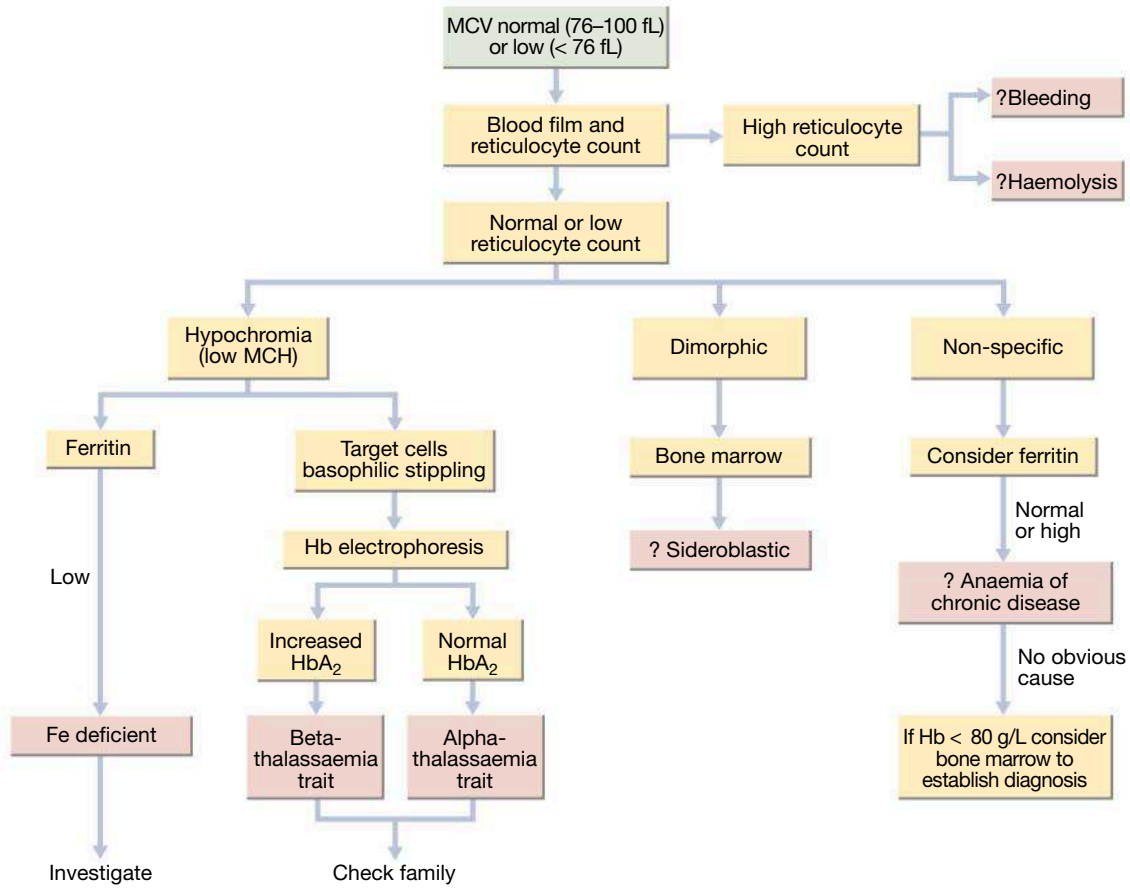

Fig. 25.10 Investigation of anaemia with normal or low mean cell volume (MCV). (Hb = haemoglobin; MCH = mean cell haemoglobin)

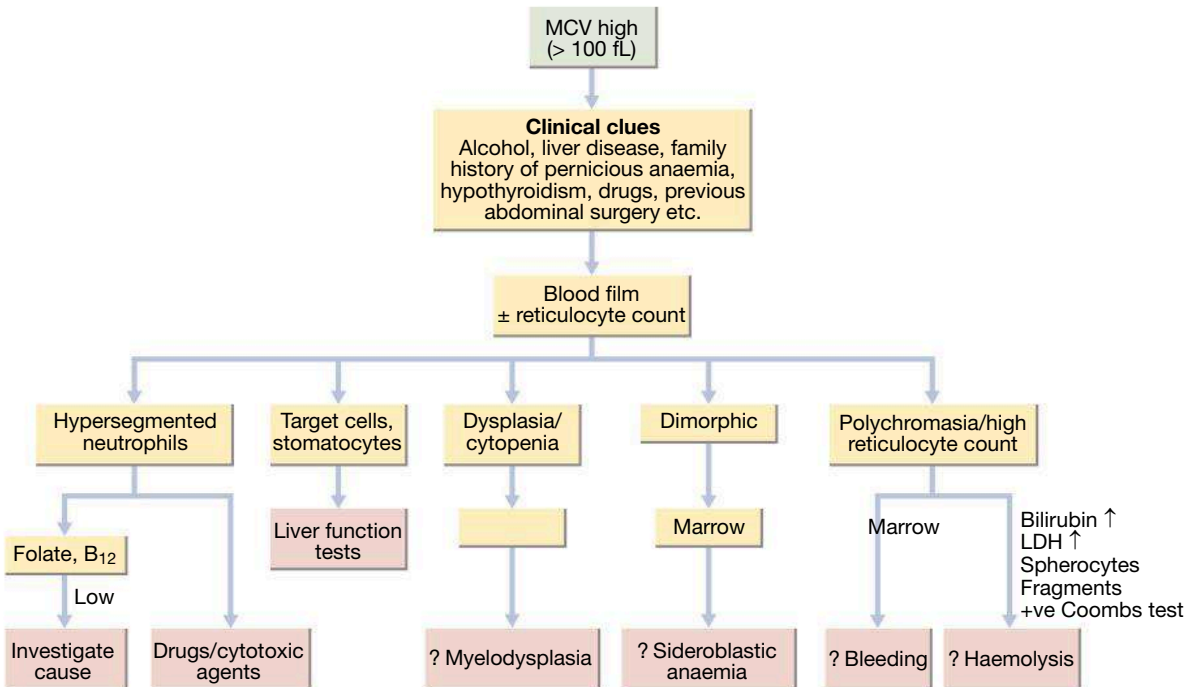

Fig. 25.11 Investigation of anaemia with high mean cell volume (MCV). (LDH = lactate dehydrogenase)

## 25.8 Classification and causes of erythrocytosis

	Absolute erythrocytosis	Relative (low-volume) erythrocytosis
Haematocrit	High	High
Red cell mass	High	Normal
Plasma volume	Normal	Low
Causes	<p><i>Primary</i></p> <p>Myeloproliferative disorder</p> <p>Polycythaemia rubra vera (primary proliferative polycythaemia)</p> <p><i>Secondary</i></p> <p>High erythropoietin due to tissue hypoxia:</p> <ul style="list-style-type: none"> <li>High altitude</li> <li>Cardiorespiratory disease</li> <li>High-affinity haemoglobins</li> </ul> <p>Inappropriately increased erythropoietin:</p> <ul style="list-style-type: none"> <li>Renal disease (hydronephrosis, cysts, carcinoma)</li> <li>Other tumours (hepatoma, bronchogenic carcinoma, uterine fibroids, pheochromocytoma, cerebellar haemangioblastoma)</li> <li>Exogenous testosterone therapy</li> </ul> <p>Exogenous erythropoietin administration:</p> <ul style="list-style-type: none"> <li>Performance-enhancing drug-taking in athletes</li> </ul>	<p>Diuretics</p> <p>Smoking</p> <p>Obesity</p> <p>Alcohol excess</p> <p>Gaisböck syndrome</p>

### Neutropenia

A reduction in neutrophil count (usually  $<1.5 \times 10^9/L$  but dependent on age and race) is called neutropenia. The main causes are listed in [Box 25.9](#) and [Fig. 25.12](#). Drug-induced neutropenia is not uncommon ([Box 25.10](#)). Clinical manifestations range from no symptoms to overwhelming sepsis. The risk of bacterial infection is related to the degree of neutropenia, with counts lower than  $0.5 \times 10^9/L$  considered to be critically low. Fever is the first and often only manifestation of infection. A sore throat, perianal pain or skin inflammation may be present. The lack of neutrophils allows the patient to become septicaemic and shocked within hours if immediate antibiotic therapy is not commenced. Management is discussed on page 269.

### Lymphopenia

This is an absolute lymphocyte count of less than  $1 \times 10^9/L$ . The causes are shown in [Box 25.9](#). Although minor reductions may be asymptomatic, deficiencies in cell-mediated immunity may result in infections (with organisms such as fungi, viruses and mycobacteria) and a propensity to lymphoid and other malignancies (particularly those associated with viral infections such as Epstein–Barr virus (EBV), human papilloma-virus (HPV) and human herpesvirus 8 (HHV-8)). Lymphopenia without any obvious cause is common with advancing age.

### Leucocytosis (high white cell count)

An increase in the total numbers of circulating white cells is called leucocytosis. This is usually due to an increase in a specific type of cell (see [Box 25.9](#)). It is important to realise that an increase in a single type of white cell (e.g. eosinophils or monocytes) may not increase the total white cell count (WCC) above the upper limit of normal and will be apparent only if the ‘differential’ of the white count is examined.

### Neutrophilia

An increase in the number of circulating neutrophils is called a neutrophilia or a neutrophil leucocytosis. It can result from an increased production of cells from the bone marrow or redistribution from the marginated pool. The normal neutrophil count depends on age, race and certain physiological parameters. During pregnancy, not only is there an increase in neutrophils, but also earlier forms, such as metamyelocytes, can be found in the blood. The causes of a neutrophilia are shown in [Box 25.9](#).

### Eosinophilia

A high eosinophil count of more than  $0.5 \times 10^9/L$  is usually secondary to infection (especially parasites; [Ch. 13](#)), allergy (e.g. eczema, asthma, reactions to drugs; ([Ch. 4](#)), immunological disorders (e.g. polyarteritis, sarcoidosis) or malignancy (e.g. lymphomas) (see [Box 25.9](#)). Usually, such eosinophilia is short-lived.

In the rarer primary disorders, there is a persistently raised, often clonal, eosinophilia, e.g. in myeloproliferative disorders, subtypes of acute myeloid leukaemia and idiopathic hypereosinophilic syndrome (HES). Specific mutations in receptor tyrosine kinase genes have been found in some primary eosinophilias (e.g. causing rearrangements of platelet-derived growth factor receptors  $\alpha$  and  $\beta$  or c-kit), which allow diagnosis and, in some cases, specific therapy with tyrosine kinase inhibitors such as imatinib.

Eosinophil infiltration can damage many organs (e.g. heart, lungs, gastrointestinal tract, skin, musculoskeletal system); evaluation of eosinophilia therefore includes not only the identification of any underlying cause and its appropriate treatment, but also assessment of any related organ damage.

### Lymphocytosis

A lymphocytosis is an increase in circulating lymphocytes above that expected for the patient’s age. In adults, this is greater than  $3.5 \times 10^9/L$ . Infants and children have higher counts; age-related reference ranges should be consulted. Causes are shown in [Box 25.9](#); the most common is viral infection.

### Lymphadenopathy

Enlarged lymph glands may be an important indicator of haematological disease, but they are not uncommon in reaction to infection or inflammation ([Box 25.11](#)). The sites of lymph node groups, and symptoms and signs that may help elucidate the underlying cause are shown on page 921). Nodes that enlarge in response to local infection or inflammation (‘reactive nodes’) usually expand rapidly and are painful, whereas those due to haematological disease are more frequently painless. Localised lymphadenopathy should elicit a search for a source of inflammation or primary malignancy in the appropriate drainage area:

- the scalp, ear, mouth and throat, face, teeth or thyroid for neck nodes
- the breast for axillary nodes
- the perineum or external genitalia for inguinal nodes.

## 25.9 How to interpret white blood cell results

### Neutrophils **A**

#### Neutrophilia

- Infection: bacterial, fungal
- Trauma: surgery, burns
- Infarction: myocardial infarct, pulmonary embolus, sickle-cell crisis
- Inflammation: gout, rheumatoid arthritis, ulcerative colitis, Crohn's disease
- Malignancy: solid tumours, Hodgkin lymphoma
- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Physiological: exercise, pregnancy

#### Neutropenia

- Infection: viral, bacterial (e.g. *Salmonella*), protozoal (e.g. malaria)
- Drugs: see [Box 25.10](#)
- Autoimmune: connective tissue disease
- Alcohol
- Bone marrow infiltration: leukaemia, myelodysplasia
- Congenital: Kostmann syndrome
- Constitutional: African Caribbean and Middle Eastern descent

### Eosinophils **B**

#### Eosinophilia

- Allergy: hay fever, asthma, eczema
- Infection: parasitic
- Drug hypersensitivity: e.g. gold, sulphonamides
- Vasculitis: e.g. eosinophilic granulomatosis with polyangiitis (Churg–Strauss), granulomatosis with polyangiitis (Wegener's)
- Connective tissue disease: polyarteritis nodosa
- Malignancy: solid tumours, lymphomas
- Primary bone marrow disorders: myeloproliferative disorders, hypereosinophilic syndrome (HES), acute myeloid leukaemia

### Basophils **C**

#### Basophilia

- Myeloproliferative disease: polycythaemia vera, chronic myeloid leukaemia
- Inflammation: acute hypersensitivity, ulcerative colitis, Crohn's disease

### Monocytes **D**

#### Monocytosis

- Infection: bacterial (e.g. tuberculosis)
- Inflammation: connective tissue disease, ulcerative colitis, Crohn's disease
- Malignancy: solid tumours, chronic myelomonocytic leukaemia

### Lymphocytes **E**

#### Lymphocytosis

- Infection: viral, bacterial (e.g. *Bordetella pertussis*)
- Lymphoproliferative disease: chronic lymphocytic leukaemia, lymphoma
- Post-splenectomy

#### Lymphopenia

- Inflammation: connective tissue disease
- Lymphoma
- Renal failure
- Sarcoidosis
- Drugs: glucocorticoids, cytotoxics
- Congenital: severe combined immunodeficiency
- Human immunodeficiency virus (HIV) infection

### 25.10 Drugs that can induce neutropenia\*

Group	Examples
<b>Analgesics/anti-inflammatory agents</b>	Gold, penicillamine, naproxen
<b>Antithyroid drugs</b>	Carbimazole, propylthiouracil
<b>Anti-arrhythmics</b>	Quinidine, procainamide
<b>Antihypertensives</b>	Captopril, enalapril, nifedipine
<b>Antidepressants/psychotropics</b>	Amitriptyline, dosulepin, mianserin
<b>Antimalarials</b>	Pyrimethamine, dapsone, sulfadoxine, chloroquine
<b>Anticonvulsants</b>	Phenytoin, sodium valproate, carbamazepine
<b>Antibiotics</b>	Sulphonamides, penicillins, cephalosporins
<b>Miscellaneous</b>	Cimetidine, ranitidine, chlorpropamide, zidovudine

\*Many drugs can induce cytopenias. Many chemotherapy drugs and immunosuppressant drugs predictably cause neutropenia. In suspected cases check drug summary of product characteristics.

## i

### 25.11 Causes of lymphadenopathy

#### Infective

- Bacterial: streptococcal, tuberculosis, brucellosis
- Viral: Epstein–Barr virus (EBV), human immunodeficiency virus (HIV)
- Protozoal: toxoplasmosis
- Fungal: histoplasmosis, coccidioidomycosis

#### Neoplastic

- Primary: lymphomas, leukaemias
- Secondary: lung, breast, thyroid, stomach, melanoma

#### Connective tissue disorders

- Rheumatoid arthritis
- Systemic lupus erythematosus (SLE)

#### Sarcoidosis

#### Amyloidosis

#### Drugs

- Phenytoin

Generalised lymphadenopathy may be secondary to infection, often viral, connective tissue disease or extensive skin disease (dermatopathic lymphadenopathy), but is more likely to signify underlying haematological malignancy. Weight loss and drenching night sweats that may require a change of nightclothes are associated with haematological malignancies, particularly lymphoma.

Initial investigations in lymphadenopathy include an FBC (to detect evidence of infection, inflammation or haematological disease such as leucocytosis, thrombocytosis or lymphopenia), measurement of erythrocyte sedimentation rate (ESR) and a chest X-ray (to detect mediastinal lymphadenopathy). If the findings suggest malignancy, a formal cutting needle or excision biopsy of a representative node is indicated to obtain a histological diagnosis. Increasingly, such lymph node biopsies are carried out under image guidance using ultrasound or CT scanning, rather than formal surgical excision biopsy. However, the quality of such specimens is variable and can be difficult to interpret, especially if they are small.

## Splenomegaly

The spleen may be enlarged due to involvement by lymphoproliferative disease, the resumption of extramedullary haematopoiesis in myeloproliferative disease, enhanced reticulo-endothelial activity in autoimmune haemolysis, expansion of the lymphoid tissue in response to infections, or vascular congestion as a result of portal hypertension (Box 25.12).

\*Causes of massive splenomegaly.

Hepatosplenomegaly is suggestive of lympho- or myeloproliferative disease, liver disease or infiltration (e.g. with amyloid). Associated lymphadenopathy is suggestive of lymphoproliferative disease. An enlarged spleen may cause abdominal discomfort, accompanied by back pain and abdominal bloating and early satiety due to stomach compression. Splenic infarction produces severe abdominal pain radiating to the left shoulder tip, associated with a splenic rub on auscultation. Rarely, spontaneous or traumatic rupture and bleeding may occur.

Investigation should focus on the suspected cause. Imaging of the spleen by ultrasound or computed tomography (CT) will detect variations in density in the spleen, which may be a feature of lymphoproliferative disease; it also allows imaging of the liver and abdominal lymph nodes. Biopsy of enlarged abdominal or superficial lymph nodes may provide the diagnosis, as might a bone marrow biopsy in splenic lymphomas. A chest X-ray or CT of the thorax will detect mediastinal lymphadenopathy. An FBC may show pancytopenia secondary to hypersplenism, when the enlarged spleen has become overactive, pooling and destroying blood cells prematurely. If other abnormalities are present, such as abnormal lymphocytes or a leucoerythroblastic blood film, a bone marrow examination is indicated. Screening for infectious or liver disease (p. 8665) may be appropriate. If all investigations are unhelpful, splenectomy may be diagnostic, but is rarely carried out in these circumstances.

## Bleeding

Normal bleeding is seen following surgery and trauma. Pathological bleeding occurs when structurally abnormal vessels rupture or when a vessel is breached in the presence of a defect in haemostasis. This may be due to a deficiency or dysfunction of platelets, the coagulation factors or von Willebrand factor, or occasionally to excessive fibrinolysis, which is most commonly observed following therapeutic thrombolysis (Ch. 16).

### Clinical assessment

'Screening' blood tests (see Box 25.3) do not reliably detect all causes of pathological bleeding (e.g. von Willebrand disease, scurvy, certain anticoagulant and anti-platelet drugs and the causes of purpura listed in Box 25.13) and should not be used indiscriminately. A careful clinical evaluation is the key to diagnosis of bleeding disorders (p. 980). It is important to consider the following:

- *Site of bleeding.* Bleeding into muscle and joints, along with retroperitoneal and intracranial haemorrhage, indicates a likely defect in coagulation factors. Purpura, prolonged bleeding from superficial cuts, epistaxis, gastrointestinal haemorrhage or menorrhagia is more likely to be due to thrombocytopenia, a platelet function disorder or von Willebrand disease. Recurrent bleeds at a single site suggest a local structural abnormality rather than coagulopathic bleeding.
- *Duration of history.* It may be possible to assess whether the disorder is congenital or acquired.
- *Precipitating causes.* Bleeding arising spontaneously indicates a more severe defect than bleeding that occurs only after trauma.
- *Surgery.* Ask about operations. Dental extractions, tonsillectomy and circumcision are stressful tests of the haemostatic system. Immediate post-surgical bleeding suggests defective platelet plug formation and primary haemostasis; delayed haemorrhage is more suggestive of a coagulation defect. However, in post-surgical

## 25.13 Causes of non-thrombocytopenic purpura

- Senile purpura
- Factitious purpura
- Henoch–Schönlein purpura (Ch. 26)
- Vasculitis (Ch. 26)
- Paraproteinaemias
- Purpura fulminans, e.g. in disseminated intravascular coagulation secondary to sepsis

**Fig. 25.13** Petechial purpura.

patients, persistent bleeding from a single site is more likely to indicate surgical bleeding than coagulopathic bleeding.

- **Family history.** While a positive family history may be present in patients with inherited disorders, the absence of affected relatives does not exclude a hereditary bleeding diathesis; about one-third of cases of haemophilia arise in individuals without a family history, and deficiencies of factor VII, X and XIII are recessively inherited. Recessive disorders are more common in cultures where there is consanguineous marriage.
- **Drugs.** Use of antithrombotic, anticoagulant and fibrinolytic drugs must be elicited. Drug interactions with warfarin and drug-induced thrombocytopenia should be considered. Some 'herbal' remedies may result in a bleeding diathesis.

Clinical examination may reveal different patterns of skin bleeding. Petechial purpura is minor bleeding into the dermis that is flat and non-blanching (Fig. 25.13). Petechiae are typically found in patients with thrombocytopenia or platelet dysfunction. Palpable purpura occurs in vasculitis. Ecchymosis, or bruising, is more extensive bleeding into deeper layers of the skin. The lesions are initially dark red or purple, but become yellow as haemoglobin is degraded. Retroperitoneal bleeding presents with a flank or peri-umbilical haematoma. Telangiectasia of lips and tongue points to hereditary haemorrhagic telangiectasia (p. 970). Joints should be examined for evidence of haemarthroses. A full examination is important, as it may give clues to an underlying associated systemic illness such as a haematological or other malignancy, liver disease, renal failure, connective tissue disease and possible causes of splenomegaly.

### Investigations

Screening investigations and their interpretation are described on page 930. If the patient has a history that is strongly suggestive of a bleeding disorder and all the preliminary screening tests give normal results, further investigations, such as measurement of von Willebrand factor and assessment of platelet function, should be performed.

## Thrombocytopenia (low platelet count)

A reduced platelet count may arise by one of two mechanisms:

- decreased or abnormal production (bone marrow failure and hereditary thrombocytopathies)
- increased consumption following release into the circulation (immune-mediated, DIC or sequestration).

Spontaneous bleeding does not usually occur until the platelet count falls below  $20 \times 10^9/L$ , unless their function is also compromised. Purpura and spontaneous bruising are characteristic, but there may also be oral,

## i

### 25.14 Causes of thrombocytopenia

#### Decreased production

##### Marrow hypoplasia

- Childhood bone marrow failure syndromes, e.g. Fanconi's anaemia, dyskeratosis congenita, amegakaryocytic thrombocytopenia
- Idiopathic aplastic anaemia
- Drug-induced: cytotoxics, antimetabolites
- Transfusion-associated graft-versus-host disease

##### Marrow infiltration

- Leukaemia
- Myeloma
- Carcinoma (rare)
- Myelofibrosis
- Osteopetrosis
- Lysosomal storage disorders, e.g. Gaucher's disease

##### Haematinic deficiency

- Vitamin B<sub>12</sub> and/or folate deficiency

##### Familial (macro-)thrombocytopathies

- Myosin heavy chain abnormalities, e.g. Alport syndrome, Fechtner syndrome, May-Hegglin anomaly
- Bernard-Soulier syndrome
- Montreal platelet syndrome
- Wiskott-Aldrich syndrome (small platelets)
- Mediterranean macrothrombocytopathy

#### Increased consumption

##### Immune mechanisms

- Idiopathic thrombocytopenic purpura\*
- Neonatal alloimmune thrombocytopenia
- Post-transfusion purpura
- Drug-associated, especially quinine, vancomycin and heparin

##### Coagulation activation

- Disseminated intravascular coagulation (DIC) (see Box 25.70)

##### Mechanical pooling

- Hypersplenism

##### Thrombotic microangiopathies

- Haemolytic uraemic syndrome (HUS) and atypical HUS
- Liver disease
- Thrombotic thrombocytopenic purpura
- Pre-eclampsia/HELLP

##### Others

- Gestational thrombocytopenia
- Type 2B von Willebrand disease
- Pseudo von Willebrand disease

\*Associated conditions include collagen vascular diseases (particularly systemic lupus erythematosus), B-cell malignancy, HIV infection and antiphospholipid syndrome.

nasal, gastrointestinal or genitourinary bleeding. Severe thrombocytopenia ( $<10 \times 10^9/L$ ) may result in retinal haemorrhage and potentially fatal intracranial bleeding, but this is rare.

Investigations are directed at the possible causes listed in Box 25.14. A blood film is the single most useful initial investigation. Examination of the bone marrow may reveal increased megakaryocytes in consumptive causes of thrombocytopenia, or the underlying cause of bone marrow failure in leukaemia, hypoplastic anaemia or myelodysplasia.

Treatment (if required) depends on the underlying cause. Platelet transfusion is rarely required and is usually confined to patients with bone marrow failure and platelet counts below  $10 \times 10^9/L$ , or to clinical situations with actual or predicted serious haemorrhage.

## Thrombocytosis (high platelet count)

The most common reason for a raised platelet count is that it is reactive to another process, such as infection, inflammation, connective tissue disease, malignancy, iron deficiency, acute haemolysis or gastrointestinal bleeding (Box 25.15). The presenting clinical features are usually those

## 25.15 Causes of a raised platelet count

### Reactive thrombocytosis

- Acute and chronic inflammatory disorders
- Infection
- Malignant disease
- Tissue damage
- Haemolytic anaemias
- Post-splenectomy
- Post-haemorrhage

### Clonal thrombocytosis

- Primary thrombocythaemia
- Polycythaemia rubra vera
- Chronic myeloid leukaemia
- Myelofibrosis
- Myelodysplastic syndromes (MDSs)
- MDS with ring sideroblasts and thrombocytosis
- MDS with isolated deletion of 5q

## 25.16 Causes of pancytopenia

### Bone marrow failure

- Hypoplastic/aplastic anaemia (p. 978): inherited, idiopathic, viral, drugs

### Bone marrow infiltration

- Acute leukaemia
- Myeloma
- Lymphoma
- Carcinoma
- Haemophagocytic syndrome
- Myelodysplastic syndromes

### Ineffective haematopoiesis

- Megaloblastic anaemia
- Acquired immunodeficiency syndrome (AIDS)

### Peripheral pooling/destruction

- Hypersplenism: portal hypertension, Felty syndrome, malaria, myelofibrosis
- Systemic lupus erythematosus

of the underlying disorder and haemostasis is rarely affected. Reactive thrombocytosis is distinguished from the myeloproliferative disorders by the presence of uniform small platelets, lack of splenomegaly and the presence of an associated underlying disorder. The key to diagnosis is the clinical history and examination, combined with observation of the platelet count over time (reactive thrombocytosis gets better with resolution of the underlying cause).

The platelets are a product of an abnormally expanding clone of cells in the myeloproliferative disorders, chronic myeloid leukaemia and some forms of myelodysplasia. As with PRV, patients with essential thrombocythaemia may present with thrombosis or, rarely, bleeding. Stroke, transient ischaemic attacks, amaurosis fugax, digital ischaemia or gangrene, aquagenic pruritus, splenomegaly and systemic upset are also features. Patients with myeloproliferative disorders may also present with features such as aquagenic pruritus, splenomegaly and systemic upset.

## Pancytopenia

Pancytopenia refers to the combination of anaemia, leucopenia and thrombocytopenia. It may be due to reduced production of blood cells as a consequence of bone marrow suppression or infiltration, or there may be peripheral destruction or splenic pooling of mature cells. Causes are shown in [Box 25.16](#). A bone marrow aspirate and trephine are usually required to establish the diagnosis.

## Infection

Infection is a major complication of haematological disorders. It relates to the immunological deficit caused by the disease itself, or its treatment with chemotherapy and/or immunotherapy (pp. 268 and 933).

## Principles of management of haematological disease

### Blood components and transfusion

Blood transfusion from an unrelated donor to a recipient inevitably carries some risk, including adverse immunological interactions between the host and infused blood (see below), and transmission of infectious agents. Although there are many compelling clinical indications for blood component transfusion, there are also many clinical circumstances where transfusion is conventional, but the evidence for its effectiveness is limited. In these settings, allogeneic transfusion may be avoided by following protocols that recommend the use of low haemoglobin thresholds for red cell transfusion, perioperative blood salvage and antifibrinolytic drugs.

### Blood components

Blood components are prepared from whole blood or specific blood constituents collected from individual donors and include red cells, platelets, plasma and cryoprecipitate ([Box 25.17](#)).

Plasma derivatives are licensed pharmaceutical products produced on a factory scale from large volumes of human plasma obtained from many people and treated to reduce the risk of transmissible infection. Examples include:

- *Coagulation factors*. Concentrates of factors VIII and IX are used for the treatment of conditions such as haemophilia A, haemophilia B and von Willebrand disease. Coagulation factors made by recombinant DNA technology are now preferred due to perceived lack of infection risk but plasma-derived products are still used in many countries.
- *Immunoglobulins*. Intravenous immunoglobulin G (IVIgG) is administered as regular replacement therapy to reduce infective complications in patients with primary and secondary immunodeficiency. A short, high-dose course of IVIgG may also be effective in some immunological disorders, including immune thrombocytopenia (p. 981) and Guillain-Barré syndrome ([Ch. 28](#)). IVIgG can cause acute reactions and must be infused strictly according to the manufacturer's product information. There is a risk of renal dysfunction in susceptible patients and in these circumstances immunoglobulin products containing low or no sucrose are preferred. Anti-zoster immunoglobulin has a role in the prophylaxis of varicella zoster ([Ch. 13](#)). Anti-Rhesus D immunoglobulin is used in pregnancy to prevent haemolytic disease of the newborn (see [Box 25.19](#)).
- *Human albumin*. This is available in two strengths. The 5% solution can be used as a colloid resuscitation fluid, but it is no more effective and is more expensive than crystalloid solutions. Human albumin 20% solution may be used in the management of hypo-proteinaemic oedema in nephrotic syndrome ([Ch. 18](#)) and refractory ascites in chronic liver disease ([Ch. 24](#)). It is hyperoncotic and expands plasma volume by more than the amount infused.

Blood components and their uses are summarised in [Box 25.17](#).

### Blood donation

A safe supply of blood components depends on a well-organised system with regular donation by healthy individuals who have no excess risk of infections transmissible in blood ([Fig. 25.14](#)). Blood donations are obtained by either venesection of a unit of whole blood or collection of a specific component, such as platelets, by apheresis. During apheresis, the donor's blood is drawn via a closed system into a machine that separates the components by centrifugation and collects the desired fraction into a bag, returning the rest of the blood to the donor. Each donation must be tested for hepatitis B virus (HBV), hepatitis C virus (HCV), HIV and human T-cell lymphotropic virus (HTLV) nucleic acid

25.17 Blood components and their use		
Component	Major haemorrhage	Other indications
<b>Red cell concentrate<sup>1</sup></b>		
Most of the plasma is removed and replaced with a solution of glucose and adenine in saline to maintain viability of red cells ABO compatibility with recipient essential	Replace acute blood loss: increase circulating red cell mass to relieve clinical features caused by insufficient oxygen delivery. Order 4–6U initially to allow high red cell to FFP transfusion ratios of (at least) 2:1	<i>Severe anaemia</i> If no cardiovascular disease, transfuse to maintain Hb at 70 g/L If known or likely to have cardiovascular disease, maintain Hb at 90 g/L
<b>Platelet concentrate</b>		
One adult dose is made from four donations of whole blood, or from a single platelet apheresis donation ABO compatibility with recipient preferable	Maintain platelet count $>50 \times 10^9/L$ , or in multiple or central nervous system trauma $>100 \times 10^9/L$ If ongoing bleeding, order when platelets $<100 \times 10^9/L$ to allow for delivery time Each adult dose has a minimum of $2.4 \times 10^{11}$ platelets, which raises platelet count by $40 \times 10^9/L$ unless there is consumptive coagulopathy, e.g. disseminated intravascular coagulation	<i>Thrombocytopenia</i> , e.g. in acute leukaemia Maintain platelet count $>10 \times 10^9/L$ if not bleeding Maintain platelet count $>20 \times 10^9/L$ if minor bleeding or at risk (sepsis, concurrent use of antibiotics, abnormal coagulation) Increase platelet count $>50 \times 10^9/L$ for minor invasive procedure (e.g. lumbar puncture, gastroscopy and biopsy, insertion of indwelling lines, liver biopsy, laparotomy) or in acute, major blood loss Increase platelet count $>100 \times 10^9/L$ for operations in critical sites such as brain or eyes
<b>Fresh frozen plasma<sup>2</sup></b>		
150–300 mL plasma from one donation of whole blood ABO compatibility with recipient recommended	Dilutional coagulopathy with a PT prolonged $>50\%$ is likely after replacement of 1–1.5 blood volumes with red cell concentrate Give initially in (at least) a ratio of 1 FFP:2 red cell concentrate; order 15–20 mL/kg and allow for thawing time. Further doses only if bleeding continues and guided by PT and APTT	<i>Replacement of coagulation factor deficiency</i> If no virally inactivated or recombinant product is available <i>Thrombotic thrombocytopenic purpura</i> Plasma exchange (using virus-inactivated plasma if available) is frequently effective
<b>Cryoprecipitate<sup>2</sup></b>		
Fibrinogen and coagulation factor concentrated from plasma by controlled thawing 10–20 mL pack contains: Fibrinogen 150–300 mg Factor VIII 80–120 U von Willebrand factor 80–120 U In UK supplied as pools of 5 U	Aim to keep fibrinogen $>1.5$ g/L. Pooled units (of 10 donations) will raise fibrinogen by 1 g/L	<i>von Willebrand disease and haemophilia</i> If virus-inactivated or recombinant products are not available
<p><sup>1</sup>Whole blood is an alternative to red cell concentrate. ABO compatibility with recipient essential. <sup>2</sup>Pooled plasma can be treated with solvent and detergent or single units treated with methylene blue as an additional viral inactivation step. Virus-inactivated plasma is indicated for large-volume exposure, as in treatment of thrombotic thrombocytopenic purpura. (APTT = activated partial thromboplastin time; FFP = fresh frozen plasma; Hb = haemoglobin; PT = prothrombin time)</p>		

and/or antibodies. Platelet concentrates may be tested for bacterial contamination. The need for other microbiological tests depends on local epidemiology. For example, testing for *Trypanosoma cruzi* (Chagas' disease; Ch. 13) is necessary in areas of South America and the United States where infection is prevalent. Tests for West Nile virus have been required in the United States and UK since this agent became more prevalent. Components for use in specific patient groups are prepared from hepatitis E virus-negative donors in the UK, and plasma donated in the UK is not used at present for producing pooled plasma derivatives in view of concerns about transmission of variant Creutzfeldt–Jakob disease (vCJD; Ch. 28).

### Adverse effects of transfusion

Death attributable to transfusion is rare, at 0.99 per 100 000 transfusions; this includes death where a delay in timely supply of components was contributory. Moderate or severe febrile, allergic and hypotensive reactions occur in around 12 per 100 000 transfusions and are usually seen in patients who have had repeated transfusions. Any symptoms or signs that arise during a transfusion must be taken seriously, as they may be the first warnings of a serious reaction. Fig. 25.16 outlines the symptoms and signs, management and investigation of acute reactions to blood components.

### Red cell incompatibility

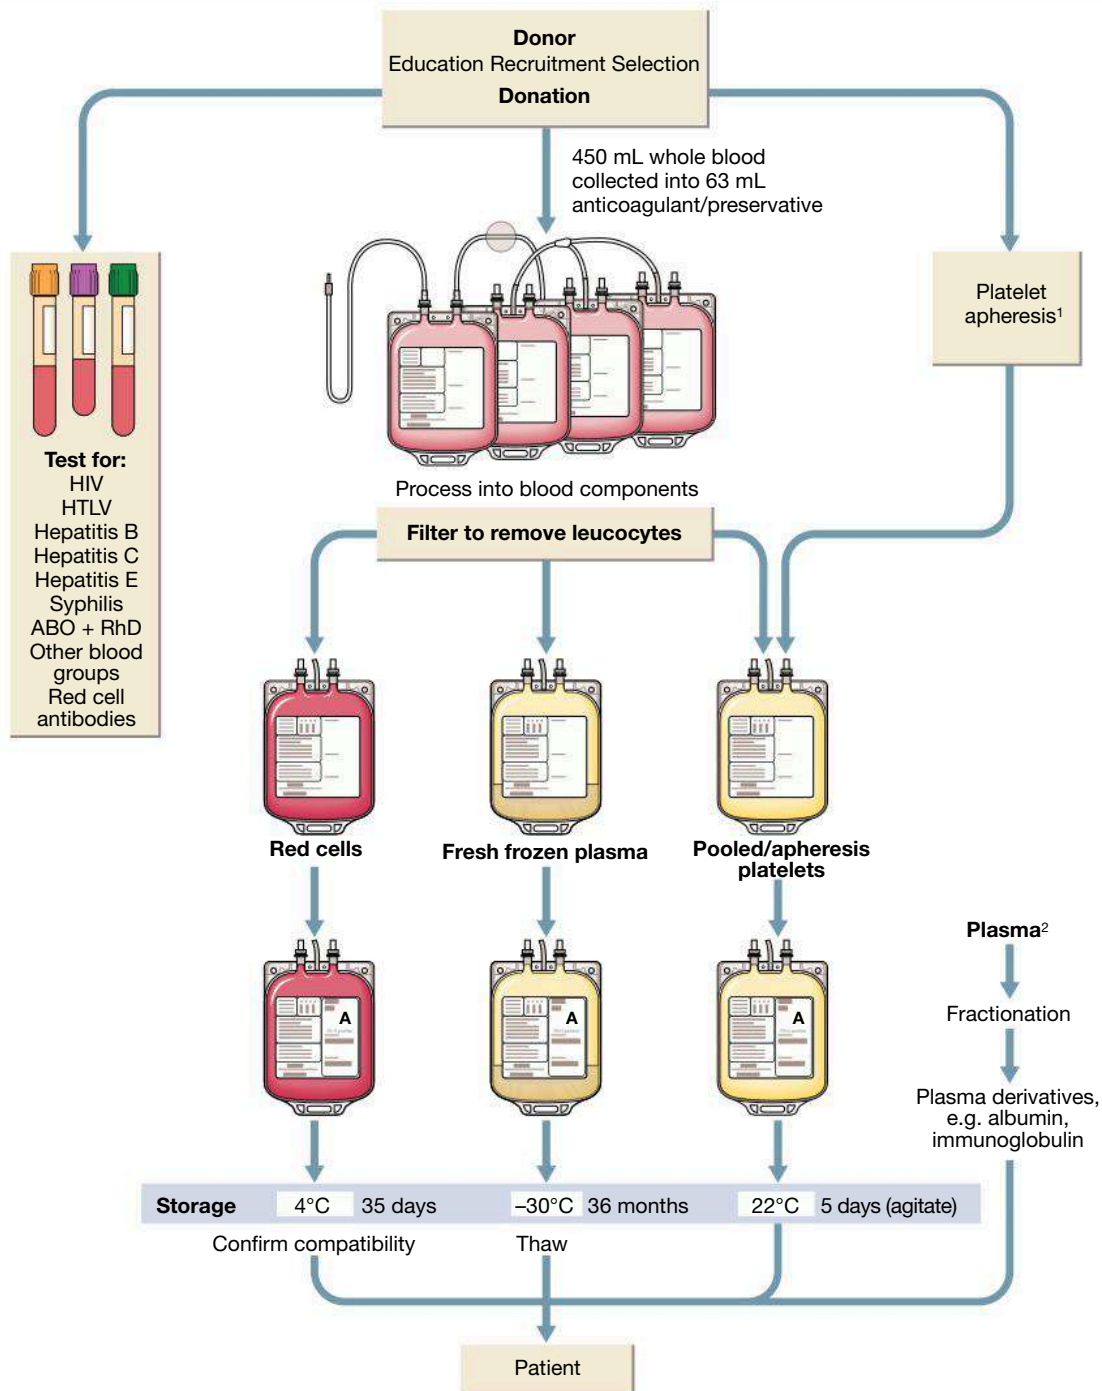

Red blood cell membranes contain numerous cell surface molecules that are potentially antigenic (see Fig. 25.4). The ABO and Rhesus D antigens are the most important in routine transfusion and antenatal practice.

### ABO blood groups

The frequency of the ABO antigens varies among different populations. The ABO blood group antigens are oligosaccharide chains that project from the red cell surface. These chains are attached to proteins and lipids that lie in the red cell membrane. The ABO gene encodes a glycosyltransferase that catalyses the final step in the synthesis of the chain, which has three common alleles: A, B and O. The O allele encodes an inactive enzyme, leaving the ABO antigen precursor (called the H antigen) unmodified. The A and B alleles encode enzymes that differ by four amino acids and hence attach different sugars to the end of the chain. Individuals are tolerant to their own ABO antigens, but do not suppress B-cell clones producing antibodies against ABO antigens that they do not carry themselves (Box 25.18). They are, therefore, capable of mounting a humoral immune response to these 'foreign' antigens.

### ABO-incompatible red cell transfusion

If red cells of an incompatible ABO group are transfused (especially if a group O recipient is transfused with group A, B or AB red cells), the

**Fig. 25.14** Blood donation, processing and storage. <sup>1</sup>Platelet apheresis involves circulating the donor's blood through a cell separator to remove platelets before returning other blood components to the donor. <sup>2</sup>In the UK, plasma for fractionation is imported as a precautionary measure against variant Creutzfeldt–Jakob disease (vCJD). (HIV = human immunodeficiency virus; HTLV = human T-cell lymphotropic virus)

<b>i</b> 25.18 ABO blood group antigens and antibodies			
ABO blood group	Red cell A or B antigens	Antibodies in plasma	UK frequency (%)
O	None	Anti-A and anti-B	46
A	A	Anti-B	42
B	B	Anti-A	9
AB	A and B	None	3

recipient's IgM anti-A, anti-B or anti-AB binds to the transfused red cells. This activates the full complement pathway (Ch. 4), creating pores in the red cell membrane and destroying the transfused red cells in the circulation (intravascular haemolysis). The anaphylatoxins C3a and C5a, released by complement activation, liberate cytokines such as tumour necrosis factor (TNF), interleukin (IL)-1 and IL-8, and stimulate degranulation of mast cells with release of vasoactive mediators. All these substances may lead to inflammation, increased vascular permeability and hypotension, which may, in turn, cause shock and renal failure. Inflammatory mediators can also cause platelet aggregation, lung peribronchial oedema and smooth muscle contraction. About 20%–30% of

ABO-incompatible transfusions cause some degree of morbidity, and 5%–10% cause or contribute to a patient's death. The main reason for this relatively low morbidity is the lack of potency of ABO antibodies in group A or B subjects; even if the recipient is group O, those who are very young or very old usually have weaker antibodies that do not lead to the activation of large amounts of complement.

### The Rhesus D blood group and haemolytic disease of the newborn

About 15% of populations of predominantly European descent are Rhesus-negative: that is, they lack the Rhesus D (RhD) red cell surface antigen (see Fig. 25.4). In other populations (e.g. in Chinese and Bengalis), only 1%–5% are Rhesus-negative. RhD-negative individuals do not normally produce substantial amounts of anti-RhD antibodies. However, if RhD-positive red cells enter the circulation of an RhD-negative individual, IgG antibodies are produced. This can occur during pregnancy if the mother is exposed to fetal cells via fetomaternal haemorrhage, or following transfusion. If a woman is sensitised, during a subsequent pregnancy anti-RhD antibodies can cross the placenta; if the fetus is RhD-positive, haemolysis with severe fetal anaemia and hyperbilirubinaemia can result. This can cause severe neurological damage or death due to haemolytic disease of the newborn (HDN). Therefore, an RhD-negative female who may subsequently become pregnant should never be transfused with RhD-positive blood.

In RhD-negative women, administration of anti-RhD immunoglobulin (anti-D) perinatally can block the immune response to RhD antigen on fetal cells and is the only effective product for preventing the development of Rhesus antibodies (Box 25.19).

HDN can also be caused by other alloantibodies against red cell antigens, usually after previous pregnancies or transfusions. These antigens include Rhc, RhC, RhE, Rhe, and the Kell, Kidd and Duffy antigen systems. HDN can also occur if there is fetomaternal ABO incompatibility, most commonly seen in a group O mother with a group A fetus. The fetus is generally less severely affected by ABO incompatibility than by RhD, Rhc or Kell antigen mismatch and the incompatibility is often picked up coincidentally after birth.

### Other immunological complications of transfusion

Rare but serious complications include transfusion-associated lung injury (TRALI) and transfusion-associated graft-versus-host disease (TA GVHD). The latter occurs when there is sharing of a human leucocyte antigen (HLA) haplotype between donor and recipient, which allows transfused lymphocytes to engraft, proliferate and recognise the recipient as foreign, resulting in acute GVHD (p. 945). Prevention is by gamma- or X-ray irradiation of blood components before their administration to prevent lymphocyte proliferation. Those at risk of TA GVHD who must receive irradiated blood components include patients with congenital T-cell immunodeficiencies or Hodgkin lymphoma, patients with aplastic anaemia receiving immunosuppressive therapy with antithymocyte

globulin (ATG), recipients of haematopoietic stem cell transplants or of blood from a family member, neonates who have received an intrauterine transfusion, and patients taking T-lymphocyte-suppressing drugs, such as fludarabine and other purine analogues.

### Transfusion-transmitted infection

Over the past 30 years, HBV, HIV-1 and HCV have been identified and effective tests introduced to detect and exclude infected donations. Where blood is from 'safe' donors and correctly tested, the current risk of a donated unit being infectious is very small. In the UK, the estimated chance that a unit of blood from a 'safe' donor might be infected with one of the viruses for which blood is tested is approximately 1 in 25 million units for HIV-1, less than 1 in 100 million for HCV and 1 in 1.2 million for HBV. However, some patients who received transfusions before these tests were available suffered serious consequences from infection; this serves as a reminder to avoid non-essential transfusion since it is impossible to exclude the emergence of new or currently unrecognised transfusion-transmissible infection. Licensed plasma derivatives that have been virus-inactivated do not transmit HIV, HTLV, HBV, HCV, cytomegalovirus or other lipid-enveloped viruses.

Variant CJD is a human prion disease linked to bovine spongiform encephalitis (BSE; Ch. 28). The risk of a recipient acquiring the agent of vCJD from a transfusion is uncertain, but of 16 recipients of blood from donors who later developed the disease, 3 have died with clinical vCJD and 1 other had postmortem immunohistological features of infection.

Bacterial contamination of a blood component – usually platelets – is extremely rare (there have been no proven cases in the UK in recent years) but can result in severe bacteraemia/sepsis in the recipient.

## Safe transfusion procedures

The proposed transfusion and any alternatives should be discussed with the patient or, if that is not possible, with a relative. Their consent to proceed with transfusion should be obtained and the discussion documented. Some patients, e.g. Jehovah's Witnesses, may refuse transfusion and require specialised management to survive profound anaemia following blood loss.

### Pre-transfusion testing

To ensure that red cells supplied for transfusion are compatible with the intended recipient, the transfusion laboratory will perform either a 'group and screen' procedure or a 'cross-match'. In the group and screen procedure, the red cells from the patient's blood sample are tested to determine the ABO and RhD type, and the patient's serum is also tested against an array of red cells expressing the most important antigens to detect any red cell antibodies. Any antibody detected can be identified by further testing, so that red cell units that lack the corresponding antigen can be selected. The patient's sample can be held in the laboratory for up to a week, so that the hospital blood bank can quickly prepare compatible blood without the need for a further patient sample. Conventional cross-matching consists of the group and antibody screen, followed by direct confirmation of the compatibility of individual units of red cells with the patient's serum. Full cross-matching takes about 45 minutes, if no red cell antibodies are present, but may require hours if a patient has multiple antibodies.

Blood can be supplied by 'electronic issue', without the need for compatibility cross-matching, if the laboratory's computer system shows that the patient's ABO and RhD groups have been identified and confirmed on two separate occasions and their antibody screen is negative. This allows group-specific units to be issued quickly and safely, for elective and emergency transfusion.

### Bedside procedures for safe transfusion

Errors leading to patients receiving the wrong blood are an important avoidable cause of mortality and morbidity. Most incompatible transfusions result from failure to adhere to standard procedures for taking correctly labelled blood samples from the patient and ensuring that the correct pack of blood component is transfused into the intended patient. In the UK in 2019, the annual incidence of transfusion of an incorrect

### 25.19 Rhesus D blood groups in pregnancy

- **Haemolytic disease of the newborn (HDN):** occurs when the mother has anti-red cell immunoglobulin G (IgG) antibodies that cross the placenta and haemolyse fetal red cells.
- **Screening for HDN in pregnancy:** at the time of booking (12–16 weeks) and again at 28–34 weeks' gestation, every pregnant woman should have a blood sample sent for determination of ABO and Rhesus D (RhD) group and testing for red cell alloantibodies that may be directed against paternal blood group antigens present on fetal red cells.
- **Anti-D immunoglobulin prophylaxis in a pregnant woman who is RhD-negative:** antenatal anti-D prophylaxis is offered at 28–34 weeks to RhD-negative pregnant women who have no evidence of immune anti-D. This prevents the formation of antibodies that could cause HDN. Following delivery of an RhD-positive baby, the mother is given further anti-D within 72 hours; a maternal sample is checked for remaining fetal red cells and additional anti-D is given if indicated. Additional anti-D is also given after potential sensitising events antenatally (e.g. early bleeding). Doses vary according to national recommendations.

blood component is approximately 15 per 100 000 units transfused. Every hospital where blood is transfused should have a written transfusion policy used by all staff who order, check or administer blood products (Fig. 25.15). Management of suspected transfusion reactions is shown in Fig. 25.16.

## Transfusion in major haemorrhage

The successful management of a patient with major haemorrhage requires frontline clinical staff to be trained to recognise significant blood loss early and to intervene before shock is established. Hospitals should have local major haemorrhage protocols and all clinical staff must be familiar with their content. Good team working and communication are essential to prevent poor clinical outcome, suboptimal or inappropriate transfusion practice and component wastage. Fresh frozen plasma (FFP) should be given as part of initial resuscitation in (at least) a 1:2 ratio with red cell concentrate (RCC) until coagulation results are available. If the patient is bleeding, a ratio of FFP to RCC of 1:1 should be given

### 25.20 Key points in transfusion medicine

- A restrictive strategy for red cell transfusion (Hb <70 g/L) is at least as effective as a liberal strategy (<100 g/L).
- The majority of reports in haemovigilance schemes such as SHOT relate to errors in the process of transfusion.
- Although transfusion-transmitted infection is a major concern for patients receiving transfusion, it is rare.
- In patients with trauma or burns or those who have had surgery, there is no evidence that resuscitation with albumin or other colloid solutions reduces the risk of death compared to resuscitation with crystalloid solutions.
- It is recommended that transfusion should be carried out overnight only in unavoidable circumstances.

(SHOT = Serious Hazards of Transfusion)

until laboratory results are available and use of cryoprecipitate should be considered. Once the bleeding is under control, further FFP transfusion should be guided by laboratory results with transfusion triggers of PT and/or APTT above 1.5 times normal for a standard dose of FFP (15–20 mL/kg). Cryoprecipitate should be given if the fibrinogen level falls below 1.5 g/L. Platelets should be kept above  $50 \times 10^9/L$ ; to allow for delivery time, platelets should be requested if there is ongoing bleeding and the platelet count has fallen below  $100 \times 10^9/L$ . Blood component use in major haemorrhage is summarised in Box 25.17 and key points in transfusion medicine in Box 25.20.

## Anti-cancer drugs

### Cytotoxic chemotherapy

Many haematological malignancies are sensitive to the effects of cytotoxic chemotherapy drugs and, as such, they remain the mainstay of treatment for most haematological cancers (Box 25.21; see also Fig. 7.2). There is a wide range of drugs available that work by damaging DNA or disrupting cellular metabolism, in such a way that natural apoptosis mechanisms, such as *TP53*, are activated and the cell dies. Despite cancer cells being more sensitive, chemotherapy is largely non-specific and kills some normal cells as well as cancer cells. This leads to common side-effects of treatment, such as transient bone marrow failure, hair loss, mucositis and infertility. The supportive care of patients undergoing chemotherapy is critical in overcoming these side-effects. It is this supportive care, including blood product support, antibiotics, antifungal drugs, growth factors and antiemetics, that has allowed specialist haematology units to achieve the best possible results from intensive chemotherapy: for example, when treating acute leukaemia.

The basic principles of chemotherapy include combining several non-cross-reacting drugs in a regimen that kills a fixed proportion of cancer cells with a given dose. Several cycles of the combination are given to achieve gradual reduction of the tumour burden, to induce remission and, in some instances, to produce a cure (Ch. 7).

#### Taking blood for pre-transfusion testing

- Positively identify the patient at the bedside
- Label the sample tube and complete the request form clearly and accurately after identifying the patient
- Do not write forms and labels in advance

#### Administering blood

- Positively identify the patient at the bedside
- Ensure that the identification of each blood pack matches the patient's identification
- Check that the ABO and RhD groups of each pack are compatible with the patient's
- Check each pack for evidence of damage
- If in doubt, do not use and return to the blood bank
- Complete the forms that document the transfusion of each pack

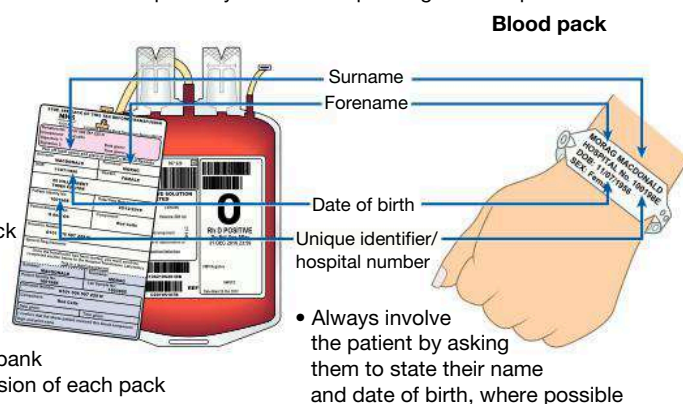

#### Record-keeping

- Record in the patient's notes the reason for transfusion, the product given, dose, any adverse effects and the clinical response

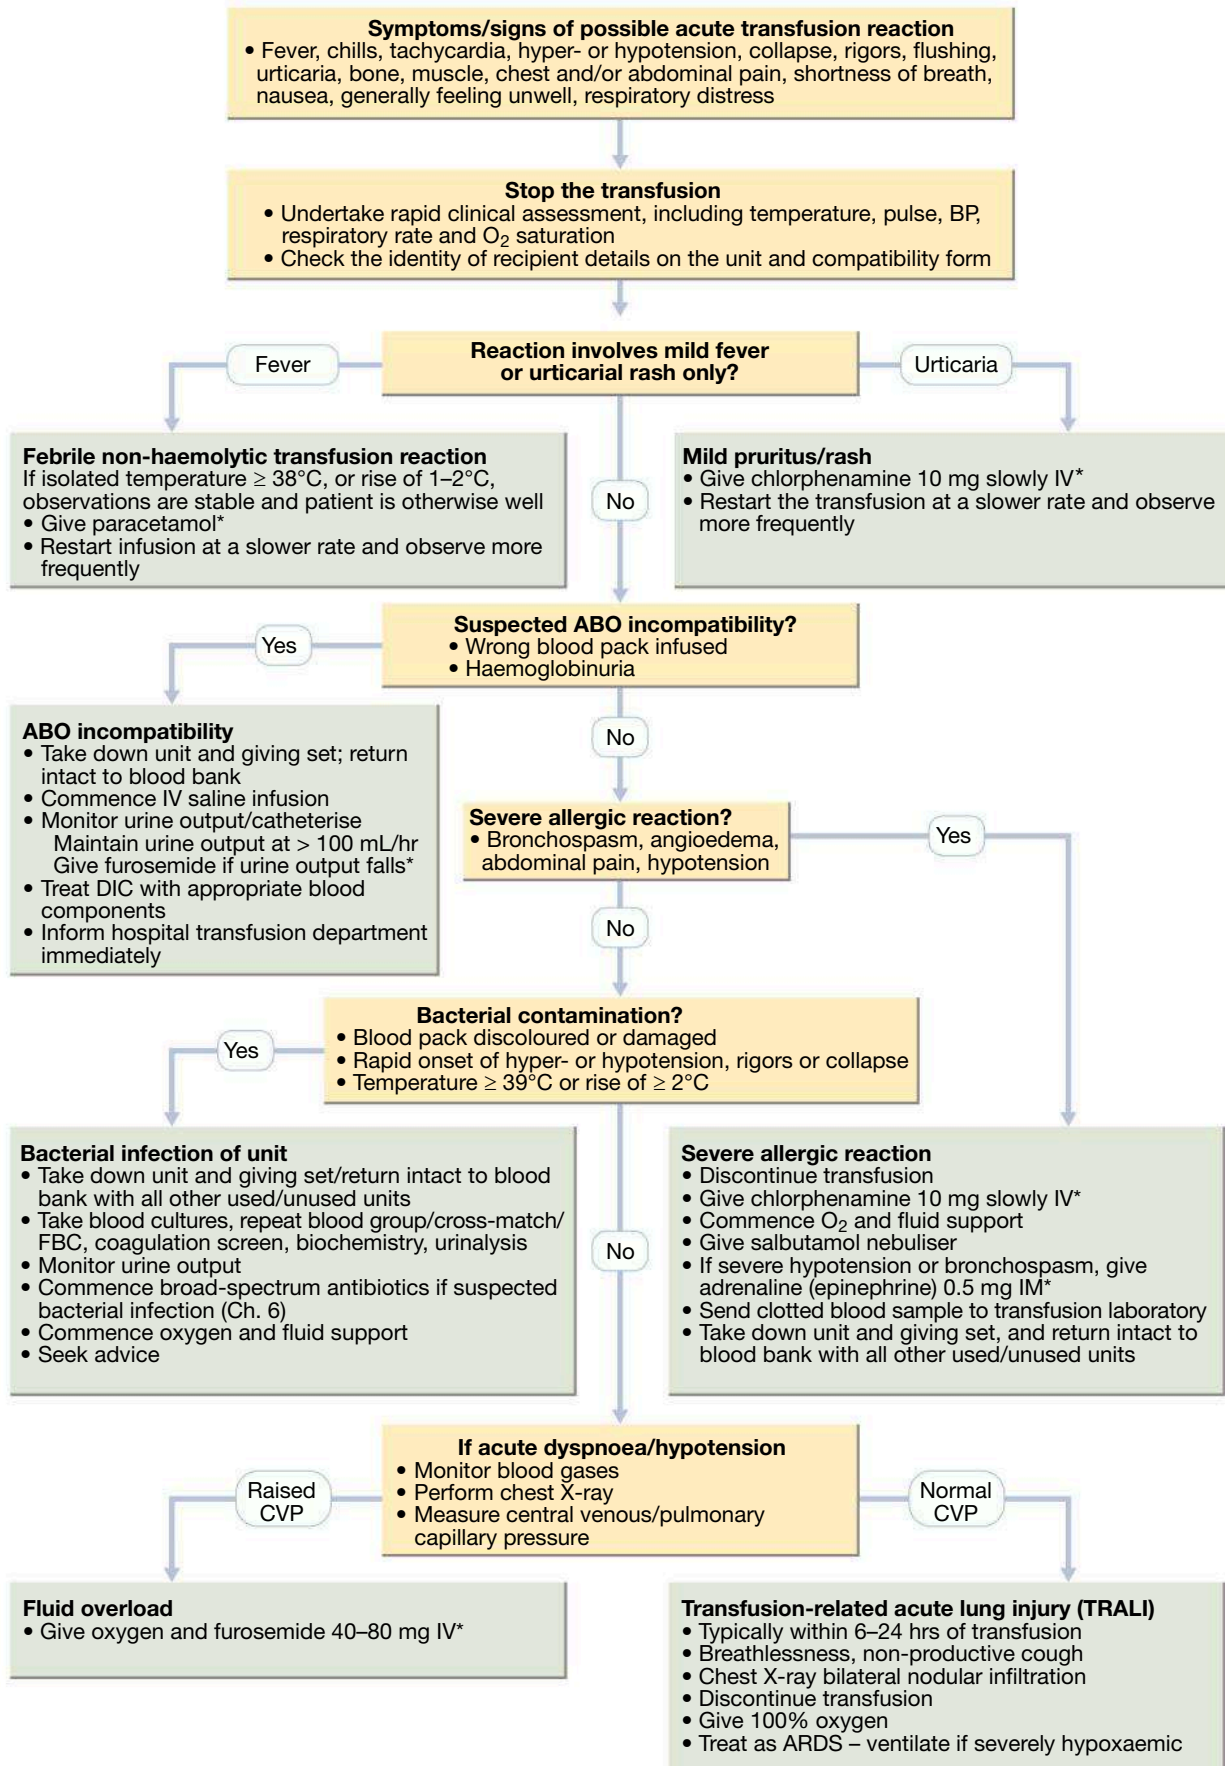

#### Observations

- Transfusions should only be given when the patient can be observed
- Blood pressure, pulse and temperature should be monitored before and 15 minutes after starting each pack
- In conscious patients, further observations are only needed if the patient has symptoms or signs of a reaction
- In unconscious patients, check pulse and temperature at intervals during transfusion
- Signs of abnormal bleeding during the transfusion could be due to disseminated intravascular coagulation resulting from an acute haemolytic reaction

- Check the compatibility label on the pack against the patient's wristband

**Fig. 25.15** Bedside procedures for safe blood transfusion. The patient's safety depends on adherence to standard procedures for taking samples for compatibility testing, administering blood, record-keeping and observations.

**Fig. 25.16** Investigation and management of acute transfusion reactions. \*Use size-appropriate dose in children. (ARDS = acute respiratory distress syndrome; BP = blood pressure; CVP = central venous pressure; DIC = disseminated intravascular coagulation; FBC = full blood count; IV = intravenous)

## Monoclonal antibodies

In recent years, chemotherapy has been improved by the addition of treatments that are more targeted to the cancer cell, particularly monoclonal antibodies; for example, rituximab (anti-CD20) has been added to CHOP (cyclophosphamide doxorubicin, vincristine, prednisolone) and other regimens. This has significantly improved the outcome in a range of CD20-positive B-cell lymphomas, including diffuse large B-cell lymphoma, follicular lymphoma and mantle cell lymphoma. As well as 'naked' monoclonal antibodies that kill malignant cells by engaging antibody-dependent cytotoxic T cells or complement, chemotherapy drugs can also be linked to a monoclonal antibody to allow targeting of the chemotherapy drug to the specific cancer cell. Examples of such antibody–drug conjugates (ADCs) or 'payload' antibodies include the linking of the intercalating antibiotic calicheamicin to anti-CD33 (gemtuzumab ozogamicin) in the treatment of acute myeloid leukaemia (see Fig. 25.27) and to anti-CD22 (inotuzumab ozogamicin) in the treatment of acute lymphoblastic leukaemia (see Fig. 25.28).

## Small molecule targeted therapies

Small molecules targeted at the mechanisms causing cancer are replacing cytotoxic chemotherapy in some disease situations. The most successful of these to date are tyrosine kinase inhibitors targeting BCR-ABL in chronic myeloid leukaemia, which have transformed the treatment of this disease over the last 20 years (see Fig. 25.29). This is a rapidly growing area of medicine and now includes inhibitors of B-cell signalling in chronic lymphocytic leukaemia and lymphomas (see Fig. 25.30) and drugs that target mutated gene products, such as FMS-like tyrosine kinase 3-internal tandem duplication (*FLT3-ITD*) in acute myeloid leukaemia. More details of specific therapies are given later in the chapter.

## Immunotherapy

This includes cellular immunotherapy (see below) and non-cellular immunotherapy such as antibody and antibody-conjugate mediated cytotoxicity as outlined above and checkpoint inhibitor therapy as described in Chapter 7. Checkpoint inhibitor therapy has, to date, proved less useful in haematological malignancies than in solid tumours. This might be because haematological malignancies tend to have less acquired mutations to stimulate T-cell attack than do solid tumours.

## Haematopoietic stem cell transplantation

Transplantation of haematopoietic stem cells (HSCT) has offered the only hope of 'cure' in a variety of haematological and non-haematological disorders (Box 25.22). As standard treatment improves, the indications for HSCT are being refined and extended, although its use remains most common in haematological malignancies. The type of HSCT is defined according to the donor and source of stem cells:

- In *allogeneic* HSCT, the stem cells come from a *donor* – either a related donor (usually an HLA-identical sibling) or a closely HLA-matched volunteer unrelated donor (VUD).
- In an *autologous* transplant, the stem cells are harvested from the *patient* and stored in the vapour phase of liquid nitrogen until required. Stem cells can be harvested from the bone marrow or, most commonly nowadays, from the blood.

## Allogeneic HSCT

Healthy bone marrow or blood stem cells from a donor are infused intravenously into the recipient, who has been suitably 'conditioned'. The conditioning treatment (chemotherapy with or without radiotherapy) is 'myeloablative' or, increasingly, 'non-myeloablative'. Myeloablative conditioning destroys malignant cells and immunosuppresses the recipient, as well as ablating the recipient's haematopoietic tissues. Reduced intensity conditioning (non-myeloablative) relies on intense immunosuppression to

provide 'immunological space' for transplanted stem cells. The infused donor cells 'home' to the marrow, engraft and produce enough erythrocytes, granulocytes and platelets for the patient's needs after about 2–4 weeks. During this period of aplasia, patients are at risk of infection and bleeding, and require intensive supportive care as described on page 966. It may take several years to regain normal immunological function and patients remain at risk from opportunistic infections, particularly in the first year.

An advantage of receiving allogeneic donor stem cells is that the donor's immune system can recognise residual recipient malignant cells and destroy them. This immunological 'graft-versus-disease' effect is a powerful tool against many haematological tumours and can be boosted post-transplantation by the infusion of T cells taken from the donor: so-called donor lymphocyte infusion (DLI).

Considerable morbidity and mortality are associated with HSCT. The best results are obtained in younger patients (<40 years) with minimal residual disease, who have an HLA-identical sibling donor. However, reduced-intensity conditioning (RIC) has enabled treatment of older or less fit patients, in whom the majority of haematological malignancies occur. In this form of transplantation, rather than using very intensive myeloablative conditioning, which causes morbidity from organ damage, relatively low doses of chemotherapy drugs, such as fludarabine and cyclophosphamide or busulfan, are used in combination with antibodies such as alemtuzumab (which targets CD52 on mature lymphoid cells) or anti-thymocyte globulin (ATG) to immunosuppress the recipient and allow donor stem cells to engraft. The emerging donor immune system then eliminates malignant cells via the 'graft-versus-disease' effect, which may be boosted by the elective use of donor T-cell infusions post-transplant. Such transplants have produced long-term remissions in some patients with acute leukaemia and myelodysplastic syndromes aged 40–70 years, who would not previously have been considered for a myeloablative allograft.

## Complications

These are outlined in Boxes 25.23 and 25.24. The risks and outcomes of transplantation depend upon several patient- and disease-related factors. In general, 25% die from procedure-related complications, such as infection and GVHD, and there remains a significant risk of the haematological malignancy relapsing. The long-term survival for patients undergoing allogeneic HSCT in acute leukaemia is around 50%.

### Graft-versus-host disease

GVHD is caused by the cytotoxic activity of donor T lymphocytes that become sensitised to their new host, regarding it as foreign. This may cause either an acute or a chronic form of GVHD.

Acute GVHD occurs in the first 100 days after transplant in about one-third of patients. It can affect the skin, causing rashes, the liver, causing jaundice, and the gut, causing diarrhoea, and may vary from mild to lethal. Prevention includes HLA-matching of the donor, immunosuppressant drugs, including methotrexate, ciclosporin, alemtuzumab or ATG. Severe presentations are very difficult to control and, despite high-dose glucocorticoids, may result in death.

Chronic GVHD may follow acute GVHD or arise independently; it occurs later than acute GVHD. It often resembles a connective tissue disorder, although in mild cases a rash may be the only manifestation. Chronic GVHD is usually treated with glucocorticoids and prolonged immunosuppression with, for example, ciclosporin. Chronic GVHD results in an increased infection risk. However, associated with chronic GVHD is the 'graft-versus-disease' effect and a lower relapse rate of the underlying malignancy.

## Autologous HSCT

This procedure can also be used in haematological malignancies. The patient's stem cells from blood or marrow are first harvested and frozen when their disease is in remission. After conditioning myeloablative therapy, the autologous stem cells are reinfused into the blood stream in order to rescue the patient from the marrow damage and aplasia caused by chemotherapy. This is an effective way of safely delivering high-dose chemotherapy to chemosensitive cancers. Autologous

HSCT may be used as consolidation chemotherapy for disorders that do not primarily involve the haematopoietic tissues, or for patients in whom very good remissions have been achieved. The most common indications are lymphomas and myeloma. The preferred source of stem cells for autologous transplants is peripheral blood (PBSCT). These stem cells engraft more quickly, marrow recovery occurring within 2–3 weeks. There is no risk of GVHD and no immunosuppression is required. Thus autologous HSCT carries a lower procedure-related mortality rate than allogeneic HSCT at around 1%–5%, but there is a higher rate of recurrence of malignancy because the anti-malignancy effect is solely dependent on the conditioning chemotherapy with no 'graft-versus-disease' effect. There is ongoing interest in using autologous HSCT to treat severe autoimmune diseases. The theory is

that the patient's immune system is 'reset' to not attack host tissues. Early success in multiple sclerosis has led to current randomised controlled trials in this area.

### Alternative cellular therapies

While HSCT remains a major cellular therapy for a range of malignant and some non-malignant haematological conditions, newer cell-based treatments have been recently introduced into practice. These include donor T cells primed to respond to specific viruses, including cytomegalovirus (CMV) and Epstein–Barr Virus (EBV). Immunocompromised patients, such as those post solid organ or haematopoietic transplantation, can suffer from reactivation of latent CMV or EBV infection and develop life-threatening complications, e.g. pneumonitis (CMV) and post-transplant lymphoproliferative disease (EBV). Primed donor T cells can be used to treat these

**Fig. 25.17** The manufacturing process for CAR-T cells. **A** The chimeric antigen receptor (CAR) is genetically engineered by combining the extracellular antigen receptor binding domain from a monoclonal antibody ( $V_H$  and  $V_L$  are the heavy and light chain variable regions) with the intracellular activation domain from a T-cell receptor ( $\zeta$ ) and a costimulatory subunit (Costim.); they are linked by a transmembrane (TM) component. During the process the extracellular domain of the T-cell receptor is cleaved and removed ( $\alpha$ – $\epsilon$ ). The new CAR uses the monoclonal antibody binding domain, e.g. anti-CD19, to bind to the target CD19 on the lymphoma cell surface and this can now activate the T-cell effector killing mechanisms via the activation domain, allowing the CAR-T cell to kill the lymphoma cell. **B** The CAR-T cells are manufactured by transducing the new gene for CAR into the patient's T cells. T cells are harvested from the patient by apheresis and then genetically altered in a laboratory process that takes about 4 weeks. The manufactured CAR-T cells are expanded in numbers during this time in tissue culture before being reinfused into the patient. (Modified from Fesnak A O'Doherty U. *Clinical development and manufacture of chimeric antigen receptor T cells and the role of leukapheresis*. *Eur Oncol Haematol* 2017; 13(1):28–34 and Majzner RG, Mackall CL. *Clinical lessons learned from the first leg of the CAR T cell journey*. *Nat Med* 2019; 25:1341–1355 with permission.)

conditions, especially when alternative approaches such as reduction in immunosuppression or anti-viral drugs have failed.

Another exciting new cellular therapy, called chimeric antigen receptor T-cell (CAR-T) therapy, has been developed for patients with some B-cell malignancies where alternative treatments have failed. This technology is based on genetic engineering where a patient's own T cells are harvested and have a new chimeric receptor gene introduced into the cell. This produces a cell surface receptor that uses the antigen binding domain of an antibody molecule to recognise a target on the malignant B cell (CD19) coupled to a T-cell receptor-activating domain (Fig. 25.17). This chimeric B/T receptor can effectively bind to the malignant B cell and activate the T cell to kill it. This treatment is licensed and available for children and young adults with relapsed acute lymphoblastic leukaemia and patients with multiply relapsed diffuse large B-cell lymphoma. This novel therapy has cured some patients who were in a desperate situation, with some data suggesting 60%–70% alive after one year.

## Anticoagulant and antithrombotic therapy

There are numerous indications for anticoagulant and antithrombotic medications (Box 25.25). The guiding principles are outlined here, but management in specific indications is discussed elsewhere in the book. Broadly speaking, antiplatelet medications are of greater efficacy in the

prevention of arterial thrombosis and of less value in the prevention of venous thromboembolism (VTE). Thus, antiplatelet agents, such as aspirin, clopidogrel and, increasingly, ticagrelor, are the drugs of choice in acute coronary events (Ch. 16) and in ischaemic cerebrovascular disease, while warfarin and other anticoagulants are favoured in VTE (p. 985) and management of atrial fibrillation (Ch. 16). In some extremely prothrombotic situations, such as coronary artery stenting, a combination of anticoagulant and antiplatelet drugs is used.

A wide range of anticoagulant and antithrombotic drugs is used in clinical practice. These drugs and their modes of action are given in Box 25.26 and Fig. 25.18. Newer agents allow predictable anticoagulation without the need for frequent monitoring and dose titration. Although warfarin remains an option for oral anticoagulation, newer oral anticoagulants (dabigatran, rivaroxaban, edoxaban and apixaban), which can be given at fixed doses with predictable effects and no need for monitoring, have now been approved for the prevention of perioperative VTE, the treatment of established VTE and the prevention of cardioembolic stroke in patients with atrial fibrillation.

## Heparins

Unfractionated heparin (UFH) and low-molecular-weight heparins (LMWHs) act as anticoagulants by binding a specific pentasaccharide

25.25 Indications for anticoagulation	
<b>Heparin/LMWH/fondaparinux</b>	
<ul style="list-style-type: none"> <li>• Prevention and treatment of VTE</li> <li>• Percutaneous coronary intervention</li> <li>• Post-thrombolysis for MI</li> <li>• Unstable angina pectoris</li> <li>• Non-Q wave MI</li> <li>• Acute peripheral arterial occlusion</li> <li>• Cardiopulmonary bypass</li> <li>• Haemodialysis and haemofiltration</li> </ul>

<b>Apixaban</b>	
<ul style="list-style-type: none"> <li>• Prevention and treatment of VTE</li> <li>• Atrial fibrillation with risk factors for stroke</li> </ul>	
<b>Edoxaban</b>	
<ul style="list-style-type: none"> <li>• Treatment of VTE</li> <li>• Atrial fibrillation with risk factors for stroke</li> </ul>	
(INR = international normalised ratio; LMWH = low-molecular-weight heparin; MI = myocardial infarction; VTE = venous thromboembolism)	

sequence to antithrombin. This enhances the avidity of anti-thrombin for its substrates, which are the activated proteases of the coagulation pathway such as Xa and thrombin (see Fig. 25.6E and Fig. 25.18). Fondaparinux is a synthetic pentasaccharide, which also binds antithrombin and has similar properties to LMWH. LMWHs preferentially augment antithrombin activity against factor Xa. For the licensed indications, LMWHs are at least as efficacious as UFH, but have several advantages:

- LMWHs are nearly 100% bioavailable and so produce reliable dose-dependent anticoagulation.
- LMWHs do not require monitoring of their anticoagulant effect (except possibly in patients with very low body weight and with a glomerular filtration rate below 30 mL/min).
- LMWHs have a half-life of around 4 hours when given subcutaneously, compared with 1 hour for UFH. This permits once-daily dosing by the subcutaneous route, rather than the therapeutic continuous intravenous infusion or twice-daily subcutaneous administration required for UFH.
- While rates of bleeding are similar between products, the risk of osteoporosis and heparin-induced thrombocytopenia is much lower for LMWH.

25.26 Modes of action of anticoagulant and antithrombotic drugs	
Mode of action	Drug
<b>Antiplatelet drugs</b>	
Cyclo-oxygenase (COX) inhibition	Aspirin
Adenosine diphosphate (ADP) receptor inhibition	Clopidogrel Prasugrel Ticagrelor
Glycoprotein IIb/IIIa inhibition	Abciximab Tirofiban Eptifibatid
Phosphodiesterase inhibition	Dipyridamole
<b>Oral anticoagulants</b>	
Vitamin K antagonism	Warfarin/coumarins
Direct thrombin inhibition	Dabigatran
Direct Xa inhibition	Rivaroxaban Apixaban Edoxaban
<b>Injectable anticoagulants</b>	
Antithrombin-dependent inhibition of thrombin and Xa	Heparin LMWH
Antithrombin-dependent inhibition of Xa	Fondaparinux Danaparoid
Direct thrombin inhibition	Argatroban Bivalirudin

UFH is, however, more completely reversed by protamine sulphate in the event of bleeding and at the end of cardiopulmonary bypass, for which UFH remains the drug of choice (Box 25.27).

LMWHs are widely used for the prevention and treatment of VTE, the management of acute coronary syndromes and for most other scenarios listed in Box 25.25. In some situations, UFH is still favoured by some clinicians, though there is little evidence that it is advantageous, except when rapid reversibility is required. UFH is useful in patients with a high risk of bleeding, e.g. those who have peptic ulceration or who may require urgent surgery. It is also favoured in the treatment of life-threatening thromboembolism, e.g. major pulmonary embolism with significant hypoxaemia, hypotension and right-sided heart strain. In this situation, UFH is started with a loading intravenous dose of 80 U/kg, followed by a continuous infusion of 18 U/kg/hr initially. The level of anticoagulation should be assessed by the APTT after 6 hours and, if satisfactory, twice daily thereafter. It is usual to aim for a patient APTT that is 1.5–2.5 times the control time of the test. Monitoring of UFH treatment by APTT is not without difficulties and other assays, such as the specific anti-Xa assay calibrated for measurement of UFH, provides more accurate guidance.

### Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a rare complication of heparin therapy, caused by induction of anti-heparin/PF4 antibodies that bind to and activate platelets via an Fc receptor. This results in platelet activation and a prothrombotic state, with a paradoxical thrombocytopenia. HIT is more common in surgical than medical patients (especially cardiac and orthopaedic patients), with use of UFH rather than LMWH, and with higher doses of heparin. Some adenovirus vector-based SARS-CoV-2 RNA vaccines have been associated with a similar condition characterised by venous thrombosis (often cerebral) and paradoxical thrombocytopenia.

### Clinical features

Patients present, typically 5–14 days after starting heparin treatment, with a fall in platelet count of more than 30% from baseline. The count may still be in the reference range. The patient may be asymptomatic, or develop venous or arterial thrombosis and skin lesions, including overt skin

**Fig. 25.18** Sites of action of antithrombotic and fibrinolytic medicines. Heparin and low molecular weight heparin (LMWH) enhance the avidity of antithrombin for Factor Xa and thrombin (Factor IIa). Fondaparinux also binds antithrombin, but only inhibits Factor Xa. The direct oral anticoagulants (DOACs) rivaroxaban, apixaban, edoxaban and dabigatran directly inhibit specific proteases in the common pathway. Glycoprotein (GP) IIb/IIIa is a receptor for fibrinogen and von Willebrand factor and aids platelet activation and aggregation. P2Y12 is the receptor for adenosine diphosphate (ADP) and its activation also triggers platelet aggregation. Aspirin is an inhibitor of cyclo-oxygenase (COX) in platelets. (t-PA = tissue plasminogen activator)

### 25.27 Treatments for emergencies in haematological practice

- Reversal of life- and limb-threatening haemorrhage in anticoagulated patients:  
Warfarin: prothrombin complex concentrate and IV vitamin K<sub>1</sub>  
Unfractionated heparin: protamine sulphate  
Dabigatran: idarucizumab  
Rivaroxaban and apixaban: andexanet alfa
- Recognition of thrombotic thrombocytopenic purpura and treatment with plasma exchange
- Recognition of coagulopathy associated with acute promyelocytic leukaemia and treatment with all-trans-retinoic acid and fibrinogen replacement
- Recognition of chest syndrome and stroke in patients with sickle-cell anaemia and red cell transfusion or exchange transfusion
- Recognition of neutropenic sepsis in patients receiving chemotherapy and early treatment with empirical broad-spectrum antibiotics

(IV = intravenous)

necrosis. Affected patients may complain of pain or itch at injection sites and of systemic symptoms, such as shivering, following heparin injections. Patients who have received heparin in the preceding 100 days and who have preformed antibodies may develop acute systemic symptoms and an abrupt fall in platelet count in the first 24 hours after re-exposure.

#### Investigations

The pre-test probability of the diagnosis is assessed using the 4Ts scoring system. This assigns a score based on:

- the Thrombocytopenia
- the Timing of the fall in platelet count
- the presence of new Thrombosis
- the likelihood of another cause for the thrombocytopenia.

Individuals at low risk need no further test. Those with intermediate and high likelihood scores should have the diagnosis confirmed or refuted using an anti-PF4 enzyme-linked immunosorbent assay (ELISA).

#### Management

Heparin should be discontinued as soon as HIT is diagnosed and an alternative anticoagulant that does not cross-react with the antibody should be substituted. Argatroban (a direct thrombin inhibitor) and danaparoid

(a heparin analogue) are licensed for use in the UK. Fondaparinux is not licensed for this indication but can also be used. In asymptomatic patients with HIT who do not receive an alternative anticoagulant, around 50% will sustain a thrombosis in the subsequent 30 days. Patients with established thrombosis have a poorer prognosis.

### Coumarins

Although several coumarin anticoagulants are used around the world, warfarin is the most common.

Coumarins inhibit the vitamin K-dependent post-translational carboxylation of factors II (prothrombin), VII, IX and X in the liver (see Fig. 25.6D). This results in anticoagulation due to an effective deficiency of these factors. This is monitored by the INR, a standardised test based on measurement of the prothrombin time (see Box 25.3). Recommended target INR values for specific indications are given in Box 25.25.

Warfarin anticoagulation typically takes more than 3–5 days to become established, even using loading doses. Patients who require rapid initiation of therapy may receive higher initiation doses of warfarin. A typical regimen in this situation is to give 10 mg warfarin on the first and second days, with 5 mg on the third day; subsequent doses are titrated against the INR. Patients without an urgent need for anticoagulation (e.g. atrial fibrillation) can have warfarin introduced slowly using lower doses. Low-dose regimens are associated with a lower risk of the patient developing a supratherapeutic INR, and hence a lower bleeding risk. The duration of warfarin therapy depends on the clinical indication and while treatment of deep vein thrombosis (DVT) or preparation for cardioversion may require a finite duration, anticoagulation to prevent cardioembolic stroke in atrial fibrillation or from heart valve disease is long-term.

The major problems with warfarin are:

- a narrow therapeutic window
- metabolism that is affected by many factors
- numerous drug interactions.

Drug interactions are common through protein binding and metabolism by the cytochrome P450 system. Inter-individual differences in warfarin doses required to achieve a therapeutic INR are mostly accounted for by naturally occurring polymorphisms in the *CYP2C9* and the *VKORC1* genes (which predict the metabolism and function of warfarin, respectively) and dietary intake of vitamin K.

## 25.28 How to assess risks of anticoagulation

### Contraindications

- Recent surgery, especially to eye or central nervous system
- Pre-existing haemorrhagic state, e.g. advanced liver disease, haemophilia, thrombocytopenia
- Pre-existing structural lesions, e.g. peptic ulcer
- Recent cerebral or gastrointestinal haemorrhage
- Uncontrolled hypertension
- Cognitive impairment
- Frequent falls

### Bleeding risk score

- Several bleeding risk scores exist for different indications for anticoagulation
- The validation of most bleeding risk scores has been poor
- Many risk factors for thrombosis are also risk factors for bleeding
- HAS BLED is the best validated score for patients with atrial fibrillation. Following anticoagulant-related bleeding, reassessment of bleeding and thrombosis risk is indicated
- In many cases, patients benefit from recommencing anticoagulants after bleeding

Major bleeding is the most common serious side-effect of warfarin and occurs in 1%–2% of patients each year. Fatal haemorrhage, which is most commonly intracranial, occurs in about 0.25% per annum. There are scoring systems that predict the annual bleeding risk and these can be used to help compare the risks and benefits of warfarin for an individual patient (Box 25.28). There are also some specific contraindications to anticoagulation (Box 25.28). Management of warfarin includes strategies for over-anticoagulation and for bleeding:

- If the INR is above the therapeutic level, warfarin should be withheld or the dose reduced. If the patient is not bleeding, it may be appropriate to give a small dose of vitamin K either orally or intravenously (1–2.5 mg), especially if the INR is greater than 8.
- In the event of bleeding, withhold further warfarin. Minor bleeding can be treated with 1–2.5 mg of vitamin K intravenously (IV). Major haemorrhage should be treated as an emergency with vitamin K 5–10 mg slowly IV, combined with coagulation factor replacement (see Box 25.27). This should optimally be a prothrombin complex concentrate (30–50 U/kg) that contains factors II, VII, IX and X; if that is not available, fresh frozen plasma (15–30 mL/kg) should be given.

## Direct oral anticoagulants

The direct oral anticoagulants (DOACs) are specific inhibitors of key proteases in the common pathway and offer an alternative to coumarins in the management of VTE and the prevention of stroke and systemic embolism in patients with atrial fibrillation. Dabigatran inhibits thrombin while rivaroxaban, apixaban and edoxaban inhibit Xa (see Fig. 25.18). The key features of these drugs include the fact that they are efficacious in fixed oral doses, have a short half-life of around 10 hours, achieve peak plasma levels 2–4 hours after oral intake, have very few drug interactions and are all moderately dependent on renal function for their excretion. An initial perceived drawback was the lack of specific reversal agents for these drugs, but the monoclonal antibody idarucizumab is now available for the reversal of dabigatran and andexanet alfa, a site-inactivated Xa molecule, has recently been licensed for the reversal of apixaban and rivaroxaban (see Box 25.27).

DOACs are now licensed for the prevention of VTE following high-risk orthopaedic surgery (except edoxaban), the acute management and prevention of recurrence of VTE and the prevention of stroke and systemic embolism in patients with atrial fibrillation with risk factors. Dosing is standard across a range of conditions, but is affected by extremes (low and high) of body weight and impaired renal function. The general perception is that in these indications they are at least as efficacious as dose-adjusted coumarin and probably associated with less clinically significant bleeding.

## Anaemias

Around 30% of the total world population is anaemic and half of these, some 600 million people, have iron deficiency. The classification of anaemia by the size of the red cells (MCV) indicates the likely cause (see Figs. 25.10 and 25.11).

Red cells in the bone marrow must acquire a minimum level of haemoglobin before being released into the blood stream (Fig. 25.19). While in the marrow compartment, red cell precursors undergo cell division driven by erythropoietin. If red cells cannot acquire haemoglobin at a normal rate, they will undergo more divisions than normal and will have a low MCV when released into the blood. The MCV is low because component parts of the haemoglobin molecule are not fully available: that is, iron in iron deficiency, globin chains in thalassaemia, haem ring in congenital sideroblastic anaemia and, occasionally, poor iron utilisation in the anaemia of chronic disease/anaemia of inflammation.

In megaloblastic anaemia, the biochemical consequence of vitamin B<sub>12</sub> or folate deficiency is an inability to synthesise new bases to make DNA. A similar defect of cell division is seen in the presence of cytotoxic drugs or haematological disease in the marrow, such as myelodysplasia. In these states, cells haemoglobinise normally, but undergo fewer cell divisions, resulting in circulating red cells with a raised MCV. The red cell membrane is composed of a lipid bilayer that will freely exchange with the plasma pool of lipid. Conditions such as liver disease, hypothyroidism, hyperlipidaemia and pregnancy are associated with raised lipids and may also cause a raised MCV. Reticulocytes are larger than mature red cells, so when the reticulocyte count is raised – e.g. in haemolysis – this may also increase the MCV.

## Iron deficiency anaemia

This occurs when iron losses or physiological requirements exceed absorption.

### Blood loss

The most common explanation in men and post-menopausal women is gastrointestinal blood loss (Ch. 23). This may result from occult gastric or colorectal malignancy, gastritis, peptic ulceration, inflammatory bowel disease, diverticulitis, polyps and angiodysplastic lesions. Worldwide, hookworm and schistosomiasis are the most common causes of gut blood loss (Ch. 13). Gastrointestinal blood loss may be exacerbated by the chronic use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), which cause intestinal erosions and impair platelet function. In women of child-bearing age, menstrual blood loss, pregnancy and breastfeeding contribute to iron deficiency by depleting iron stores; in developed countries, one-third of pre-menopausal women have low iron stores, but only 3% display iron-deficient haematopoiesis. Very rarely, chronic haemoptysis or haematuria may cause iron deficiency.

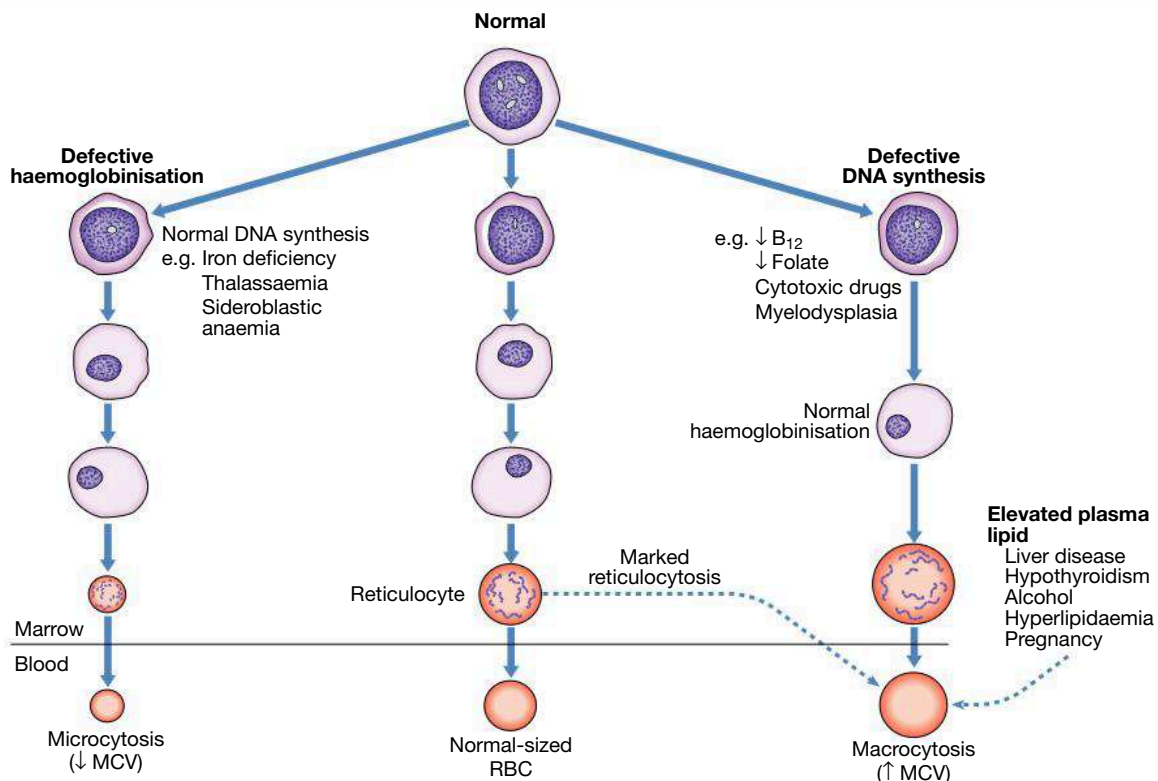

### Malabsorption

A dietary assessment should be made in all patients to ascertain their iron intake (Ch. 22). Gastric acid is required to release iron from food and helps to keep iron in the soluble ferrous state (Fig. 25.20). Achlorhydria in older people or that due to drugs such as proton pump inhibitors may contribute to the lack of iron availability from the diet, as may previous gastric surgery. Iron is absorbed actively in the upper small intestine and hence can be affected by coeliac disease (p. 819).

### Physiological demands

At times of rapid growth, such as infancy and puberty, iron requirements increase and may outstrip absorption. In pregnancy, iron is diverted to the fetus, the placenta and the increased maternal red cell mass, and is lost with bleeding at parturition (Box 25.29).

**Fig. 25.19** Factors that influence the size of red cells in anaemia. In microcytosis, the MCV is <76 fL. In macrocytosis, the MCV is >100 fL. (MCV = mean cell volume; RBC = red blood cell)

**Fig. 25.20** The regulation of iron absorption, uptake and distribution in the body. The transport of iron is regulated in a similar fashion to enterocytes in other iron-transporting cells such as macrophages.

### 25.29 Haematological physiology in pregnancy

- **Full blood count:** increased plasma volume (40%) lowers normal haemoglobin (reference range reduced to  $> 105$  g/L at 28 weeks). The mean cell volume (MCV) may increase by 5 fL. A progressive neutrophilia occurs. Gestational thrombocytopenia (rarely  $< 60 \times 10^9$ /L) is a benign phenomenon.
- **Depletion of iron stores:** iron deficiency is a common cause of anaemia in pregnancy and, if present, should be treated with oral iron supplement.
- **Vitamin B<sub>12</sub>:** serum levels are physiologically low in pregnancy but deficiency is uncommon.
- **Folate:** tissue stores may become depleted, and folate supplementation is recommended in all pregnancies (see Box 22.29).
- **Coagulation factors:** from the second trimester, procoagulant factors increase approximately threefold, particularly fibrinogen, von Willebrand factor and factor VIII. This causes activated protein C resistance and a shortened activated partial thromboplastin time (APTT), and contributes to a prothrombotic state.
- **Anticoagulants:** levels of protein C increase from the second trimester, while levels of free protein S fall as C4b binding protein increases.

## Investigations

### Confirmation of iron deficiency

Serum ferritin is a measure of iron stores in tissues and is the best single test to confirm iron deficiency (Box 25.30). A subnormal level is most often due to iron deficiency or, very rarely, hypothyroidism or vitamin C deficiency. Ferritin levels can be raised in liver disease and in the acute phase response; in these conditions, a ferritin level of up to  $100 \mu\text{g/L}$  may still be compatible with low bone marrow iron stores.

Plasma iron and total iron binding capacity (TIBC) are measures of iron availability; hence they are affected by many factors besides iron stores. Plasma iron has a marked diurnal and day-to-day variation and becomes very low during an acute phase response, but is raised in liver disease and haemolysis. Levels of transferrin, the binding protein for iron, are lowered by malnutrition, liver disease, the acute phase response and nephrotic syndrome, but raised by pregnancy and the oral contraceptive pill. A transferrin saturation (i.e.  $\text{iron}/\text{TIBC} \times 100$ ) of less than 16% is consistent with iron deficiency, but is less specific than a low ferritin measurement.

All proliferating cells express membrane transferrin receptors to acquire iron; a small amount of this receptor is shed into blood, where it can be detected in a free soluble form. When iron stores are low, cells up-regulate transferrin receptor expression and the levels of soluble plasma transferrin receptor increase. This can be measured by immunoassay and used to distinguish storage iron depletion in the presence of an acute phase response or liver disease, when a raised level indicates iron deficiency. In difficult cases, it may still be necessary to examine a bone marrow aspirate for iron stores.

### Investigation of the cause

This will depend on the age and sex of the patient, as well as the history and clinical findings. In men and in post-menopausal women with a normal diet, the upper and lower gastrointestinal tract should be investigated by endoscopy or radiological studies. Current guidelines suggest exclusion of coeliac disease by antibody testing at an early stage of investigation of iron deficiency. In the tropics, stool and urine should be examined for parasites (Box 13.19).

### Management

Unless the patient has angina, heart failure or evidence of cerebral hypoxia, transfusion is not indicated and oral iron replacement is appropriate. Ferrous sulphate 200 mg 3 times daily (195 mg of elemental iron per day) is adequate and should be continued for 3–6 months to replete iron stores. Many patients suffer gastrointestinal side-effects with ferrous sulphate, including dyspepsia and altered bowel habit. When this occurs, reduction in dose or another alternative oral preparation should be tried. Delayed-release preparations are not useful, since they release iron beyond the upper small intestine, where it cannot be absorbed.

The haemoglobin should rise by around 10 g/L every 7–10 days and a reticulocyte response will be evident within a week. A failure to respond adequately may be due to non-adherence, continued blood loss, malabsorption or an incorrect diagnosis. Patients with malabsorption, chronic gut disease or inability to tolerate any oral preparation may need parenteral iron therapy. Previously, iron dextran or iron sucrose was used, but new preparations of ferric isomaltose and ferric carboxymaltose have fewer allergic effects and are preferred. Doses required can be calculated based on the patient's starting haemoglobin and body weight. Observation for anaphylaxis following an initial test dose is recommended.

## Anaemia of chronic disease

Anaemia of chronic disease (ACD), also known as anaemia of inflammation (AI), is a common type of anaemia, particularly in hospital populations. It occurs in the setting of chronic infection, chronic inflammation or neoplasia. The anaemia is not related to bleeding, haemolysis or marrow infiltration, is mild, with haemoglobin in the range of 85–115 g/L, and is usually associated with a normal MCV (normocytic, normochromic), though this may be reduced in long-standing inflammation. The serum iron is low, but iron stores are normal or increased, as indicated by the ferritin or stainable marrow iron.

### Pathogenesis

It has become clear that the key regulatory protein that accounts for the findings characteristic of ACD/AI is hepcidin, which is produced by the liver (see Fig. 25.20). Hepcidin production is induced by pro-inflammatory cytokines, especially IL-6. Hepcidin binds to ferroportin on the membrane of iron-exporting cells, such as small intestinal enterocytes and macrophages, internalising the ferroportin and thereby inhibiting the export of iron from these cells into the blood. The iron remains trapped inside the cells in the form of ferritin, levels of which are therefore normal or high in the face of significant anaemia. Inhibition or blockade of hepcidin is a potential target for treatment of this form of anaemia.

### Diagnosis and management

It is often difficult to distinguish ACD associated with a low MCV from iron deficiency. Box 25.30 summarises the investigations and results. Examination of the marrow may ultimately be required to assess iron stores directly. A trial of oral iron can be given in difficult situations. A positive response occurs in true iron deficiency, but not in ACD. Measures that reduce the severity of the underlying disorder generally help to improve the ACD. Trials of higher-dose intravenous iron are under way to try to bypass the hepcidin-induced blockade.

## Megaloblastic anaemia

This results from a deficiency of vitamin B<sub>12</sub> or folic acid, or from disturbances in folic acid metabolism. Folate is an important substrate of, and vitamin B<sub>12</sub> a co-factor for, the generation of the essential amino acid methionine from homocysteine. This reaction produces tetrahydrofolate, which is converted to thymidine monophosphate for incorporation into DNA. Deficiency of either vitamin B<sub>12</sub> or folate will therefore produce high plasma levels of homocysteine and impaired DNA synthesis.

The end result is cells with arrested nuclear maturation, but normal cytoplasmic development: so-called nucleocytoplasmic asynchrony. All proliferating cells will exhibit megaloblastosis; hence changes are evident in the buccal mucosa, tongue, small intestine, cervix, vagina and uterus. The high proliferation rate of bone marrow results in striking changes in the haematopoietic system in megaloblastic anaemia. Cells become arrested in development and die within the marrow; this ineffective erythropoiesis results in an expanded hypercellular marrow. The megaloblastic changes are most evident in the early-nucleated red cell precursors and haemolysis within the marrow results in a raised bilirubin and lactate dehydrogenase (LDH), but without the reticulocytosis

### 25.30 Investigations to differentiate anaemia of chronic disease from iron deficiency anaemia

	Ferritin	Iron	TIBC	Transferrin saturation	Soluble transferrin receptor
<b>Iron deficiency anaemia</b>	↓	↓	↑	↓	↑
<b>Anaemia of chronic disease</b>	↑/Normal	↓	↓	↓	↓/Normal

(TIBC = total iron binding capacity)

### 25.31 Clinical features of megaloblastic anaemia

#### Symptoms

- Malaise (90%)
- Breathlessness (50%)
- Paraesthesiae (80%)
- Sore mouth (20%)
- Weight loss
- Impotence
- Poor memory
- Depression
- Personality change
- Hallucinations
- Visual disturbance

#### Signs

- Smooth tongue
- Angular cheilosis
- Vitiligo
- Skin pigmentation
- Heart failure
- Pyrexia

characteristic of other forms of haemolysis (see [Box 25.31](#)). Iron stores are usually raised. The mature red cells are large and oval, and sometimes contain nuclear remnants. Nuclear changes are seen in the immature granulocyte precursors and a characteristic appearance is that of 'giant' metamyelocytes with a large 'sausage-shaped' nucleus. The mature neutrophils show hypersegmentation of their nuclei, with cells having six or more nuclear lobes. If severe, a pancytopenia may be present in the peripheral blood.

Vitamin B<sub>12</sub> deficiency, but not folate deficiency, is associated with neurological disease in up to 40% of cases, although advanced neurological disease due to B<sub>12</sub> deficiency is now uncommon in the developed world. The main pathological finding is focal demyelination affecting the spinal cord, peripheral nerves, optic nerves and cerebrum. The most common manifestations are sensory, with peripheral paraesthesiae and ataxia of gait. The clinical and diagnostic features of megaloblastic anaemia are summarised in [Boxes 25.31](#) and [25.32](#), and the neurological features of B<sub>12</sub> deficiency in [Box 25.33](#).

## Vitamin B<sub>12</sub>

### Vitamin B<sub>12</sub> absorption

The average daily diet contains 5–30 µg of vitamin B<sub>12</sub>, mainly in meat, fish, eggs and milk – well in excess of the 1 µg daily requirement. In the stomach, gastric enzymes release vitamin B<sub>12</sub> from food and at gastric pH it binds to a carrier protein termed R protein. The gastric parietal cells produce intrinsic factor, a vitamin B<sub>12</sub>-binding protein that optimally binds vitamin B<sub>12</sub> at pH 8. As gastric emptying occurs, pancreatic secretion raises the pH and vitamin B<sub>12</sub> released from the diet switches from the R protein to intrinsic factor. Bile also contains vitamin B<sub>12</sub> that is available for reabsorption in the intestine. The vitamin B<sub>12</sub>-intrinsic factor complex binds to specific receptors in the terminal ileum, and vitamin B<sub>12</sub> is actively transported by the enterocytes to plasma, where it binds to transcobalamin II, a transport protein produced by the liver, which carries it to the tissues for utilisation. The liver stores enough vitamin B<sub>12</sub> to last for approximately 3 years and this, together with the enterohepatic circulation, means that vitamin B<sub>12</sub> deficiency takes years to become manifest, even if all dietary intake is stopped or severe B<sub>12</sub> malabsorption supervenes.

Blood levels of vitamin B<sub>12</sub> (cobalamin) provide a reasonable indication of tissue stores, are usually diagnostic of deficiency and remain the first-line tests for most laboratories. Additional tests have been evaluated,

### 25.32 Investigations in megaloblastic anaemia

Investigation	Result
<b>Haemoglobin</b>	Often reduced, may be very low
<b>Mean cell volume</b>	Usually raised, commonly >120 fL
<b>Erythrocyte count</b>	Low for degree of anaemia
<b>Blood film</b>	Oval macrocytosis, poikilocytosis, red cell fragmentation, neutrophil hypersegmentation
<b>Reticulocyte count</b>	Low for degree of anaemia
<b>Leucocyte count</b>	Low or normal
<b>Platelet count</b>	Low or normal
<b>Bone marrow</b>	Increased cellularity, megaloblastic changes in erythroid series, giant metamyelocytes, dysplastic megakaryocytes, increased iron in stores, pathological non-ring sideroblasts
<b>Serum ferritin</b>	Elevated
<b>Plasma lactate dehydrogenase</b>	Elevated, often markedly

### 25.33 Neurological findings in B<sub>12</sub> deficiency

#### Peripheral nerves

- Glove and stocking paraesthesiae
- Loss of ankle reflexes

#### Spinal cord

- Subacute combined degeneration of the cord
  - Posterior columns – diminished vibration sensation and proprioception
  - Corticospinal tracts – upper motor neuron signs

#### Cerebrum

- Dementia
- Optic atrophy
- Autonomic neuropathy

including measurement of methylmalonic acid, holotranscobalamin and plasma homocysteine levels, but do not add much in most clinical situations. Levels of cobalamins fall in normal pregnancy. Reference ranges vary between laboratories, but levels below 150 ng/L are common and, in the last trimester, 5%–10% of women have levels below 100 ng/L. Spurious low B<sub>12</sub> values occur in women using the oral contraceptive pill and in patients with myeloma, in whom paraproteins can interfere with vitamin B<sub>12</sub> assays.

### Causes of vitamin B<sub>12</sub> deficiency

#### Dietary deficiency

This occurs only in strict vegans, but the onset of clinical features can occur at any age between 10 and 80 years. Less strict vegetarians often have slightly low vitamin B<sub>12</sub> levels, but are not tissue vitamin B<sub>12</sub>-deficient.

#### Gastric pathology

Release of vitamin B<sub>12</sub> from food requires normal gastric acid and enzyme secretion and this is impaired by hypochlorhydria in older patients or

following gastric surgery. Total gastrectomy invariably results in vitamin B<sub>12</sub> deficiency within 5 years, often combined with iron deficiency; these patients need life-long 3-monthly vitamin B<sub>12</sub> injections. After partial gastrectomy, vitamin B<sub>12</sub> deficiency only develops in 10%–20% of patients by 5 years; an annual injection of vitamin B<sub>12</sub> should prevent deficiency in this group. Patients may develop B<sub>12</sub> deficiency after certain types of bariatric surgery (see Ch. 22).

### Pernicious anaemia

This is an organ-specific autoimmune disorder in which the gastric mucosa is atrophic, with loss of parietal cells causing intrinsic factor deficiency. In the absence of intrinsic factor, less than 1% of dietary vitamin B<sub>12</sub> is absorbed. Pernicious anaemia has an incidence of 25/100 000 population over the age of 40 years in developed countries, but an average age of onset of 60 years. It is more common in individuals with other autoimmune disease (Hashimoto's thyroiditis, Graves' disease, vitiligo or Addison's disease; Ch. 20) or a family history of these or pernicious anaemia. The finding of anti-intrinsic factor antibodies in the context of B<sub>12</sub> deficiency is diagnostic of pernicious anaemia without further investigation. Antiparietal cell antibodies are present in over 90% of cases, but are also present in 20% of normal females over the age of 60 years; a negative result makes pernicious anaemia less likely, but a positive result is not diagnostic. The Schilling test, involving measurement of absorption of radio-labelled B<sub>12</sub> after oral administration before and after replacement of intrinsic factor, has fallen out of favour with the availability of autoantibody tests, greater caution in the use of radioactive tracers and limited availability of intrinsic factor.

### Small bowel pathology

One-third of patients with pancreatic exocrine insufficiency fail to transfer dietary vitamin B<sub>12</sub> from R protein to intrinsic factor. This usually results in slightly low vitamin B<sub>12</sub> values, but no tissue evidence of vitamin B<sub>12</sub> deficiency. Inflammatory disease of the terminal ileum, such as Crohn's disease, may impair the absorption of vitamin B<sub>12</sub>-intrinsic factor complex, as may surgery on that part of the bowel. Motility disorders or hypogammaglobulinaemia can result in bacterial overgrowth and the ensuing competition for free vitamin B<sub>12</sub> can lead to deficiency. A small number of people heavily infected with the fish tapeworm (Ch. 13) develop vitamin B<sub>12</sub> deficiency.

## Folate

### Folate absorption

Folates are produced by plants and bacteria; hence dietary leafy vegetables (spinach, broccoli, lettuce), fruits (bananas, melons) and animal protein (liver, kidney) are a rich source. An average Western diet contains more than the minimum daily intake of 50 µg, but excess cooking destroys folates. Most dietary folate is present as polyglutamates; these are converted to monoglutamate in the upper small bowel and actively transported into plasma. Plasma folate is loosely bound to plasma proteins such as albumin and there is an enterohepatic circulation. Total body stores of folate are small and deficiency can occur in a matter of weeks.

### Folate deficiency

The causes and diagnostic features of folate deficiency are shown in Boxes 25.34 and 25.35. Edentulous older people or psychiatric patients are particularly susceptible to dietary deficiency and this is exacerbated in the presence of gut disease or malignancy. Pregnancy-induced folate deficiency is the most common cause of megaloblastosis worldwide and is more likely in the context of twin pregnancies, multiparity and hyperemesis gravidarum. Serum folate measurement is very sensitive to dietary intake; a single folate-rich meal can normalise it in a patient with true folate deficiency, whereas anorexia, alcohol and anticonvulsant therapy can reduce it in the absence of megaloblastosis. For this reason, red cell folate levels are a more accurate indicator of folate stores and tissue folate deficiency.

## 25.34 Causes of folate deficiency

### Diet

- Poor intake of vegetables

### Malabsorption

- e.g. Coeliac disease, small bowel surgery including some forms of bariatric surgery

### Increased demand

- Cell proliferation, e.g. haemolysis
- Pregnancy

### Drugs\*

- Certain anticonvulsants (e.g. phenytoin)
- Contraceptive pill
- Certain cytotoxic drugs (e.g. methotrexate)

\*Usually only a problem in patients deficient in folate from another cause.

## 25.35 Investigation of folic acid deficiency

### Diagnostic findings

- Serum folate levels may be low but are difficult to interpret
- Low red cell folate levels indicate prolonged folate deficiency and are probably the most relevant measure

### Corroborative findings

- Macrocytic dysplastic blood picture
- Megaloblastic marrow

## Management of megaloblastic anaemia

If a patient with a severe megaloblastic anaemia is very ill and treatment must be started before vitamin B<sub>12</sub> and red cell folate results are available, that treatment should always include both folic acid and vitamin B<sub>12</sub>. The use of folic acid alone in the presence of vitamin B<sub>12</sub> deficiency may result in worsening of neurological features.

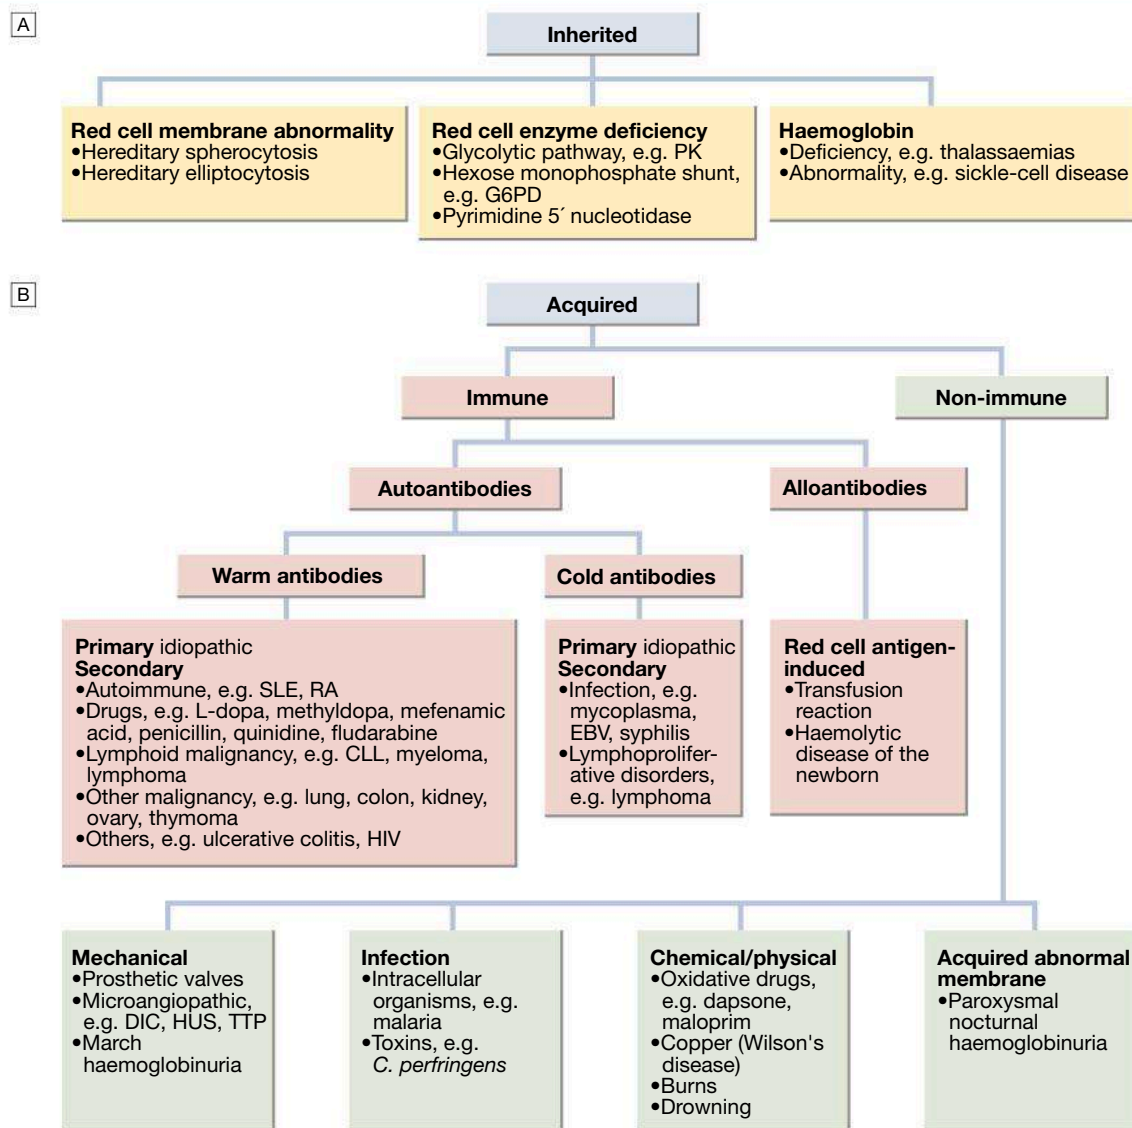

Rarely, if severe angina or heart failure is present, transfusion can be used. The cardiovascular system is adapted to the chronic anaemia present in megaloblastosis and the volume load imposed by transfusion may result in decompensation and severe cardiac failure. In such circumstances, exchange transfusion or slow administration of 1 U of red cells with diuretic cover may be given.

### Vitamin B<sub>12</sub> deficiency

Vitamin B<sub>12</sub> deficiency is treated with hydroxycobalamin. In cases of malabsorption, 1000 µg IM for 6 doses 2 or 3 days apart, followed by maintenance therapy of 1000 µg every 3 months for life, is recommended. In the presence of neurological involvement, a dose of 1000 µg on alternate days until there is no further improvement, followed by maintenance as above, is recommended. In dietary deficiency oral B<sub>12</sub> replacement will suffice. The reticulocyte count will peak by the 5th–10th day after starting replacement therapy. The haemoglobin will rise by 10 g/L every week until normalised. The response of the marrow is associated with a fall in plasma potassium levels and rapid depletion of iron stores. If an initial response is not maintained and the blood film is dimorphic (i.e. shows a mixture of microcytic and macrocytic cells), the patient may need additional iron therapy. A sensory neuropathy may take 6–12 months to correct; long-standing neurological damage may not improve.

### Folate deficiency

Oral folic acid (5 mg daily for 3 weeks) will treat acute deficiency and 5 mg once weekly is adequate maintenance therapy. Prophylactic folic acid in pregnancy prevents megaloblastosis in women at

**Fig. 25.21** Causes and classification of haemolysis. **A** Inherited causes. **B** Acquired causes. (CLL = chronic lymphocytic leukaemia; DIC = disseminated intravascular coagulation; EBV = Epstein-Barr virus; G6PD = glucose-6-phosphate dehydrogenase; HUS = haemolytic uraemic syndrome; PK = pyruvate kinase; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; TTP = thrombotic thrombocytopenic purpura)

risk and reduces the risk of fetal neural tube defects (Box 22.29). Prophylactic supplementation is also given in chronic haematological disease associated with reduced red cell lifespan (e.g. haemolytic anaemias).

## Haemolytic anaemia

Haemolysis indicates that there is shortening of the normal red cell lifespan of 120 days. There are many causes, as shown in Fig. 25.21. To compensate, the bone marrow may increase its output of red cells six- to eightfold by increasing the proportion of red cells produced, expanding the volume of active marrow, and releasing reticulocytes prematurely. Anaemia occurs only if the rate of destruction exceeds this increased production rate.

There are some general features of haemolysis and other specific features that help to identify the reason for haemolysis. Results of investigations that establish the presence of haemolysis are shown in Box 25.36. Red cell destruction overloads pathways for haemoglobin breakdown in the liver (p. 864), causing a modest rise in unconjugated bilirubin in the blood and mild jaundice. Increased reabsorption of urobilinogen from the

### 25.36 Investigation results indicating active haemolysis

#### Hallmarks of haemolysis

- ↓ Haemoglobin
- ↑ Unconjugated bilirubin
- ↑ Lactate dehydrogenase
- ↑ Reticulocytes
- ↑ Urinary urobilinogen

#### Additional features of intravascular haemolysis

- ↓ Haptoglobin
- ↑ Methaemalbumin
- Positive urinary haemosiderin
- Haemoglobinuria

gut results in an increase in urinary urobilinogen (pp. 870 and 924). Red cell destruction releases LDH into the serum. The bone marrow compensation results in a reticulocytosis and sometimes nucleated red cell precursors appear in the blood. Increased proliferation of the bone marrow can result in a thrombocytosis, neutrophilia and, if marked, immature

granulocytes in the blood, producing a leucoerythroblastic blood film. The appearances of the red cells may give an indication of the likely cause of the haemolysis:

- spherocytes are small, dark red cells that suggest autoimmune haemolysis or hereditary spherocytosis
- sickle cells suggest sickle-cell disease
- red cell fragments indicate microangiopathic haemolysis
- bite cells (normal-sized red cells that look as if they have been partially eaten) suggest oxidative haemolysis.

The compensatory erythroid hyperplasia may give rise to folate deficiency, with megaloblastic blood features.

The differential diagnosis of haemolysis is determined by the clinical scenario in combination with the results of blood film examination and Coombs testing for antibodies directed against red cells (see below and Fig. 25.21).

### Extravascular haemolysis

Physiological red cell destruction occurs in the reticulo-endothelial cells in the liver or spleen, so avoiding free haemoglobin in the plasma. In most haemolytic states, haemolysis is predominantly extravascular.

To confirm the haemolysis, patients' red cells can be labelled with <sup>51</sup>chromium. When re-injected, they can be used to determine red cell survival; when combined with body surface radioactivity counting, this test may indicate whether the liver or the spleen is the main source of red cell destruction. However, this is seldom performed in clinical practice.

### Intravascular haemolysis

Less commonly, red cell lysis occurs within the blood stream due to membrane damage by complement (ABO transfusion reactions, paroxysmal nocturnal haemoglobinuria), infections (malaria, *Clostridium perfringens*), mechanical trauma (heart valves, DIC) or oxidative damage (e.g. enzymopathies such as glucose-6-phosphate dehydrogenase deficiency, which may be triggered by drugs such as dapsone and maloprim). When intravascular red cell destruction occurs, free haemoglobin is released into the plasma. Free haemoglobin is toxic to cells and binding proteins have evolved to minimise this risk. Haptoglobin is an  $\alpha_2$ -globulin produced by the liver which binds free haemoglobin, resulting in a fall in its levels during active haemolysis. Once haptoglobins are saturated, free haemoglobin is oxidised to form methaemoglobin, which binds to albumin in turn forming methaemalbumin, which can be detected spectrophotometrically in Schumm's test. Methaemoglobin is degraded and any free haem is bound to a second binding protein called haemopexin. If all the protective mechanisms are saturated, free haemoglobin may appear in the urine (haemoglobinuria). When fulminant, this gives rise to black urine, as in severe *falciparum* malaria infection (Ch. 13). In smaller amounts, renal tubular cells absorb the haemoglobin, degrade it and store the iron as haemosiderin. When the tubular cells are subsequently sloughed into the urine, they give rise to haemosiderinuria, which is always indicative of intravascular haemolysis (see Box 25.36).

### Causes of haemolytic anaemia

These can be classified as inherited or acquired (see Fig. 25.21).

- *Inherited* red cell abnormalities resulting in chronic haemolytic anaemia may arise from pathologies of the red cell membrane (hereditary spherocytosis or elliptocytosis), haemoglobin (haemoglobinopathies), or protective enzymes that prevent cellular oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD).
- *Acquired* causes include auto- and alloantibody-mediated destruction of red blood cells and other mechanical, toxic and infective causes.

## Red cell membrane defects

The structure of the red cell membrane is shown in Fig. 25.4. The basic structure is a cytoskeleton 'stapled' on to the lipid bilayer by special protein complexes. This structure ensures great deformability and elasticity;

the red cell diameter is 8  $\mu$ m, but the narrowest capillaries in the circulation are in the spleen, measuring just 2  $\mu$ m in diameter. When the normal red cell structure is disturbed, usually by a quantitative or functional deficiency of one or more proteins in the cytoskeleton, cells lose their elasticity. Each time such cells pass through the spleen, they lose membrane relative to their cell volume. This results in an increase in mean cell haemoglobin concentration (MCHC), abnormal cell shape (see Box 25.2) and reduced red cell survival due to extravascular haemolysis.

### Hereditary spherocytosis

This is usually inherited as an autosomal dominant condition, although 25% of cases have no family history and represent new mutations. The incidence is approximately 1:5000 in high-income countries, but this may be an under-estimate since the disease may present de novo in patients aged over 65 years and is often discovered as a chance finding on a blood count. The most common abnormalities are deficiencies of beta spectrin or ankyrin (see Fig. 25.4). The severity of spontaneous haemolysis varies. Most cases are associated with an asymptomatic compensated chronic haemolytic state with spherocytes present on the blood film, a reticulocytosis and mild hyperbilirubinaemia. Pigment gallstones are present in up to 50% of patients and may cause symptomatic cholecystitis. Occasional cases are associated with more severe haemolysis; these may be due to coincidental polymorphisms in alpha spectrin or co-inheritance of a second defect involving a different protein. These cases tend to present earlier in life with symptomatic, sometimes transfusion-dependent anaemia.

The clinical course may be complicated by crises:

- *Haemolytic crisis* occurs when the severity of haemolysis increases; this is rare, and usually associated with infection.
- *Megaloblastic crisis* follows the development of folate deficiency; this may occur as a first presentation of the disease in pregnancy.
- *Aplastic crisis* occurs in association with parvovirus (erythrovirus) infection (p. 280). Parvovirus causes a common exanthem in children, but if individuals with chronic haemolysis become infected, the virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count.

### Investigations

The patient and other family members should be screened for features of compensated haemolysis (see Box 25.36). This may be all that is required to confirm the diagnosis. Haemoglobin levels are variable, depending on the degree of compensation. The blood film will show spherocytes, but the direct Coombs test (Fig. 25.22) is negative, excluding immune haemolysis. An osmotic fragility test may show increased sensitivity to lysis in hypotonic saline solutions, but is limited by lack of sensitivity and specificity. More specific flow cytometric tests detecting binding of eosin-5-maleimide to red cells are recommended in borderline cases.

### Management

Folic acid prophylaxis (5 mg daily) should be given for life. In severe cases, consideration may be given to splenectomy, which improves but does not normalise red cell survival. Potential indications for splenectomy include moderate to severe haemolysis with complications (anaemia and gallstones), although splenectomy should be delayed where possible until after 6 years of age in view of the subsequent risk of sepsis. Guidelines for the management of patients after splenectomy are presented in Box 25.37.

Acute, severe haemolytic crises require transfusion support, but cross-matched blood must be transfused slowly as haemolytic transfusion reactions may occur (see Fig. 25.16).

### Hereditary elliptocytosis

This term refers to a heterogeneous group of disorders that produce an increase in elliptocytic red cells on the blood film and a variable degree of haemolysis. This is due to a functional abnormality of one or more anchor proteins in the red cell membrane, e.g. alpha spectrin or protein 4.1

Fig. 25.22 Direct and indirect antiglobulin tests.

### 25.37 Management of the splenectomised patient

- Vaccinate with pneumococcal, *Haemophilus influenzae* type B, meningococcal group C and influenza vaccines at least 2–3 weeks before elective splenectomy. Vaccination should be given after emergency surgery but may be less effective
- Pneumococcal re-immunisation should be given at least 5-yearly and influenza annually. Vaccination status must be documented
- Life-long prophylactic penicillin V (500 mg twice daily) is recommended. In penicillin-allergic patients, consider a macrolide
- Patients should be educated regarding the risks of infection and methods of prophylaxis
- A card or bracelet should be carried to alert health professionals to the risk of overwhelming sepsis
- In sepsis, patients should be resuscitated and given intravenous antibiotics to cover pneumococcus, *Haemophilus* and meningococcus, according to local resistance patterns
- The risk of cerebral malaria is increased in the event of infection
- Animal bites should be promptly treated with local disinfection and antibiotics to prevent serious soft tissue infection and sepsis

(see Fig. 25.4). Inheritance may be autosomal dominant or recessive. Hereditary elliptocytosis is less common than hereditary spherocytosis in Western countries, with an incidence of 1/10 000, but is more common in equatorial Africa and parts of South-east Asia. The clinical course is variable and depends on the degree of membrane dysfunction caused by the inherited molecular defect(s); most cases present as an asymptomatic blood film abnormality, but occasional cases result in neonatal haemolysis or a chronic compensated haemolytic state. Management of the latter is the same as for hereditary spherocytosis.

A characteristic variant of hereditary elliptocytosis occurs in South-East Asia, particularly Malaysia and Papua New Guinea, with stomatocytes and ovalocytes in the blood. This has a prevalence of up to 30% in some communities because it offers relative protection from malaria and thus has sustained a high gene frequency. The blood film is often very abnormal and immediate differential diagnosis is broad.

### Red cell enzymopathies

The mature red cell must produce energy via ATP to maintain a normal internal environment and cell volume while protecting itself from the oxidative stress presented by oxygen carriage. ATP is generated by glycolysis, while the hexose monophosphate shunt produces nicotinamide adenine dinucleotide phosphate (NADPH) and glutathione to protect against oxidative stress. The impact of functional or quantitative defects in the enzymes in these pathways depends on the importance of the steps affected and the presence of alternative pathways. In general, defects in the hexose monophosphate shunt pathway result in periodic haemolysis precipitated by episodic oxidative stress, while those in the glycolysis pathway result in shortened red cell survival and chronic haemolysis.

#### *Glucose-6-phosphate dehydrogenase deficiency*

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is pivotal in the hexose monophosphate shunt pathway. Deficiencies result in the most common human enzymopathy, affecting 10% of the world's population, with a geographical distribution that parallels the malaria belt because heterozygotes are protected from malarial parasitisation. The enzyme is a heteromeric structure made of catalytic subunits that are encoded by a gene on the X chromosome. The deficiency therefore affects males and rare homozygous females (Ch. 3), but it is carried by females. Carrier heterozygous females are usually only affected in the neonatal period or in the presence of skewed X-inactivation.

Over 400 subtypes of G6PD are described. The most common types associated with normal activity are the B<sup>+</sup> enzyme present in most populations of European descent and 70% of those of African Caribbean origin, and the A<sup>+</sup> variant present in 20% of African Caribbeans. The two common variants associated with reduced activity are the A<sup>-</sup> variety in approximately 10% of African Caribbeans, and the Mediterranean or B<sup>-</sup> variety in those of European origin. In East and West Africa, up to 20% of males and 4% of females (homozygotes) are affected and have enzyme levels of about 15% of normal. The deficiency in European and East Asian populations is more severe, with enzyme levels as low as 1%.

### 25.38 Glucose-6-phosphate dehydrogenase deficiency

#### Clinical features

- Acute drug-induced haemolysis to (e.g.):  
Analgesics: aspirin, phenacetin  
Antimalarials: primaquine, quinine, chloroquine, pyrimethamine  
Antibiotics: sulphonamides, nitrofurantoin, ciprofloxacin  
Miscellaneous: quinidine, probenecid, vitamin K, dapsone
- Chronic compensated haemolysis
- Infection or acute illness
- Neonatal jaundice: may be a feature of the B<sup>-</sup> enzyme
- Favism, i.e. acute haemolysis after ingestion of broad beans (*Vicia faba*)

#### Laboratory features

##### Non-spherocytic intravascular haemolysis during an attack

The blood film will show:

- Bite cells (red cells with a 'bite' of membrane missing)
- Blister cells (red cells with surface blistering of the membrane)
- Irregularly shaped small cells
- Polychromasia reflecting the reticulocytosis
- Denatured haemoglobin visible as Heinz bodies within the red cell cytoplasm with a supravital stain such as methyl violet

##### G6PD level

- Can be indirectly assessed by screening methods that usually depend on the decreased ability to reduce dyes
- Direct assessment of G6PD is made in those with low screening values
- Care must be taken close to an acute haemolytic episode because reticulocytes may have higher enzyme levels and give rise to a false normal result

Clinical features and investigation findings are shown in [Box 25.38](#).

Management aims to stop the intake of any precipitant drugs or foods and treat any underlying infection. Favism due to the consumption of fava beans is the classically described precipitant of haemolysis in patients with G6PD deficiency. Acute transfusion support may be life-saving.

#### Pyruvate kinase deficiency

This is the second most common red cell enzyme defect. It results in deficiency of ATP production and a chronic haemolytic anaemia. It is inherited as an autosomal recessive trait. The extent of anaemia is variable; the blood film shows characteristic 'prickle cells' that resemble holly leaves. Enzyme activity is only 5%–20% of normal. Transfusion support may be necessary during periods of haemolysis.

#### Pyrimidine 5' nucleotidase deficiency

The pyrimidine 5' nucleotidase enzyme catalyses the dephosphorylation of nucleoside monophosphates and is important during the degradation of RNA in reticulocytes. It is inherited as an autosomal recessive trait and is as common as pyruvate kinase deficiency in Mediterranean, African and Jewish populations. The accumulation of excess ribonucleoprotein results in coarse basophilic stippling (see [Box 25.2](#)), associated with a chronic haemolytic state. The enzyme is very sensitive to inhibition by lead and this is the reason why basophilic stippling is a feature of lead poisoning.

### Autoimmune haemolytic anaemia

This results from increased red cell destruction due to red cell autoantibodies. The antibodies may be IgG or IgM, or more rarely IgE or IgA. If an antibody avidly fixes complement, it will cause intravascular haemolysis, but if complement activation is weak, the haemolysis will be extravascular (in the reticulo-endothelial system). Antibody-coated red cells lose membrane to macrophages in the spleen and hence spherocytes are present in the blood. The optimum temperature at which the antibody is active (thermal specificity) is used to classify immune haemolysis:

- *Warm antibodies* bind best at 37°C and account for 80% of cases. The majority are IgG and often react against Rhesus antigens.

- *Cold antibodies* bind best at 4°C but can bind up to 37°C in some cases. They are usually IgM and bind complement. To be clinically relevant, they must act within the range of normal body temperatures. They account for the other 20% of cases.

#### Warm autoimmune haemolysis

The incidence of warm autoimmune haemolysis is approximately 1/100 000 population per annum; it occurs at all ages, but is more common in middle age and in females. No underlying cause is identified in up to 50% of cases. The remainder are secondary to a wide variety of other conditions (see [Fig. 25.21B](#)).

#### Investigations

There is evidence of haemolysis, spherocytes and polychromasia on the blood film. The diagnosis is confirmed by the direct Coombs or antiglobulin test (see [Fig. 25.22](#)). The patient's red cells are mixed with Coombs reagent, which contains antibodies against human IgG/IgM/complement. If the red cells have been coated by antibody *in vivo*, the Coombs reagent will induce their agglutination and this can be detected visually. The relevant antibody can be eluted from the red cell surface and tested against a panel of typed red cells to determine against which red cell antigen it is directed. The most common specificity is for Rhesus antigens and most often anti-e; this is helpful when choosing blood to cross-match. The direct Coombs test can be negative in the presence of brisk haemolysis. A positive test requires about 200 antibody molecules to attach to each red cell; with a very avid complement-fixing antibody, haemolysis may occur at lower levels of antibody-binding. The standard Coombs reagent will miss IgA or IgE antibodies. Around 10% of all warm autoimmune haemolytic anaemias are Coombs test-negative.

#### Management

If the haemolysis is secondary to an underlying cause, this must be treated and any implicated drugs stopped.

It is usual to treat patients initially with prednisolone (1 mg/kg orally). A response is seen in 70%–80% of cases, but may take up to 3 weeks; a rise in haemoglobin will be matched by a fall in bilirubin, LDH and reticulocyte levels. Once the haemoglobin has normalised and the reticulocytosis resolved, the glucocorticoid dose can be reduced slowly over several weeks. Glucocorticoids probably work by decreasing macrophage destruction of antibody-coated red cells and reducing antibody production.

Transfusion support may be required for life-threatening problems, such as the development of heart failure or rapid unabated falls in haemoglobin. The least incompatible blood should be used, but this may still give rise to transfusion reactions or the development of alloantibodies.

If the haemolysis fails to respond to glucocorticoids or can only be stabilised by large doses, then second-line therapy with the anti-CD20 monoclonal antibody rituximab should be considered. Failure to respond to rituximab can be followed by consideration of treatment with a range of immunomodulatory/ immunosuppressive agents or splenectomy. Pharmacological agents include azathioprine, ciclosporin, danazol and mycophenolate mofetil. Splenectomy is associated with a good response in 50%–60% of cases. The operation can be performed laparoscopically with reduced morbidity. There are concerns about all modes of third-line therapy as long-term immunosuppression carries a risk of malignancy, while splenectomy is associated with an excess of severe infection due to the capsule organisms pneumococcus and meningococcus (see [Box 25.40](#)).

#### Cold agglutinin disease

This is mediated by antibodies, usually IgM, which bind to the red cells at low temperatures and cause them to agglutinate. It may cause intravascular haemolysis if complement fixation occurs. This can be chronic when the antibody is monoclonal, or acute or transient when the antibody is polyclonal.

### Chronic cold agglutinin disease

This typically affects older adult patients and may be associated with an underlying low-grade B-cell lymphoma. It causes a low-grade intravascular haemolysis with cold, painful and often blue fingers, toes, ears or nose (so-called acrocyanosis). The latter is due to red cell agglutination in the small vessels in these colder, exposed areas. The blood film shows red cell agglutination and the MCV may be spuriously high because the automated analysers detect red cell aggregates as single cells. Monoclonal IgM usually has anti-I or, less often, anti-i specificity. Treatment is primarily by transfusion support, but may also be directed at any underlying lymphoma. Patients must keep extremities warm, especially in winter. Some patients respond to rituximab. Fludarabine can be added in if a clonal abnormality is detected. For patients requiring blood transfusion, the cross-match sample must be placed in a transport flask at a temperature of 37°C and blood must be administered via a blood-warmer. All patients should receive folic acid supplementation.

### Other causes of cold agglutination

Cold agglutination can occur in association with *Mycoplasma pneumoniae* or with infectious mononucleosis. Paroxysmal cold haemoglobinuria is a very rare cause seen in children, in association with viral or bacterial infection. An IgG antibody binds to red cells in the peripheral circulation, but lysis occurs in the central circulation when complement fixation takes place. This antibody is termed the Donath–Landsteiner antibody and has specificity against the P antigen on the red cells.

## Alloimmune haemolytic anaemia

Alloimmune haemolytic anaemia is caused by antibodies against non-self red cells. It has two main causes, occurring after:

- unmatched blood transfusion (see Fig. 25.16)
- maternal sensitisation to paternal antigens on fetal cells (haemolytic disease of the newborn, see Box 25.19).

## Non-immune haemolytic anaemia

### Endothelial damage

Disruption of red cell membrane may occur in a number of conditions and is characterised by the presence of red cell fragments on the blood film and markers of intravascular haemolysis:

- *Mechanical heart valves*. High flow through incompetent valves or periprosthetic leaks through the suture ring holding a valve in place result in shear stress damage.
- *March haemoglobinuria*. Vigorous exercise, such as prolonged marching or marathon running, can cause red cell damage in the capillaries in the feet.
- *Thermal injury*. Severe burns cause thermal damage to red cells, characterised by fragmentation and the presence of microspherocytes in the blood.
- *Microangiopathic haemolytic anaemia*. Fibrin deposition in capillaries can cause severe red cell disruption. It may occur in a wide variety of conditions: disseminated carcinomatosis, malignant or pregnancy-induced hypertension, haemolytic uraemic syndrome (Ch. 18), thrombotic thrombocytopenic purpura and disseminated intravascular coagulation (p. 988).

### Infection

*Plasmodium falciparum* malaria (p. 319) may be associated with intravascular haemolysis; when severe, this is termed blackwater fever because of the associated haemoglobinuria. *Clostridium perfringens* sepsis (p. 271), usually in the context of ascending cholangitis or necrotising fasciitis, may cause severe intravascular haemolysis with marked spherocytosis due to bacterial production of a lecithinase that destroys the red cell membrane.

### Chemicals or drugs

Dapsone and sulfasalazine cause haemolysis by oxidative denaturation of haemoglobin. Denatured haemoglobin forms Heinz bodies in the red cells, visible on supravital staining with brilliant cresyl blue. Arsenic gas, copper, chlorates, nitrites and nitrobenzene derivatives may all cause haemolysis.

## Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare acquired, non-malignant clonal expansion of haematopoietic stem cells deficient in glycosylphosphatidylinositol (GPI) anchor protein. GPI anchors several key molecules to cells and its absence results in clinical outcomes that reflect this, causing intravascular haemolysis and anaemia because of increased sensitivity of red cells to lysis by complement. This happens because key defence mechanisms that protect cells from complement-mediated lysis (CD55 and CD59) are GPI-anchored to red cells under normal circumstances. Episodes of intravascular haemolysis result in haemoglobinuria, most noticeable in early morning urine, which has a characteristic red-brown colour. The disease is associated with an increased risk of venous and arterial thrombosis in unusual sites, such as the liver or abdomen. PNH clones are also associated with hypoplastic bone marrow failure, aplastic anaemia and myelodysplastic syndrome (see later). Management is supportive with transfusion and folate supplements and prophylaxis or treatment of thrombosis. Standard care now includes the anti-complement C5 monoclonal antibodies eculizumab and ravulizumab. This has been shown to be effective in reducing haemolysis, transfusion requirements and thrombotic risk. The C5 inhibitory antibodies both carry a risk of infection, particularly for *Neisseria meningitidis*, and all treated patients must be vaccinated against this organism.

## Haemoglobinopathies

These disorders are caused by mutations affecting the genes encoding the globin chains of haemoglobin. Normal haemoglobin is composed of two alpha and two non-alpha globin chains. Alpha globin chains are produced throughout life, including in the fetus, so severe mutations in these may cause intrauterine death. Production of non-alpha chains varies with age; fetal haemoglobin (HbF- $\alpha\alpha/\gamma\gamma$ ) has two gamma chains, while the predominant adult haemoglobin (HbA- $\alpha\alpha/\beta\beta$ ) has two beta chains. Thus, disorders affecting the beta chains do not present until after 6 months of age. A constant small amount of haemoglobin A<sub>2</sub> (HbA<sub>2</sub>- $\alpha\alpha/\delta\delta$ , usually less than 2%) is made from birth.

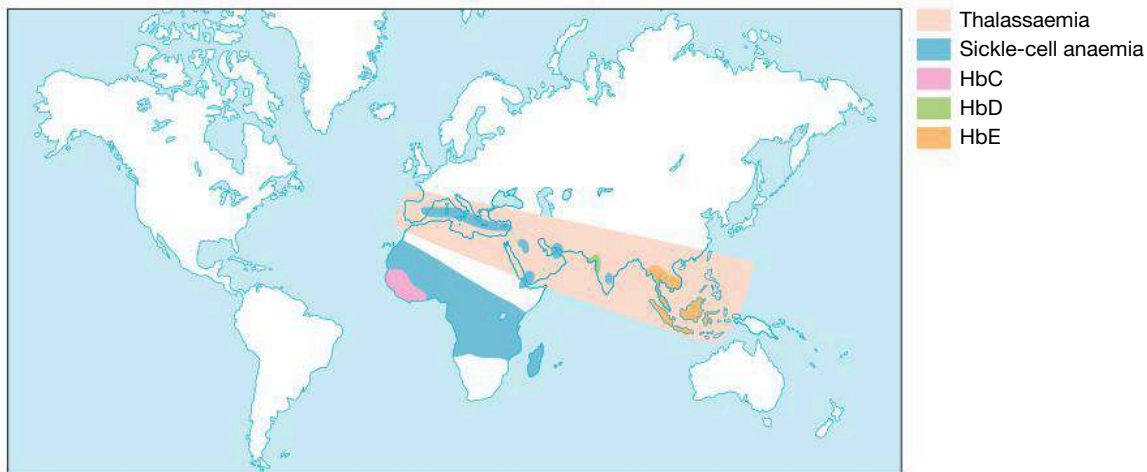

The geographical distribution of the common haemoglobinopathies is shown in Fig. 25.23. The haemoglobinopathies can be classified into qualitative or quantitative abnormalities.

### Qualitative abnormalities – abnormal haemoglobins

In qualitative abnormalities (called the abnormal haemoglobins) there is a functionally important alteration in the amino acid structure of the polypeptide chains of the globin chains. Several hundred such variants are known; they were originally designated by letters of the alphabet, e.g. S, C, D or E, but the more recently described ones are known by names that are usually taken from the town or district in which they were first described. The best-known example is haemoglobin S, found in sickle-cell anaemia. Mutations around the haem-binding pocket cause the haem ring to fall out of the structure and produce an unstable haemoglobin. These substitutions often change the charge of the globin chains, producing different electrophoretic mobility, and this forms the basis for the diagnostic use of haemoglobin electrophoresis to identify haemoglobinopathies.

### Quantitative abnormalities – thalassaemias

In quantitative abnormalities (the thalassaemias), there are mutations causing a reduced rate of production of one or other of the globin chains,

**Fig. 25.23** The geographical distribution of the haemoglobinopathies. From Hoffbrand AV, Pettit JE. *Essential haematology*, 3rd edn. Edinburgh: Blackwell Science; 1992.

altering the ratio of alpha to non-alpha chains. In alpha-thalassaemia excess beta chains are present, while in beta-thalassaemia excess alpha chains are present. The excess chains precipitate, causing red cell membrane damage and reduced red cell survival due to haemolysis.

### Sickle-cell anaemia

Sickle-cell disease results from a single glutamic acid to valine substitution at position 6 of the beta globin polypeptide chain. It is inherited as an autosomal recessive trait (Ch. 3). Homozygotes only produce abnormal beta chains that make haemoglobin S (HbS, termed SS), and this results in the clinical syndrome of sickle-cell disease. Heterozygotes produce a mixture of normal and abnormal beta chains that make normal HbA and HbS (termed AS), and this results in sickle-cell trait; although this was previously thought of as asymptomatic, it may be associated with an increased risk of sudden and cardiovascular death in young adults.

#### Epidemiology

The heterozygote frequency is over 20% in tropical Africa (see Fig. 25.23). In African American populations, sickle-cell trait has a frequency of 8%. Individuals with sickle-cell trait are relatively resistant to the effects of *falciparum* malaria in early childhood; the high prevalence in equatorial Africa can thus be explained by the survival advantage it confers in areas where *falciparum* malaria is endemic. However, homozygous patients with sickle-cell anaemia do not have correspondingly greater resistance to *falciparum* malaria.

#### Pathogenesis

When haemoglobin S is deoxygenated, the molecules of haemoglobin polymerise to form pseudocrystalline structures known as 'tactoids'. These distort the red cell membrane and produce characteristic sickle-shaped cells (Fig. 25.24). The polymerisation is reversible when reoxygenation occurs. The distortion of the red cell membrane, however, may become permanent and the red cell 'irreversibly sickled'. The greater the concentration of sickle-cell haemoglobin in the individual cell, the more easily tactoids are formed, but this process may be enhanced or retarded by the presence of other haemoglobins. Thus the abnormal haemoglobin C variant participates in polymerisation more readily than haemoglobin A, whereas haemoglobin F strongly inhibits polymerisation.

#### Clinical features

Sickling is precipitated by hypoxia, acidosis, dehydration and infection. Irreversibly sickled cells have a shortened survival and plug vessels in the

microcirculation. This results in a number of acute syndromes, termed 'crises', and chronic organ damage (see Fig. 25.24):

- **Painful vaso-occlusive crisis.** Plugging of small vessels in the bone produces acute severe bone pain. This affects areas of active marrow: the hands and feet in children (so-called dactylitis) or the femora, humeri, ribs, pelvis and vertebrae in adults. Patients usually have a systemic response with tachycardia, and fever. This is the most common form of crisis.
- **Stroke.** The single most devastating consequence of sickle-cell disease is stroke. Stroke or silent stroke occurs in 10%–15% of children with sickle-cell disease. Children at risk of stroke can be identified by screening with transcranial Doppler ultrasound, with fast flow associated with increased stroke risk. These children may be offered strategies such as transfusion or treatment with hydroxycarbamide to reduce the risk of stroke.
- **Sickle chest syndrome.** This may follow a vaso-occlusive crisis and is the most common cause of death in adult sickle-cell disease. Bone marrow infarction results in fat emboli to the lungs, which cause further sickling and infarction, leading to ventilatory failure if not treated.
- **Sequestration crisis.** Thrombosis of the venous outflow from an organ causes loss of function and acute painful enlargement. In children, the spleen is the most common site. Massive splenic enlargement may result in severe anaemia, circulatory collapse and death. Recurrent sickling in the spleen in childhood results in infarction and adults may have no functional spleen. In adults, the liver may undergo sequestration with severe pain due to capsular stretching. Priapism may occur in affected individuals.
- **Aplastic crisis.** Infection of adult sicklers with human parvovirus B19 (erythrovirus) may result in a severe but self-limiting red cell aplasia. This results in profound anaemia, which may cause heart failure. Unlike in all other sickle crises, the reticulocyte count is low.
- **Pregnancy.** Pregnancy in sickle-cell disease requires planning and multidisciplinary management. Women with sickle-cell disease have increased pregnancy-related morbidity, which includes painful crisis, placental failure and thrombosis (Box 25.39).

#### Investigations

Patients with sickle-cell disease have a compensated anaemia, usually around 60–80 g/L. The blood film shows sickle cells, target cells and features of hyposplenism from a young age. A reticulocytosis is present. The presence of HbS can be demonstrated by exposing red cells to a reducing agent such as sodium dithionite; HbA gives a clear solution, whereas HbS polymerises to produce a turbid solution. This forms the basis of

Fig. 25.24 Clinical and laboratory features of sickle-cell disease.

### 25.39 Sickle-cell disease in pregnancy

- **Pre-conceptual counselling:** advice on the effect of sickle-cell disease on pregnancy, and vice versa, should be offered.
- **Vaccination status:** should be updated before conception.
- **Testing of partner:** testing for haemoglobinopathy status is advised.
- **Folic acid:** should be taken in high dose (5 mg daily) prior to and throughout pregnancy.
- **Hydroxycarbamide:** should be discontinued 3 months prior to conception.
- **Angiotensin-converting enzyme (ACE) inhibitors:** should be discontinued prior to conception.
- **Pulmonary hypertension:** should be excluded prior to conception.
- **Placental failure:** women with sickle-cell disease have increased rates, resulting in pre-eclampsia and intrauterine growth retardation.
- **Aspirin 75 mg:** should be given throughout pregnancy.
- **Thromboprophylaxis after delivery:** all women with sickle-cell disease should receive thromboprophylaxis with low-molecular-weight heparin for at least 10 days post vaginal delivery and for 6 weeks post caesarean section. Antenatal thromboprophylaxis should be considered for women with additional risk factors for venous thromboembolism (see Box 25.67).
- **Transfusion:** extended cross-matched blood for Rhesus and Kell status should be provided. Blood should be cytomegalovirus-negative.

emergency screening tests before surgery in appropriate ethnic groups, but cannot distinguish between sickle-cell trait and disease. The definitive diagnosis requires haemoglobin electrophoresis to demonstrate the absence of HbA, 2%–20% HbF and the predominance of HbS. Both parents of the affected individual will have sickle-cell trait.

### Management

All patients with sickle-cell disease should receive prophylaxis with daily folic acid, and appropriate management of the hyposplenic state that is uniformly found in these patients from an early age (see Box 25.37). Seasonal vaccination against influenza is also advised.

Vaso-occlusive crises are managed by aggressive rehydration, oxygen therapy, adequate analgesia (which often requires opiates) and antibiotics. Transfusion should be with fully genotyped blood wherever possible. Simple top-up transfusion may be used in a sequestration or aplastic crisis. A regular transfusion programme to suppress HbS production and maintain the HbS level below 30% may be indicated in patients with recurrent severe complications, such as cerebrovascular accidents in children or chest syndromes in adults. Exchange transfusion, in which a patient is simultaneously venesected and transfused to replace HbS with HbA, may be used in life-threatening crises or to prepare patients for surgery.

A high HbF level inhibits polymerisation of HbS and reduces sickling. Patients with sickle-cell disease and high HbF levels have a mild clinical course with few crises. Some agents are able to increase synthesis of HbF and this has been used to reduce the frequency of severe crises. The oral cytotoxic agent hydroxycarbamide has been shown to have clinical benefit with acceptable side-effects in children and adults who have recurrent severe crises. The P-selectin inhibitor, crizanlizumab, is currently under review as an agent to reduce vasoocclusive crisis.

Relatively few allogeneic stem cell transplants from HLA-matched siblings have been performed, but this procedure appears to be potentially curative (p. 945).

## Prognosis

In Africa, few children with sickle-cell anaemia survive to adult life without medical attention. Even with standard medical care, approximately 15% die by the age of 20 years and 50% by the age of 40 years.

## Other abnormal haemoglobins

Haemoglobin C (HbC) disease, another beta-chain haemoglobinopathy, is clinically silent but associated with microcytosis and target cells on the blood film. Compound heterozygotes inheriting one *HbS* gene and one *HbC* gene from their parents have haemoglobin SC disease, which behaves like a mild form of sickle-cell disease. SC disease is associated with a reduced frequency of crises, but is not uncommonly associated with complications in pregnancy and retinopathy.

## Thalassaemias

Thalassaemia is an inherited impairment of haemoglobin production, in which there is partial or complete failure to synthesise a specific type of globin chain. In alpha-thalassaemia, disruption of one or both alleles on chromosome 16 may occur, with production of some or no alpha globin chains. In beta-thalassaemia, defective production usually results from disabling point mutations causing no ( $\beta^0$ ) or reduced ( $\beta^-$ ) beta chain production.

### Beta-thalassaemia

Failure to synthesise beta chains (beta-thalassaemia) is the most common type of thalassaemia, most prevalent in the Mediterranean area. Heterozygotes have thalassaemia minor, a condition in which there is usually mild microcytic anaemia and little or no clinical disability, which may be detected only when iron therapy for a mild microcytic anaemia fails. Homozygotes (thalassaemia major) either are unable to synthesise haemoglobin A or, at best, produce very little; after the first 4–6 months of life, they develop profound transfusion-dependent hypochromic anaemia. The diagnostic features are summarised in [Box 25.40](#). Intermediate grades of severity occur.

### Management and prevention

See [Box 25.41](#). Cure is now a possibility for selected children, with allogeneic HSCT (p. 945).

It is possible to identify a fetus with homozygous beta-thalassaemia by obtaining chorionic villous material for DNA analysis sufficiently early in pregnancy to allow termination. This examination is appropriate only if both parents are known to be carriers (beta-thalassaemia minor) and will accept a termination.

### Alpha-thalassaemia

Reduced or absent alpha-chain synthesis is common in South-east Asia. There are two alpha gene loci on chromosome 16 and therefore each individual carries four alpha gene alleles.

- If one is deleted, there is no clinical effect.
- If two are deleted, there may be a mild hypochromic anaemia.
- If three are deleted, the patient has haemoglobin H disease.
- If all four are deleted, the baby is stillborn (hydrops fetalis).

Haemoglobin H is a beta-chain tetramer, formed from the excess of beta chains, which is functionally useless, so that patients rely on their low levels of HbA for oxygen transport. Treatment of haemoglobin H disease is similar to that of beta-thalassaemia of intermediate severity, involving folic acid supplementation, transfusion if required and avoidance of iron therapy.

Some considerations specific to anaemia in old age are listed in [Box 25.42](#).

## 25.40 Diagnostic features of beta-thalassaemia

### Beta-thalassaemia major (homozygotes)

- Profound hypochromic anaemia
- Evidence of severe red cell dysplasia
- Erythroblastosis
- Absence or gross reduction of the amount of haemoglobin A
- Raised levels of haemoglobin F
- Evidence that both parents have thalassaemia minor

### Beta-thalassaemia minor (heterozygotes)

- Mild anaemia
- Microcytic hypochromic erythrocytes (not iron-deficient)
- Some target cells
- Punctate basophilia
- Raised haemoglobin A<sub>2</sub> fraction

## 25.41 Treatment of beta-thalassaemia major

Problem	Management
Erythropoietic failure	Allogeneic HSCT from HLA-compatible sibling Transfusion to maintain Hb >100 g/L Folic acid 5 mg daily
Iron overload	Iron therapy contraindicated Iron chelation therapy
Splenomegaly causing mechanical problems, excessive transfusion needs	Splenectomy; see <a href="#">Box 25.37</a>

(Hb = haemoglobin; HLA = human leucocyte antigen; HSCT = haematopoietic stem cell transplantation)

## 25.42 Anaemia in old age

- **Mean haemoglobin:** falls with age in both sexes but remains well within the reference range. When a low haemoglobin does occur, it is generally due to disease.
- **Anaemia can never be considered 'normal' in old age.**
- **Symptoms:** may be subtle and insidious. Cardiovascular features such as dyspnoea and oedema, and cerebral features such as dizziness and apathy, tend to predominate.
- **Ferritin:** if lower than 45 µg/L in older people, is highly predictive of iron deficiency. Conversely, ferritin may be raised by chronic disease and so a normal ferritin does not exclude iron deficiency.
- **Serum iron and transferrin:** fall with age because of the prevalence of other disorders, and are not reliable indicators of deficiency.
- **Most common cause of iron deficiency:** gastrointestinal blood loss.
- **Most common cause of vitamin B<sub>12</sub> deficiency:** pernicious anaemia, as the prevalence of chronic atrophic gastritis rises in old age.
- **Neuropsychiatric symptoms associated with vitamin B<sub>12</sub> deficiency:** well-established association but a causal relationship has not been clearly shown. Dementia associated with vitamin B<sub>12</sub> deficiency in the absence of haematological abnormalities is rare.
- **Anaemia of chronic disease:** frequent in old age because of the rising prevalence of diseases that inhibit iron transport.

## Haematological malignancies

Haematological malignancies arise when the processes controlling proliferation or apoptosis are corrupted in blood cells because of acquired mutations in key regulatory genes. If mature differentiated cells are involved, the cells will have a low growth fraction and produce indolent

### 25.43 Consequences of haematological malignancy in adolescence

- **Tailored management protocols:** the most effective treatment schedules for leukaemia and lymphoma differ between children and adults. Adolescent patients may be most appropriately managed in specialist centres.
- **Psychosocial effects:** adolescents undergoing treatment for haematological malignancy may suffer significant consequences for their schooling and social development, and require support from a multidisciplinary team.
- **'Late effects':** adolescents who have been treated with chemotherapy and/or radiotherapy in childhood may be at risk of a wide range of complications, depending on the region irradiated, radiation dose and the drugs used. Particularly relevant complications in this age group include short stature, growth hormone deficiency, delayed puberty and cognitive dysfunction affecting schooling (after cranial irradiation). Life-long follow-up is often undertaken to detect and manage these late effects and to deal with consequences such as infertility and second malignancy.

neoplasms, such as the low-grade lymphomas or chronic leukaemias, when patients have an expected survival of many years. In contrast, if more primitive stem or progenitor cells are involved, the cells can have the highest growth fractions of all human neoplasms, producing rapidly progressive, life-threatening illnesses such as the acute leukaemias or high-grade lymphomas. Involvement of pluripotent stem cells produces the most aggressive acute leukaemias. In general, haematological neoplasms are diseases of older patients, the exceptions being acute lymphoblastic leukaemia, which predominantly affects children, and Hodgkin lymphoma, which affects people aged 20–40 years. Management of young patients with haematological malignancy is particularly challenging (Box 25.43).

## Leukaemias

Leukaemias are malignant disorders of the white cell compartment, characteristically associated with increased numbers of white cells in the bone marrow and/or peripheral blood. The course of leukaemia may vary from a few days or weeks to many years, depending on the type.

### Terminology and classification

Leukaemias are traditionally classified into four main groups:

- acute lymphoblastic leukaemia (ALL)
- acute myeloid leukaemia (AML)
- chronic lymphocytic leukaemia (CLL)
- chronic myeloid leukaemia (CML).

In acute leukaemia, there is proliferation of mutated haematopoietic stem and progenitor cells, with limited accompanying differentiation, leading to an accumulation of blasts, predominantly in the bone marrow, which causes bone marrow failure. In chronic leukaemia, the malignant clone is able to differentiate, resulting in an accumulation of more mature cells. Lymphocytic and lymphoblastic cells are those derived from the lymphoid progenitor cells (B cells and T cells). Myeloid refers to the other lineages: that is, precursors of red cells, granulocytes, monocytes and platelets (see Fig. 25.2).

The diagnosis of leukaemia is usually suspected from an abnormal blood count, often including a raised white count, and is confirmed by examination of the bone marrow. This includes the morphology of the abnormal cells, analysis of cell surface markers (immunophenotyping), clone-specific chromosome abnormalities and molecular changes. These results are incorporated in the World Health Organization (WHO) classification of tumours of haematopoietic and lymphoid tissues; the subclassification of acute leukaemias is shown in Box 25.44. The features in the bone marrow not only provide an accurate diagnosis, but also give valuable prognostic information, increasingly allowing therapy to be tailored to the patient's disease.

### 25.44 WHO classification of acute leukaemia

#### Acute myeloid leukaemia (AML) with recurrent genetic abnormalities

- AML with t(8;21)(q22;q22.1), gene product *RUNX1-RUNX1T1*
- AML with inv(16)(p13.1;q22), gene product *CBFB-MYHL1*
- Acute promyelocytic leukaemia t(15;17), gene product *PML-RARA*
- AML with t(9;11)(p21.3;q23.3), gene product *MLL3-KMT2A*
- AML with t(6;9)(p23;q34), gene product *DEK-NUP214*
- AML with inv(3)(q21.3;q26.2) or t(3;3)(q21.3;q26.2), gene products *GATA2, MECOM*
- AML (megakaryoblastic) with t(1;22)(p13.3;q13.3), gene product *RBM15-MKL1*
- AML with mutated *NPM1*
- AML with biallelic mutations of *CEBPA*

#### Acute myeloid leukaemia with myelodysplasia-related changes

- e.g. Following a myelodysplastic syndrome

#### Therapy-related myeloid neoplasms

- e.g. Alkylating agent or topoisomerase II inhibitor

#### Myeloid sarcoma

#### Myeloid proliferations related to Down syndrome

#### Acute myeloid leukaemia not otherwise specified

- e.g. AML with or without differentiation, acute myelomonocytic leukaemia, erythroleukaemia, megakaryoblastic leukaemia

#### Acute lymphoblastic leukaemia (ALL)

- B-lymphoblastic leukaemia/lymphoma
- T-lymphoblastic leukaemia/lymphoma

### 25.45 Risk factors for leukaemia

#### Ionising radiation

- After atomic bombing of Japanese cities (myeloid leukaemia)
- Radiotherapy
- Diagnostic X-rays of the fetus in pregnancy

#### Cytotoxic drugs

- Especially alkylating agents and topoisomerase II inhibitors (therapy-related myeloid malignancies), usually after a latent period of several years with alkylating agents and a few months to 2 years with topoisomerase II inhibitors
- Industrial exposure to benzene

#### Retroviruses

- Adult T-cell leukaemia/lymphoma (ATLL) caused by human T-cell lymphotropic virus 1 (HTLV-1), most prevalent in Japan, the Caribbean and some areas of Central and South America and Africa

#### Genetic

- Identical twin of patients with leukaemia
- Down syndrome and certain other genetic disorders

#### Immunological

- Immune deficiency states (e.g. hypogammaglobulinaemia)

### Epidemiology and aetiology

The incidence of leukaemia of all types in the population is approximately 10/10000 per annum, of which just under half are cases of acute leukaemia. Males are affected more frequently than females, the ratio being about 3:2 in acute leukaemia, 2:1 in chronic lymphocytic leukaemia and 1.3:1 in chronic myeloid leukaemia. Geographical variation in incidence does occur, the most striking being the rarity of chronic lymphocytic leukaemia in Chinese and related races. Acute leukaemia occurs at all ages. Acute lymphoblastic leukaemia shows a peak of incidence in children aged 1–5 years. All forms of acute myeloid leukaemia have their lowest incidence in children and young adult life and there is a striking rise over the age of 50. Chronic leukaemias occur mainly in middle and old age.

The cause of the leukaemia is unknown in the majority of patients. Several risk factors have been identified (Box 25.45).

## Acute leukaemia

Mutations in haematopoietic stem cells produce leukaemic stem cells. Proliferation of these cells that do not mature leads to an accumulation of primitive cells that take up more and more marrow space at the expense of the normal haematopoietic cells. Eventually, this proliferation spills into the blood. Acute myeloid leukaemia (AML) is about four times more common than acute lymphoblastic leukaemia (ALL) in adults. In children, the proportions are reversed, the lymphoblastic variety being more common. The clinical features are usually those of bone marrow failure (anaemia, bleeding or infection; pp. 932, 937 and 939).

### Investigations

Blood examination usually shows anaemia with a normal or raised MCV. The leucocyte count may vary from as low as  $1 \times 10^9/L$  to as high as  $500 \times 10^9/L$  or more. In the majority of patients, the count is below  $100 \times 10^9/L$ . Severe thrombocytopenia is usual but not invariable. Frequently, blast cells are seen in the blood film, but sometimes the blast cells may be infrequent or absent. A bone marrow examination will confirm the diagnosis. The bone marrow is usually hypercellular, with replacement of normal elements by leukaemic blast cells in varying degrees (but more than 20% of the cells) (Fig. 25.25). The presence of Auer rods in the cytoplasm of blast cells indicates a myeloblastic type of leukaemia. Classification and prognosis are determined by immunophenotyping and chromosome and molecular analysis, as shown in Fig. 25.26.

### Management

Ideally, whenever possible, patients with acute leukaemia should be treated within a clinical trial. If a decision to embark on specific therapy has been taken, the patient should be prepared as recommended in Box 25.46. It is unwise to attempt aggressive management of acute leukaemia unless adequate supportive therapy can be provided.

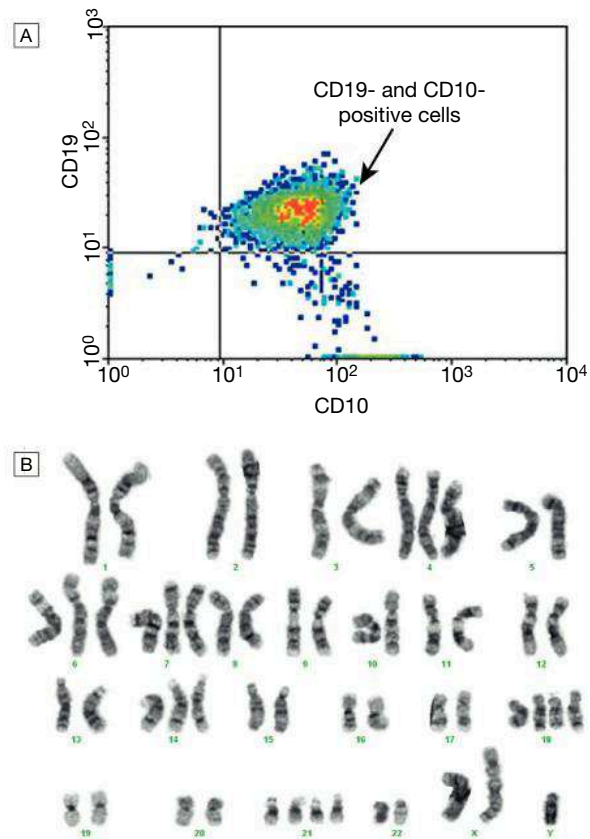

The aim of treatment is to destroy the leukaemic clone of cells without destroying the residual normal stem cell compartment from which repopulation of the haematopoietic tissues will occur. The detail of the schedules for treatments can be found in specialist texts. The drugs most commonly employed are listed in Box 25.47. Generally, if a patient fails to go into remission with induction treatment, alternative drug combinations may be tried, but the outlook is poor unless remission can be achieved. Disease that relapses during treatment or soon after the end of treatment, including after HSCT, carries a poor prognosis and is difficult to treat. The longer after the end of treatment that relapse occurs, the more likely it is that further treatment will be effective. In some patients, alternative palliative chemotherapy, not designed to achieve remission, may be used to curb excessive leucocyte proliferation. Drugs used for this purpose include hydroxycarbamide and mercaptopurine. The aim is to reduce the blast count without inducing bone marrow failure.

### Specific therapy

**Acute myeloid leukaemia (AML)** AML is predominantly a disease of those in old age and many patients are frail. Treatment has become more complex in the recent years and is increasingly tailor-made for AML subgroups defined by genetic abnormalities or persistence of measurable residual disease (MRD). The first decision must be whether or not to give specific treatment to attempt to achieve remission. The most effective remission induction therapy is based around intensive combination chemotherapy. This is generally aggressive, has numerous side-effects and may not be appropriate for the very old or patients with serious comorbidities. In these patients, supportive treatment can effect considerable improvement in well-being, but there remains considerable unmet need. Low-intensity chemotherapy, such as low-dose cytosine arabinoside or azacitidine, is frequently used in older and frailer patients, but this induces remission in less than 20% of patients. Recently, the addition of the BCL-2 inhibitor venetoclax to cytosine and azacitidine has shown improved overall survival, especially the combination with azacitidine (Fig. 25.27).

**Fig. 25.25 Acute myeloid leukaemia.** Bone marrow aspirate showing infiltration with large blast cells, which display nuclear folding and prominent nucleoli.

**Fig. 25.26 Investigation of acute lymphoblastic leukaemia (ALL).** **A** Flow cytometric analysis of blasts labelled with the fluorescent antibodies anti-CD19 (y axis) and anti-CD10 (x axis). ALL blasts are positive for both CD19 and CD10 (arrow). **B** Chromosome analysis (karyotype) of blasts showing additional chromosomes X, 4, 6, 7, 14, 18 and 21.

There are currently three phases of specific treatment for AML:

- **Remission induction.** In this phase, a fraction of the tumour is killed by combinations of chemotherapy drugs. The standard of care for remission induction in AML is daunorubicin with cytosine arabinoside given for 7–10 days in two cycles. Patients with a good or standard risk karyotype, including normal karyotype, benefit from the addition of the antibody-drug conjugate gemtuzumab ozogamicin which targets CD33 on the AML cell and delivers the DNA damaging drug calicheamicin directly into the cell (see Fig. 25.27), while AML with the *FLT3-ITD* mutation benefits from the addition of the

### 25.46 Preparation for specific therapy in acute leukaemia

- Existing infections identified and treated (e.g. urinary tract infection, oral candidiasis, dental, gingival and skin infections)
- Screen for COVID-19
- Anaemia corrected by red cell concentrate transfusion
- Thrombocytopenic bleeding controlled by platelet transfusions
- If possible, central venous catheter (e.g. Hickman line) inserted to facilitate access to the circulation for delivery of chemotherapy, fluids, blood products and other supportive drugs
- Tumour lysis risk assessed and prevention started: fluids with allopurinol or rasburicase
- Therapeutic regimen carefully explained to the patient and informed consent obtained
- Consideration of entry into clinical trial

### 25.47 Drugs commonly used in the treatment of acute leukaemia

Phase	Acute lymphoblastic leukaemia	Acute myeloid leukaemia
<b>Induction</b>	Vincristine (IV) Prednisolone (oral) L-Asparaginase (IM) Daunorubicin (IV) Methotrexate (intrathecal) Imatinib (oral)*	Daunorubicin (IV) Cytarabine (IV) Etoposide (IV and oral) Gentuzumab ozogamicin (IV) All- <i>trans</i> retinoic acid (ATRA) (oral) Arsenic trioxide (ATO) (IV)
<b>Consolidation</b>	Daunorubicin (IV) Cytarabine (IV) Etoposide (IV) Methotrexate (IV) Imatinib (oral)*	Cytarabine (IV) Amsacrine (IV) Mitoxantrone (IV)
<b>Maintenance</b>	Prednisolone (oral) Vincristine (IV) Mercaptopurine (oral) Methotrexate (oral) Imatinib (oral)*	
<b>Relapse</b>	Fludarabine (IV) Cytarabine (IV) Idarubicin (IV)	Fludarabine (IV) Cytarabine (IV) Arsenic trioxide (ATO) (IV) Idarubicin (IV)

\*If Philadelphia chromosome-positive.  
(IM = intramuscular; IV = intravenous)

FLT3 inhibitor midostaurin (see Fig. 25.27). The patient goes through a period of severe bone marrow hypoplasia lasting 3–4 weeks and requires intensive support and inpatient care from a specially trained multidisciplinary team. The aim is to achieve remission, a state in which the blood counts return to normal and the marrow blast count is less than 5%. Quality of life is highly dependent on achieving remission, hence remission induction is the preferred therapy for all patients who are considered fit enough to undergo such treatment.

- **Remission consolidation.** If remission has been achieved, residual disease is attacked by therapy during the consolidation phase. This consists of a number of courses of chemotherapy, most commonly 1–2 courses of high-dose cytosine arabinoside, again resulting in periods of marrow hypoplasia. In poor-prognosis AML, defined by poor risk cytogenetic/molecular genetic abnormalities or persistent MRD, this may include allogeneic HSCT.
- **Remission maintenance.** Maintenance therapy has only recently become an effective tool for some patients with AML compared to its long-established role in ALL. Patients not undergoing allogeneic HSCT with *FLT3* mutated AML receive one year of maintenance with midostaurin and other patients may benefit from azacitidine.

**Fig. 25.27 Targeted therapies for acute myeloid leukaemia (AML).** Small molecule midostaurin inhibits mutant FLT3 molecules and is used in combination with chemotherapy. Gilteritinib inhibits mutant FLT3 and is used on its own for relapsed patients. Venetoclax inhibits BCL-2 and so induces apoptosis; it is used with the drug azacitidine in older, frailer patients. Gentuzumab ozogamicin is a conjugate of an antibody and a chemotherapy agent. The antibody binds to CD33 on the cell surface; antibody and CD33 are internalised and the chemotherapy agent calicheamicin causes DNA damage. (BCL-2 = B-cell lymphoma 2; FLT-3 = FMS-like tyrosine kinase)

Relapsed AML carries a poor prognosis. Increasingly, this is prevented by monitoring MRD and intervening before haematological relapse occurs. However, the aim is to attempt to achieve further remission and deliver an allogeneic HSCT, if possible.

**Acute promyelocytic leukaemia (APML)** A subtype of AML, called acute promyelocytic leukaemia (APML), is characterised by a block in differentiation of malignant promyelocytes. These cells accumulate and lead to bone marrow failure and a tendency to severe bleeding, including into the CNS, because of enhanced fibrinolysis and DIC induced by the procoagulant proteins in the malignant cells, e.g. tPA and uPA. This leukaemia is caused by a translocation of genes on chromosomes 15 (*PML*) and 17 (*RARA*) producing the *PML-RARA* rearrangement which drives the leukaemia. APML carries the best prognosis of all AML if the patient survives the initial bleeding risk. Furthermore, low risk cases can be treated with a non-chemotherapy regimen of differentiation therapy with all-*trans*-retinoic acid (ATRA) and arsenic trioxide (ATO). Higher-risk patients are treated with ATRA and anthracycline-based chemotherapy. The prognosis is excellent with 90% cure rate for patients receiving treatment. However, the early death rate from bleeding remains problematic and intensive supportive care and immediate introduction of ATRA therapy is vital to prevent this.

**Acute lymphoblastic leukaemia (ALL)** This is predominantly a disease of childhood with a mean age of 2–4 years. However, it also occurs in adulthood where it is more difficult to treat and carries a poorer prognosis. Once again there are three phases of therapy with treatment tailor-made to risk groups based on genetic abnormalities and levels of MRD:

- **Remission induction** – As with AML the aim is to achieve remission using a combination of chemotherapy drugs given over a 4-week period. The drugs commonly used are dexamethasone, vincristine, anthracyclines, methotrexate, mercaptopurine and asparaginase. Induction therapy in ALL is often less damaging and better tolerated than AML, however, the high dosage of steroids coupled with neutropenia carries a high risk of infections, including fungal

**Fig. 25.28 Targeted therapies for acute lymphoblastic leukaemia (ALL).** Chimeric antigen receptor T (CAR-T) cells and bi-specific T-cell engager (BITE) both promote T-cell killing of the ALL cell. CAR-T as described in Fig. 25.17 and BITE by using an antibody that can simultaneously bind to a leukaemia cell and a T cell to bring them together. TKIs include imatinib, dasatinib and ponatinib. Inotuzumab-ozogamicin is a conjugate of an antibody and a chemotherapy agent. The antibody binds to CD22 on the cell surface; antibody and CD22 are internalised and the chemotherapy agent calicheamicin causes DNA damage. (TKI = tyrosine kinase inhibitor)

infections. Adult patients are more likely to have a poor-risk genetic abnormality. A *BCR-ABL* rearrangement occurs in about 25% of adult patients and TKI therapy, e.g. dasatinib, is included with the chemotherapy (Fig. 25.28). Once again, old and frail patients tolerate treatment much less well and treatment is modified accordingly. Adolescent and young adult patients require special support and have been shown to do better with children's protocols than adult protocols.

- **Remission consolidation** – The consolidation phase builds on the remission by further decreasing the leukaemic burden. The intensity of consolidation depends on the level of MRD at the end of remission induction and includes blocks of chemotherapy drugs. Allogeneic HSCT is used as consolidation for fit adults with ALL and a suitable donor, but rarely in children unless they relapse.
- **Remission maintenance** – If the patient is still in remission after the consolidation phase for ALL, a period of maintenance therapy is given, with the individual as an outpatient and treatment consisting of a repeating cycle of drug administration. This may extend for up to 3 years if relapse does not occur. In ALL prophylactic treatment to the central nervous system is required, as this is a sanctuary site where standard therapy does not penetrate. This usually consists of a combination of cranial irradiation, intrathecal chemotherapy and high-dose methotrexate, which crosses the blood–brain barrier. Such therapy is integrated into the induction, remission and consolidation phases of therapy

Relapsed ALL is a complex area and ranges from positive MRD, isolated CNS or testicular relapse to full blown haematological relapse. The aim is once again to achieve further remission and frequently to deliver allogeneic HSCT. Newer therapies for relapse include blinatumomab, a bi-specific antibody against CD19 and CD3 to promote T-cell killing (BITE – bi-specific T-cell engager), inotuzumab ozogamicin (which targets CD22 and delivers calicheamicin directly into the cell; see Fig. 25.28), nelarabine in T-cell ALL and CAR-T-cell therapy (see Fig. 25.17). Some long-term cures have been achieved with these therapies.

### Supportive therapy

Aggressive and potentially curative therapy, which involves periods of severe bone marrow failure, would not be possible without appropriate supportive care. The following problems commonly arise.

**Anaemia** Anaemia is treated with red cell concentrate transfusions.

**Bleeding** Thrombocytopenic bleeding requires platelet transfusions, unless the bleeding is trivial. Recent trials have confirmed that in acute leukaemia prophylactic platelet transfusion should be given to maintain the platelet count above  $10 \times 10^9/L$ . Coagulation abnormalities occur and need accurate diagnosis and treatment, especially in APML (see above).

**Infection** So-called neutropenic sepsis is a major complication of acute leukaemia and its treatment. Every leukaemia centre will have a written definition and management policy for this common event. UK NICE guidelines define neutropenic sepsis as fever ( $>38^\circ C$ ) lasting over 1 hour in a neutropenic patient (neutrophils  $<0.5 \times 10^9/l$ ) or with other signs or symptoms of significant sepsis (see also p. 198). Parenteral broad-spectrum antibiotic therapy is essential. Empirical therapy is given according to the perceived severity of the sepsis illness and local bacteriological resistance patterns. Increasingly, low-risk cases of neutropenic sepsis are treated with single antibiotics, e.g. piperacillin/tazobactam. Higher-risk cases are managed with regimens such as a combination of an aminoglycoside (e.g. gentamicin) and a broad-spectrum penicillin (e.g. piperacillin/tazobactam) or a single-agent beta-lactam (e.g. meropenem). The organisms most commonly associated with severe neutropenic sepsis are Gram-positive bacteria, such as *Staphylococcus aureus* and *Staphylococcus epidermidis*, which are present on the skin and gain entry via cannulae and central lines. Gram-negative infections often originate from the gastrointestinal tract, which is affected by chemotherapy-induced mucositis; organisms such as *Escherichia coli*, *Pseudomonas* and *Klebsiella* spp. are likely to cause rapid clinical deterioration and must be covered with initially empirical antibiotic therapy. Gram-positive infection may require vancomycin or teicoplanin therapy. If fever has not resolved after 3–5 days and there is evidence for a disseminated fungal infection on CT scans or sensitive blood tests, empirical antifungal therapy (e.g. a liposomal amphotericin B preparation, voriconazole or caspofungin) is added.

Patients with ALL are susceptible to infection with *Pneumocystis jirovecii* (Ch. 14), which causes a severe pneumonia. Prophylaxis with co-trimoxazole is given during chemotherapy. Diagnosis may require either induced sputum, bronchoalveolar lavage or open lung biopsy. Treatment is with high-dose co-trimoxazole, initially intravenously, changing to oral treatment as soon as possible.

Oral and pharyngeal *Candida* infection is common. Fluconazole is effective for the treatment of established local infection and for prophylaxis against systemic candidaemia. Prophylaxis against other systemic fungal infections including *Aspergillus*, for example itraconazole or posaconazole, is usual practice during high-risk intensive chemotherapy. This is often used along with sensitive markers of early fungal infection to guide treatment initiation (a 'pre-emptive approach').

For systemic fungal infection with *Candida* or aspergillosis, intravenous liposomal amphotericin, caspofungin or voriconazole is required for up to 3 weeks. In systemic *Candida* infection intravenous catheters should be removed.

Reactivation of herpes simplex infection (Ch. 13) occurs frequently around the lips and nose during ablative therapy for acute leukaemia, and is treated with aciclovir. This may also be prescribed prophylactically to patients with a history of cold sores or elevated antibody titres to herpes simplex. Herpes zoster manifesting as chickenpox or, after reactivation, as shingles (Ch. 13) should be treated in the early stage with high-dose aciclovir, as it can be fatal in immunocompromised patients.

The value of isolation facilities, such as laminar flow rooms, is debatable but may contribute to staff awareness of careful reverse barrier nursing practice. The isolation can be psychologically stressful for the patient.

**Metabolic problems** Frequent monitoring of fluid balance and renal, hepatic and haemostatic function is necessary. Patients are often severely anorexic and diarrhoea is common as a consequence of the side-effects of therapy; they may find drinking difficult and hence require intravenous fluids and electrolytes. Renal toxicity occurs with some antibiotics (e.g. aminoglycosides) and antifungal agents (amphotericin). Cellular breakdown during induction therapy (tumour lysis syndrome; p. 142) releases intracellular ions and nucleic acid breakdown products, causing hyperkalaemia, hyperuricaemia, hyperphosphataemia and hypocalcaemia. This may lead to renal failure. Allopurinol and intravenous hydration are given to try to prevent this. In patients at high risk of tumour lysis syndrome, e.g. acute leukaemia with a white cell count of more than  $100 \times 10^9/L$ , prophylactic rasburicase (a recombinant urate oxidase enzyme) is used. Occasionally, dialysis may be required.

**Psychological problems** Psychological support is a key aspect of care. Patients should be kept informed, and their questions answered and fears allayed as far as possible. A multidisciplinary approach to patient care involves input from many services, including psychology. Key members of the team include haematology specialist nurses, who are often the central point of contact for patients and families throughout the illness.

### Haematopoietic stem cell transplantation (HSCT)

This is described on page 945. In patients with high-risk acute leukaemia, allogeneic HSCT can improve 5-year survival from 20% to around 50%. Reduced-intensity conditioning has allowed HSCT to be delivered to a higher proportion of patients with acute leukaemias, up to the age of about 65 years. Improved knowledge of the biology of leukaemia alters the definition of high risk. For example, patients with AML with a normal karyotype and isolated *NPM1* gene mutations are considered good risk and are not routinely transplanted in first remission. However, otherwise similar patients with isolated *FLT3-ITD* mutations are poor risk and considered for transplant in first remission.

### Prognosis

Without treatment, the median survival of patients with acute leukaemia is about 5 weeks. This may be extended to a number of months with supportive treatment. Patients who achieve remission with specific therapy have a better outlook. Around 80% of adult patients under 60 years of age with ALL or AML achieve remission, although remission rates are lower for older patients. However, the relapse rate continues to be high. Box 25.48 shows the survival in ALL and AML and the influence of prognostic features. The level of detectable leukaemia cells after induction therapy, called measurable residual disease (MRD), can be a powerful prognostic tool and is now used routinely in some forms of acute leukaemia (e.g. ALL and AML with *NPM1* mutation) to determine subsequent consolidation therapy.

Advances in treatment have led to steady improvement in survival from acute leukaemia. Some 90% of children with ALL are cured and about 50% of adults aged less than 60 years are cured from AML. As discussed above, APML has a 90% cure rate. Prognosis remains poor in most other groups of patients with acute leukaemias, especially in old age. Current trials aim to improve survival, especially in standard and poor-risk disease, with strategies that include better use of allogeneic HSCT, better ability to predict relapse using MRD and new targeted therapies (see Figs. 25.27 and 25.28).

## Chronic myeloid leukaemia

Chronic myeloid leukaemia (CML) is a myeloproliferative stem cell disorder resulting in proliferation of all haematopoietic lineages, but manifesting predominantly in the granulocytic series. Maturation of cells proceeds fairly normally. The disease occurs chiefly between the ages of 30 and 80 years, with a peak incidence at 55 years. It is rare, with an annual incidence in the UK of 1.8/100 000, and accounts for 15% of all leukaemias. It is found in all races.

### 25.48 Outcome in adult acute leukaemia

Disease/risk	Risk factors	5-year overall survival
<b>Acute myeloid leukaemia (AML)</b>		
Good risk	Promyelocytic leukaemia t(15;17) t(8;21) inv(16) or t(16;16)	90% 65% 70%
Poor risk	Cytogenetic abnormalities -5, -7, del 5q, abn(3q), complex (>5)	21%
Intermediate risk	AML with none of the above	48%
<b>Acute lymphoblastic leukaemia (ALL)</b>		
Poor risk	Philadelphia chromosome High white count $>100 \times 10^9/L$ Abnormal short arm of chromosome 11 t(1;19)	20%
Standard	ALL with none of the above	37%

The defining characteristic of CML is the chromosome abnormality known as the Philadelphia (Ph) chromosome. This is a shortened chromosome 22 resulting from a reciprocal translocation of material with chromosome 9. The break on chromosome 22 occurs in the break-point cluster region (BCR). The fragment from chromosome 9 that joins the BCR carries the *abl* oncogene, which forms a fusion gene with the remains of the BCR. This *BCR-ABL* fusion gene codes for a 210kDa protein with tyrosine kinase activity, which plays a causative role in the disease as an oncogene (p. 132), influencing cellular proliferation, differentiation and survival and is a target for very effective tyrosine kinase inhibitor (TKI) therapy (Fig. 25.29 and see Box 25.21). In some patients in whom conventional chromosomal analysis does not detect a Ph chromosome, the BCR-ABL gene product is detectable by molecular techniques.

### Natural history

The disease has three phases:

- A *chronic phase*, in which the disease is responsive to treatment and is easily controlled, which used to last 3–5 years. With the introduction of the tyrosine kinase inhibitors (TKI) (Box 25.49), this phase has been prolonged to encompass a normal life expectancy in many patients.
- An *accelerated phase* (not always seen), in which disease control becomes more difficult.
- *Blast crisis*, in which the disease transforms into an acute leukaemia, either myeloblastic (70%) or lymphoblastic (30%), which is relatively refractory to treatment. This is the cause of death in the majority of patients; survival is therefore dictated by the timing of blast crisis, which cannot be predicted. Prior to TKI therapy (see below), approximately 10% of patients per year would transform; the transformation rate has been reduced to 0.5%–2.5% per year with TKI therapy.

### Clinical features

Symptoms at presentation may include lethargy, weight loss, abdominal discomfort, gout and sweating, but about 25% of patients are asymptomatic at diagnosis. Splenomegaly is present in 90%; in about 10% the enlargement is massive, extending to over 15 cm below the costal margin. A friction rub may be heard in cases of splenic infarction. Hepatomegaly occurs in about 50%. Lymphadenopathy is unusual.

### Investigations

FBC results are variable between patients. There is usually a normocytic, normochromic anaemia. The leucocyte count can vary from 10 to  $600 \times 10^9/L$ . In about one-third of patients, there is a very high platelet

**Fig. 25.29** Mode of action in tyrosine kinase inhibition of BCR-ABL.

**A** Untreated CML. The BCR-ABL protein acts as 'rogue' tyrosine kinase. It phosphorylates tyrosine residues on substrate molecules, and hence activates these molecules, by transferring phosphate groups from ATP. In turn these molecules activate down-stream effector molecules that cause CML. **B** Tyrosine kinase inhibitor (TKI) treatment (imatinib, dasatinib, nilotinib, ponatinib, bosutinib). These molecules bind to the tyrosine kinase domain of BCR-ABL and block the phosphorylation process and hence inhibit the downstream effector pathways, so reversing the process causing CML. (CML = chronic myeloid leukaemia)

count, sometimes as high as  $2000 \times 10^9/L$ . In the blood film, the full range of granulocyte precursors, from myeloblasts to mature neutrophils, is seen but the predominant cells are neutrophils and myelocytes (see Fig. 25.3). Myeloblasts usually constitute less than 10% of all white cells. There is often an absolute increase in eosinophils and basophils,

## 25.49 Tyrosine kinase inhibition in chronic myeloid leukaemia

### Agents

#### First-line

- Imatinib
- Nilotinib
- Dasatinib

#### Second-line

- Imatinib
- Nilotinib
- Dasatinib
- Bosutinib
- Ponatinib\*

### Outcomes

- 90% achieve complete cytogenetic response
- Responses faster with nilotinib and dasatinib
- Median survival comparable to normal population

\*For patients with T315I kinase domain mutations use ponatinib.

and nucleated red cells are common. If the disease progresses through an accelerated phase, the percentage of more primitive cells increases. Blast transformation is characterised by a dramatic increase in the number of circulating blasts. In patients with thrombocytosis, very high platelet counts may persist during treatment, in both chronic and accelerated phases, but usually drop dramatically at blast transformation. Basophilia tends to increase as the disease progresses.

Bone marrow should be obtained to confirm the diagnosis and phase of disease by morphology, chromosome analysis to demonstrate the presence of the Ph chromosome, and RNA analysis to demonstrate the presence of the BCR-ABL gene product. Blood LDH is elevated and uric acid may be high due to increased cell breakdown.

## Management

### Chronic phase

There are now five available tyrosine kinase inhibitors (TKIs) for the treatment of CML (see Box 25.49). These specifically inhibit BCR-ABL tyrosine kinase activity. Imatinib, nilotinib and dasatinib are recommended as first-line therapy in chronic phase CML; they usually normalise the blood count within a month and within 3–6 months produce complete cytogenetic response (disappearance of the Ph chromosome) in some 90% of patients. Patients are monitored by 3-monthly real-time quantitative polymerase chain reaction (PCR) for BCR-ABL mRNA transcripts in blood. The aim is to reduce the BCR-ABL transcript levels by 3–5 logs from baseline and this is called major molecular response (MR3–MR5). A proportion of patients achieve a complete molecular response where the transcripts are not detectable by PCR. Up to 50% of patients with a complete or major molecular response may be able to discontinue TKI therapy. For those failing to respond or who lose their response and progress on first-line therapy, options include switching to a different TKI (see Box 25.49). Some patients develop detectable mutations in the BCR-ABL gene, which causes resistance to one or more of the TKIs. The T315I mutation is particularly problematic as this causes wide-ranging resistance, but the third-generation TKI ponatinib can be effective. Allogeneic HSCT (p. 945) is now reserved for patients who fail TKI therapy. Hydroxycarbamide and interferon were previously used for control of disease. Hydroxycarbamide is still useful in palliative situations and interferon is used in women planning pregnancy.

### Accelerated phase and blast crisis

Management is more difficult. For patients in accelerated phase, TKI therapy is indicated, most commonly with nilotinib or dasatinib. When blast transformation occurs, the type of blast cell should be determined. Response to appropriate acute leukaemia treatment (see Box 25.49) is better if disease is lymphoblastic rather than myeloblastic. Second- or third-generation TKIs such as dasatinib are used in combination with chemotherapy to try to achieve remission. In younger and fitter patients

**Fig. 25.30 Targeted therapies for chronic lymphocytic leukaemia (CLL).** CLL cells are 'addicted' to stimulation of the B-cell receptor (BCR), which is surface immunoglobulin. This pathway can now be inhibited by drugs that block the downstream effector pathways of BCR involving BTK and PI3K molecules. CLL cells also depend on anti-apoptosis signals, especially increased BCL-2. Venetoclax inhibits BCL-2 and induces apoptosis. The anti-CD20 'naked' antibodies are used with chemotherapy to enhance CLL cell killing. (BCR = B-cell receptor; BTK = Bruton's tyrosine kinase; PI3K = phosphatidylinositol-3-kinase)

an allogeneic HSCT is appropriate therapy if a return to chronic phase is achieved. Hydroxycarbamide can be an effective single agent and low-dose cytarabine can also be used palliatively in older patients.

## Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is the most common variety of leukaemia, accounting for 30% of cases. The male-to-female ratio is 2:1 and the median age at presentation is 65–70 years. CLL is characterised by the clonal expansion of small mature-looking B cells. Failure to apoptose because of overexpression of BCL-2 and in some cases mutations in *TP53* leads to an ever-increasing accumulation of immuno-incompetent leukaemic B cells. This is to the detriment of immune function and normal bone marrow haematopoiesis. CLL cells are dependent on abnormal and persistent signalling through the B-cell receptor (BCR) pathway. Drugs that can inhibit these pathways are now available and show great promise (Fig. 25.30).

### Clinical features

The onset is usually insidious. Indeed, in around 70% of patients the diagnosis is made incidentally on a routine FBC. Presenting problems may be anaemia, infections, painless lymphadenopathy, and systemic symptoms such as night sweats or weight loss; these more often occur later in the course of the disease or in disease that is advanced at presentation.

### Investigations

The diagnosis is based on the peripheral blood findings of a mature lymphocytosis ( $>5 \times 10^9/L$ ) with characteristic morphology and cell surface markers. Immunophenotyping reveals the lymphocytes to be monoclonal B cells expressing the B-cell antigens CD19 and CD23, with either kappa or lambda immunoglobulin light chains and, characteristically, an aberrant T-cell antigen CD5. On flow cytometry, some people are shown to have circulating CLL cells at a level less than  $5 \times 10^9/L$ . This is known

## 25.50 Staging of chronic lymphocytic leukaemia

### Clinical stage A (60% patients)

- No anaemia or thrombocytopenia and fewer than three areas of lymphoid enlargement

### Clinical stage B (30% patients)

- No anaemia or thrombocytopenia, with three or more involved areas of lymphoid enlargement

### Clinical stage C (10% patients)

- Anaemia and/or thrombocytopenia, regardless of the number of areas of lymphoid enlargement

as monoclonal B lymphocytosis of uncertain significance (MBL). Such patients progress to CLL at a rate of 1% per year.

Other useful investigations in CLL include a reticulocyte count and a direct Coombs test, as autoimmune haemolytic anaemia may occur (p. 958). Serum immunoglobulin levels should be estimated to establish the degree of hypogammaglobulinaemia, which is common and progressive. Bone marrow examination by aspirate and trephine is not essential for the diagnosis of CLL, but may be helpful in difficult cases, for prognosis (patients with diffuse marrow involvement have a poorer prognosis) and to monitor response to therapy. The main prognostic factor is stage of disease (Box 25.50); however, loss of chromosome 17p or mutation in the *TP53* gene, which resides at this genetic locus, is a powerful prognostic marker of poor outcome and predictor of response to therapy. A mutation in *TP53* is present in <10% of patients at presentation, but rises to 30% of cases at relapse. This test should be performed in all patients prior to the initiation of therapy.

### Management

No specific treatment is required for most clinical stage A patients, unless progression occurs. The patient should be offered clear information about CLL and be reassured about the indolent nature of the disease, as the diagnosis of leukaemia inevitably causes anxiety.

Treatment is required only if there is evidence of bone marrow failure, massive or progressive lymphadenopathy or splenomegaly, systemic symptoms such as weight loss or night sweats, a rapidly increasing lymphocyte count, autoimmune haemolytic anaemia or thrombocytopenia. Initial therapy for those requiring treatment (progressive stage A and stages B and C) is based on the age and fitness of the patient and the *TP53* mutation status. For patients who are under 70 years, fit and *TP53* mutation-negative, fludarabine in combination with the alkylating agent cyclophosphamide and the anti-CD20 monoclonal antibody rituximab (FCR) is standard care. For older, less fit patients, rituximab is combined with gentler chemotherapy: bendamustine or oral chlorambucil. A more potent anti-CD20 antibody, obinotuzumab, produces better responses in combination with chlorambucil than rituximab.

Ibrutinib inhibits Bruton's tyrosine kinase and idelalisib inhibits PI3 kinase, both components of the BCR pathway (see Fig. 25.30). Ibrutinib and idelalisib are licensed for relapsed CLL, but are effective in *TP53*-mutated disease at all stages. Ibrutinib is first-line standard of care in *TP53*-mutated CLL. CLL cells are resistant to apoptosis and express increased levels of anti-apoptotic proteins, including BCL-2. Venetoclax is an inhibitor of BCL-2 and is so effective at killing CLL cells that it frequently causes tumour lysis syndrome when first administered. Venetoclax is licensed in combination with obinotuzumab for the treatment of adult patients with previously untreated CLL and is attractive as it is given for a fixed period of two years. Venetoclax can also be used for patients with *TP53* mutation or who have failed previous therapy. Bone marrow failure or autoimmune cytopenias may respond to glucocorticoid treatment or rituximab.

Supportive care is increasingly required in progressive disease, such as transfusions for symptomatic anaemia or thrombocytopenia, prompt treatment of infections and, for some patients with

hypogammaglobulinaemia, immunoglobulin replacement. Radiotherapy may be used for lymphadenopathy that is causing discomfort or local obstruction and for symptomatic splenomegaly. Splenectomy may be required to improve low blood counts due to autoimmune destruction or to hypersplenism and can relieve massive splenomegaly.

### Prognosis

The majority of clinical stage A patients have a normal life expectancy, but patients with advanced CLL are more likely to die from their disease or infectious complications. Survival is influenced by other prognostic features of the leukaemia, particularly *TP53* mutation status, and traditionally whether patients can tolerate and respond to fludarabine-based treatment. In those able to be treated with chemotherapy and rituximab, 90% are alive 4 years later. The newer agents may replace and surpass immunochemotherapy as first-line therapy. As in other haematological malignancies the presence of MRD is prognostically important. Ibrutinib and especially venetoclax are more likely to produce an MRD negative state. Rarely, CLL transforms to an aggressive high-grade lymphoma, called Richter's transformation.

## Prolymphocytic leukaemia

Prolymphocytic leukaemia (PLL) is a form of chronic leukaemia found mainly in males over the age of 60 years; 25% of cases are of T cell origin. There is typically massive splenomegaly with little lymphadenopathy and a very high leucocyte count, often in excess of  $400 \times 10^9/L$ . Effusions and involvement of skin are well recognized. The characteristic cell is a large lymphocyte with a prominent nucleolus. Treatment is generally unsuccessful and the prognosis very poor. Leukapheresis, splenectomy and chemotherapy may be tried. The anti-CD52 antibody alemtuzumab, when given intravenously, has produced responses in some 90% of patients with T-PLL. Younger patients who respond to treatment may be considered for allogeneic HSCT.

## Hairy cell leukaemia

This is a rare chronic B-cell lymphoproliferative disorder. The male-to-female ratio is 6:1 and the median age at diagnosis is 50 years. Presenting symptoms are general ill health and recurrent infections. Splenomegaly occurs in 90% but lymph node enlargement is unusual.

Severe neutropenia, monocytopenia and the characteristic hairy cells in the blood and bone marrow are typical. These cells usually have a B-lymphocyte immunotype, but they also characteristically express CD25 and CD103. Recently, all patients with hairy cell leukaemia have been found to have a mutation in the *BRAF* gene and this may become a therapeutic target. Chemotherapy treatments such as cladribine and deoxycoformycin can produce long-lasting remissions.

## Myelodysplastic syndromes

Myelodysplastic syndromes (MDSs) constitute a group of clonal haematopoietic disorders with the common features of ineffective blood cell production and a tendency to progress to AML. As such, they are pre-leukaemic and represent genetic steps in the development of leukaemia. These genetic abnormalities have been identified and are increasingly present with age as a manifestation of clonal haematopoiesis, occurring in about 20% of patients over the age of 80. Blood counts are normal (clonal haematopoiesis of indeterminate potential, CHIP), but there is an increased risk of developing MDS, AML or non-haematological disease such as coronary artery disease. The common CHIP gene mutations include *DNMT3a*, *TET2* and *ASXL1*.

Some 80% of patients with MDS have one or more acquired mutations in specific genes and these are now routinely identified by multi-gene next generation sequencing (NGS) using a so-called 'myeloid gene panel'. Some are associated with specific phenotypes of MDS, e.g. 80% of cases with ring sideroblasts have a mutation in the splice factor gene *SF3B1*. Others have prognostic significance, e.g. *TP53* or two or

### 25.51 WHO classification of myelodysplastic syndromes (MDS)

Disease	Bone marrow findings
MDS with single-lineage dysplasia	<5% blasts and single-lineage dysplasia only
MDS with ring sideroblasts (MDS-RS)	>15% ring sideroblasts, or 6%–14% and presence of <i>SF3B1</i> gene mutation
MDS with multilineage dysplasia	<5% blasts and dysplasia in two or more lineages
MDS with excess blasts	5%–19% blasts
MDS with isolated del(5q)	Myelodysplastic syndrome associated with a del(5q) cytogenetic abnormality <5% blasts Often normal or increased blood platelet count
MDS, unclassifiable	None of the above or inadequate material

more mutations carry a poor prognosis. Chromosome analysis frequently reveals abnormalities, particularly of chromosome 5 or 7.

MDS presents with consequences of bone marrow failure (anaemia, recurrent infections or bleeding), usually in older people (median age at diagnosis is 73 years). The overall incidence is 4/100 000 in the population, rising to more than 30/100 000 in the over-seventies. The blood film is characterised by cytopenias and abnormal-looking (dysplastic) blood cells, including macrocytic red cells and hypogranular neutrophils with nuclear hyper- or hyposegmentation. The bone marrow is hypercellular, with dysplastic changes in at least 10% of cells of one or more cell lines. Blast cells may be increased but do not reach the 20% level that indicates acute leukaemia. The WHO classification of MDS is shown in [Box 25.51](#).

### Prognosis

The natural history of MDS is progressive worsening of dysplasia leading to fatal bone marrow failure or progression to AML in 30% of cases. The time to progression varies (from months to years) with the subtype of MDS, being slowest in MDS with ring sideroblasts and single-lineage dysplasia and most rapid in MDS with excess blasts. The revised International Prognostic Scoring System (IPSS-R) predicts clinical outcome based on karyotype and cytopenias in blood, as well as percentage of bone marrow blasts ([Box 25.52](#)). There are five prognostic groups. The median survival for low-risk patients (IPSS-R very low and low) is 5–9 years, that for the intermediate group is 3 years and that for high-risk patients (IPSS-R high and very high) is 1–1.5 years.

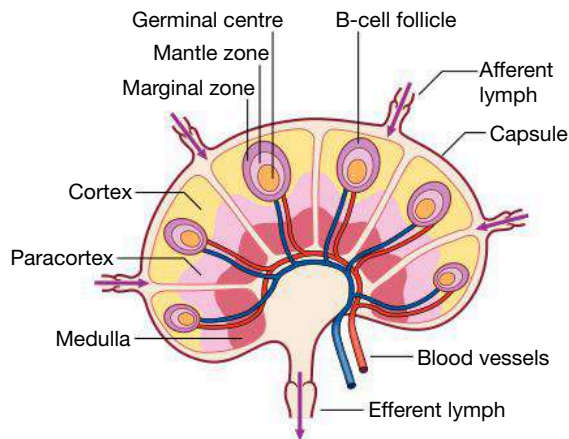

### Management

For the vast majority of patients who are in old age, the disease is incurable, and supportive care with red cell and platelet transfusions is the mainstay of treatment. A trial of erythropoiesis stimulating agents (ESA) is recommended in some patients with low-risk MDS (IPSS-R very low, low and intermediate) to improve haemoglobin. Responders have better quality of life, lower risk of progression to AML and possibly better overall survival. Granulocyte colony stimulating factor (G-CSF) is recommended for short-term use in neutropenic patients with active infection. A rare subtype called MDS with isolated del(5q) responds well to the immunomodulatory drug lenalidomide, with two-thirds of anaemic patients becoming transfusion-independent for up to 2 years. Allogeneic stem cell transplantation may afford a cure in patients with a good performance status and is considered in high-risk patients (IPSS-R high and very high) and some low-risk patients. The hypomethylating agent azacitidine has improved survival by a median of 9 months compared to supportive care or low intensity chemotherapy for high-risk patients, and is a recommended standard of care for those not eligible for transplantation.

### 25.52 Revised International Prognostic Scoring System and outcomes in myelodysplasia\*

Risk category	Overall score	Median survival (years)	25% progression to acute myeloid leukaemia (years)
Very low	≤1.5	8.8	Not reached
Low	>1.5–3	5.3	10.8
Intermediate	>3–4.5	3.0	3.2
High	>4.5–6	1.6	1.4
Very high	>6	0.8	0.73

\*The IPSS-R is based on three prognostic factors: the blast percentage in bone marrow; karyotype; and number and degree of blood cytopenias. A score is derived from which patients can be stratified into five risk categories for survival and leukaemic transformation.

**Fig. 25.31** Schema of lymph node architecture. Different lymphocyte populations reside in different areas of the node: B cells in the follicles, T cells in the paracortex and plasma cells in the medulla. B cells are selected for antigen in the follicle centre. Errors during this process result in B-cell lymphomas, which are by far the most common type.

## Lymphomas

These neoplasms arise from lymphoid tissues and are diagnosed from the pathological findings on biopsy as Hodgkin or non-Hodgkin lymphoma. The majority are of B-cell origin. Non-Hodgkin lymphomas are classified as low- or high-grade tumours on the basis of their proliferation rate. The normal architecture of the lymph node is outlined in Fig. 25.31.

- *High-grade tumours* divide rapidly, are typically present for a matter of weeks before diagnosis, and may be life-threatening with high risk of extranodal involvement.
- *Low-grade tumours* divide slowly, may be present for many months before diagnosis, and typically behave in an indolent fashion.

## Hodgkin lymphoma

The histological hallmark of Hodgkin lymphoma (HL) is the presence of Reed–Sternberg cells: large, malignant lymphoid cells of B-cell origin (Fig. 25.32). They are often present only in small numbers, but are surrounded by large numbers of reactive non-malignant T cells, plasma cells and granulocytes, including eosinophils.

The epidemiology of HL is shown in Box 25.53 and its histological WHO classification in Box 25.54.

**Fig. 25.32** Hodgkin lymphoma. In the centre of this lymph node biopsy is a large typical Reed–Sternberg cell with two nuclei containing a prominent eosinophilic nucleolus.

### 25.53 Epidemiology and aetiology of Hodgkin lymphoma

#### Incidence

- Approximately 4 new cases/100 000 population/year

#### Sex ratio

- Slight male excess (1.5:1)

#### Age

- Median age 31 years; first peak at 20–35 years and second at 50–70 years

#### Aetiology

- Unknown
- More common in patients from well-educated backgrounds and small families
- Three times more likely with a past history of infectious mononucleosis but no definitive causal link to Epstein–Barr virus infection proven

### 25.54 WHO pathological classification of Hodgkin lymphoma (HL)

Type	Histology classification	Proportion of HL
Nodular lymphocyte-predominant HL		5%
Classical HL	Nodular sclerosing	70%
	Mixed cellularity	20%
	Lymphocyte-rich	5%
	Lymphocyte-depleted	Rare

Nodular lymphocyte-predominant HL is slow-growing, localised and rarely fatal. It has biological features, such as CD20-positive Hodgkin cells, and clinical features that make it more akin to a low-grade B-cell non-Hodgkin lymphoma. Classical HL is divided into four histological subtypes from the appearance of the Reed–Sternberg cells and surrounding reactive cells. The nodular sclerosing type is more common in young patients and in women. Mixed cellularity is more common in older patients. Lymphocyte-rich HL usually presents in men. Lymphocyte-depleted HL is rare and probably represents large-cell or anaplastic non-Hodgkin lymphoma.

#### Clinical features

There is painless, rubbery lymphadenopathy, usually in the neck or supraclavicular fossae; the lymph nodes may fluctuate in size. Young patients with nodular sclerosing disease may have large mediastinal masses that are surprisingly asymptomatic, but may cause dry cough and some

25.55 Clinical stages of Hodgkin lymphoma (Ann Arbor classification)	
Stage	Definition
I	Involvement of a single lymph node region (I) or extralymphatic* site (I <sub>e</sub> )
II	Involvement of two or more lymph node regions (II) or an extralymphatic site and lymph node regions on the same side of (above or below) the diaphragm (II <sub>e</sub> )
III	Involvement of lymph node regions on both sides of the diaphragm with (III <sub>e</sub> ) or without (III) localised extralymphatic involvement or involvement of the spleen (III <sub>s</sub> ), or both (III <sub>se</sub> )
IV	Diffuse involvement of one or more extralymphatic tissues, e.g. liver or bone marrow
Each stage is subclassified	
A	No systemic symptoms
B	Weight loss >10%, drenching sweats, fever
*The lymphatic structures are defined as the lymph nodes, spleen, thymus, Waldeyer's ring, appendix and Peyer's patches.	

breathlessness. Isolated subdiaphragmatic nodes occur in fewer than 10% at diagnosis. Hepatosplenomegaly may be present, but does not always indicate disease in those organs. Spread is contiguous from one node to the next, and extranodal disease, such as bone, brain or skin involvement, is rare. Systemic symptoms include so-called 'B symptoms' of drenching night sweats, fever and loss of 10% body weight. Other symptoms can include pruritis and rarely, but dramatically, alcohol-induced pain within lymph nodes.

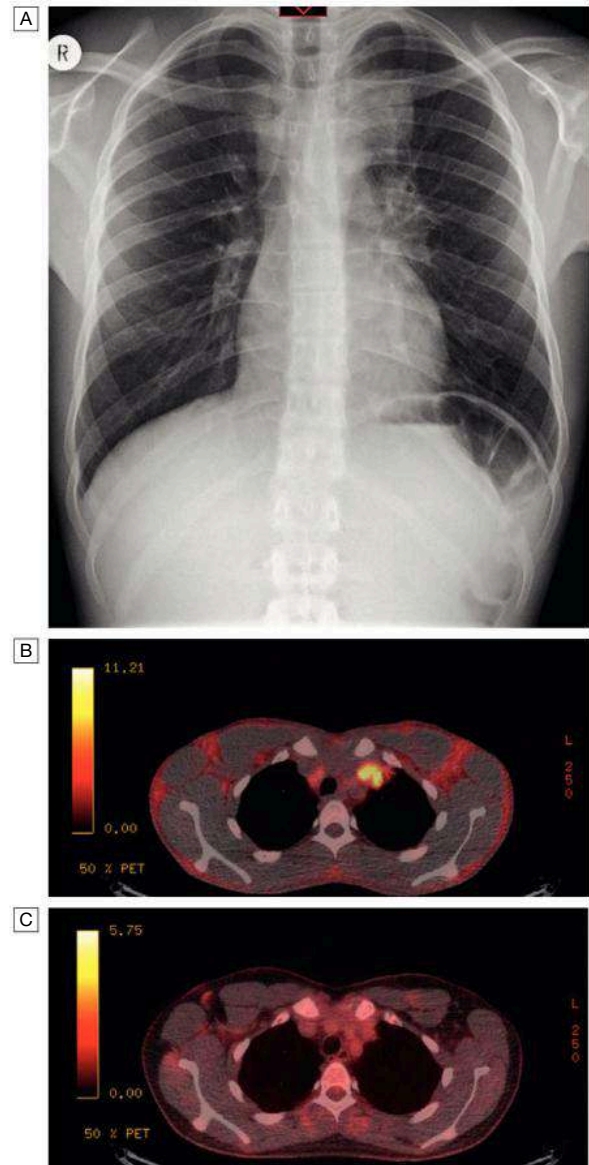

### Investigations

Treatment of HL depends on the stage at presentation; investigations therefore aim not only to diagnose lymphoma, but also to determine the extent of disease (Box 25.55).

- *FBC* may be normal. If a normochromic, normocytic anaemia or lymphopenia is present, this is a poor prognostic factor, particularly in advanced disease. An eosinophilia, neutrophilia or thrombocytosis may be present.
- *ESR* may be raised and is an adverse prognostic factor.
- *Renal function tests* are required to ensure function is normal prior to treatment.
- *Liver function* may be abnormal in the absence of disease or may reflect hepatic infiltration. An obstructive pattern may be caused by nodes at the porta hepatis.
- *LDH* may be raised and is an adverse prognostic factor.
- *Chest X-ray* may show a mediastinal mass.
- *CT scan* of chest, abdomen and pelvis permits staging. Bulky disease (>10 cm in a single node mass) is an adverse prognostic feature.
- *Positron emission tomography-CT (PET-CT) scanning* identifies nodes involved with HL that are <sup>18</sup>fluorodeoxyglucose (FDG)-avid and this allows more accurate staging and monitoring of response (Fig. 25.33).
- *Lymph node biopsy* may be undertaken surgically or by percutaneous needle biopsy under radiological guidance (Fig. 25.34).

### Management

Given the high cure rate and excellent prognosis of a majority of young and middle-aged patients with HL, the aim is to maximize cure rates while minimising long-term treatment-related toxicity. Treatment approaches involve defining patients as early-stage disease (stages IA and IIA) or advanced stage disease (IB, IIB, III and IV). The ABVD regimen (doxorubicin (adriamycin), bleomycin, vinblastine and dacarbazine) is widely

**Fig. 25.33** Positron emission tomography (PET) scans in Hodgkin lymphoma, demonstrating response to treatment. **A** Chest X-ray from a young man with Hodgkin lymphoma at presentation, showing a left-sided anterior-superior mediastinal mass with tracheal deviation to the right. **B** Fused PET-CT image showing intense fluorodeoxyglucose (FDG) uptake (avidity) in the mass at presentation. **C** Fused PET-CT image showing no FDG uptake (PET negativity), representing complete response at the end of treatment.

used in the UK, while the more intensive BEACOPP regimen (bleomycin, etoposide, doxorubicin (adriamycin), cyclophosphamide, vincristine (oncovin), procarbazine, prednisolone) is a more effective alternative, though with a greater risk of side-effects including infertility and treatment-related MDS and AML.

Standard therapy for early-stage patients without additional risk factors, such as bulky disease or high ESR, is two cycles of ABVD combined with 20 Gy radiotherapy to the involved sites of disease. Standard therapy for early-stage patients with additional risk factors is four cycles of ABVD combined with 30 Gy radiotherapy. Careful planning of radiotherapy is required to limit the doses delivered to normal tissues and new planning techniques continue to improve targeting of radiotherapy. Nevertheless, the long-term risks of second cancers and heart and lung disease within the radiation fields remain a concern, especially for young people with a high cure rate and potentially decades of life ahead of them. Early-stage patients who have a negative FDG PET-CT scan after

**Fig. 25.34** CT-guided percutaneous needle biopsy of retroperitoneal nodes involved by lymphoma.

three or four cycles of combination chemotherapy can safely omit radiotherapy. Young women receiving breast irradiation during the treatment of chest disease have an increased risk of breast cancer and should participate in a breast screening programme. Patients continuing to smoke after lung irradiation are at particular risk of future lung cancer.

ABVD chemotherapy can cause cardiac and pulmonary toxicity, due to doxorubicin and bleomycin, respectively. The incidence of infertility and secondary myelodysplasia/AML is low with this regimen but higher with BEACOPP.

Patients with advanced-stage disease are most commonly managed with chemotherapy alone. Standard treatment in the UK is 6–8 cycles of ABVD, followed by an assessment of response. A negative FDG PET-CT after two cycles of ABVD (interim PET-2 response) predicts a very good outcome from continuing with up to six cycles of ABVD. Indeed, the same outcome can be achieved by omitting the bleomycin from the last four cycles and using just AVD, thus reducing the risk of lung toxicity. Even more impressive results of >90% 5-year progression-free survival can be achieved with just four cycles of BEACOPP if the interim PET-2 scan is negative. Patients who have a positive FDGPET-CT after two cycles, however, have a very high relapse risk if they continue with ABVD, with only 13% being relapse-free at 2 years. Switching to BEACOPP from ABVD or continuing with BEACOPP for six cycles in these patients improves the relapse-free survival to approximately 65%–90%.

Patients with relapsed disease that responds to salvage chemotherapy and ideally becomes FDG PET-CT-negative should be considered for autologous stem cell transplantation (p. 945). Those with resistant disease might benefit from an allogeneic stem cell transplant. Brentuximab vedotin is an antibody–drug conjugate directed against CD30 on the Reed–Sternberg cell surface. This antibody delivers the antimitotic toxin monomethyl auristatin E to the Hodgkin cells and, as a single agent, can produce good responses in patients who have failed, or are not suitable for, an autologous transplant and can be a ‘bridge’ to an allogeneic transplant. Reed–Sternberg cells over-express the cell surface protein Programme Death Ligand 1 (PDL-1). This engages with Programmed Death Protein 1 (PD-1) on T cells and leads to T-cell ‘exhaustion’ (see Fig. 7.12). This ‘immune checkpoint’ is an important survival mechanism for Reed–Sternberg cells. The immunotherapy drugs pembrolizumab and nivolumab can inhibit this ‘checkpoint’ in the immune response and allow T-cell killing of Reed–Sternberg cells. Both drugs are available for patients who have failed multiple lines of treatment and can produce further remissions.

### Prognosis

Over 90% of patients with early-stage HL achieve complete remission when treated with chemotherapy, followed by involved field radiotherapy,

i 25.56 The Hasenclever prognostic index for advanced Hodgkin lymphoma		
Score 1 for each of the following risk factors present at diagnosis:		
<ul style="list-style-type: none"> <li>• Age &gt;45 years</li> <li>• Male gender</li> <li>• Serum albumin &lt;40 g/L</li> <li>• Hb &lt;105 g/L</li> <li>• Stage IV disease</li> <li>• White blood cell count &gt;15 × 10<sup>9</sup>/L</li> <li>• Lymphopenia &lt;0.6 × 10<sup>9</sup>/L</li> </ul>		
Score	5-year rate of freedom from progression (%)	5-year rate of overall survival (%)
0–1	79	90
>2	60	74
>3	55	70
>4	47	59

and the great majority are cured. The major challenge is how to reduce treatment intensity, and hence long-term toxicity, without reducing the excellent cure rates in this group. Omitting radiotherapy in the majority of FDG PET-CT-negative patients is one major step forward in this regard.

Historically, between 50% and 70% of those with advanced-stage HL were cured. The Hasenclever index (Box 25.56) can be helpful in assigning approximate chances of cure when discussing treatment plans with patients. More recent data using FDG PET-CT to direct therapy suggests that long-term survival is improving to beyond 80%. Patients who fail to respond to initial chemotherapy or relapse within a year of initial therapy have a poor prognosis, but some may achieve long-term survival after autologous HSCT. Patients relapsing after 1 year may obtain long-term survival with further chemotherapy alone, but fit patients frequently proceed to autologous HSCT.

### Non-Hodgkin lymphoma

Non-Hodgkin lymphoma (NHL) represents a monoclonal proliferation of lymphoid cells of B-cell (90%) or T-cell (10%) origin. The incidence of these tumours increases with age, to 62.8/million population per annum at age 75 years, and the overall rate is increasing at about 3% per year.

The epidemiology of NHL is shown in Box 25.57. Previous classifications were based principally on histological appearances. The current WHO classification stratifies according to cell lineage (T or B cells) and incorporates clinical features, histology, genetic abnormalities and concepts related to the biology of the lymphoma. Clinically, the most important factor is grade, which is a reflection of proliferation rate. High-grade NHL has high proliferation rates, rapidly produces symptoms, is fatal if untreated, but is potentially curable. Low-grade NHL has low proliferation rates, may be asymptomatic for many months or even years before presentation, runs an indolent course, but is frequently disseminated at diagnosis and not curable by conventional therapy. Of all cases of NHL in the developed world, over 50% are either diffuse large B-cell NHL (high-grade) or follicular NHL (low-grade) (Fig. 25.35). Other forms of NHL, including Burkitt lymphoma, mantle cell lymphoma, mucosa-associated lymphoid tissue (MALT) lymphomas and T-cell lymphomas, are individually less common.

### Clinical features

Unlike Hodgkin lymphoma, NHL is often widely disseminated at presentation, including in extranodal sites. Patients present with lymph node enlargement (Fig. 25.36), which may be associated with systemic upset: weight loss, sweats, fever and itching. Hepatosplenomegaly may be present. Sites of extranodal involvement include the bone marrow, gut, thyroid, lung, skin, testis, brain and, more rarely, bone. Bone marrow involvement is more common in low-grade (50%–60%) than high-grade

### 25.57 Epidemiology and aetiology of non-Hodgkin lymphoma

#### Incidence

- 12 new cases/100 000 people/year

#### Sex ratio

- Slight male excess

#### Age

- Median age 65–70 years

#### Aetiology

- No single causative abnormality described
- Lymphoma is a late manifestation of HIV infection (Ch. 14)
- Specific lymphoma types are associated with viruses: e.g. Epstein–Barr virus (EBV) with post-transplant NHL, human herpesvirus 8 (HHV8) with a primary effusion lymphoma, and human T-cell lymphotropic virus (HTLV-1) with adult T-cell leukaemia lymphoma
- Gastric lymphoma can be associated with *Helicobacter pylori* infection
- Some lymphomas are associated with specific chromosomal translocations:
  - The t(14;18) in follicular lymphoma results in the dysregulated expression of the *BCL-2* gene product, which inhibits apoptotic cell death
  - The t(8;14) found in Burkitt lymphoma and the t(11;14) in mantle cell lymphoma alter function of *c-myc* and *cyclin D1*, respectively, resulting in malignant proliferation
  - Large B-cell lymphomas with rearrangements of *c-myc* with *BCL-2* and/or *BCL-6* (double and triple hit lymphomas)
- Lymphoma occurs in congenital immunodeficiency states and in immunosuppressed patients after organ transplantation

**Fig. 25.36** Bulky axillary lymphadenopathy with distended superficial veins in a patient presenting with high-grade lymphoma. From Howard MR, Hamilton PJ. *Haematology: An illustrated colour text*, 4th edn. Edinburgh: Elsevier Ltd; 2013.

**Fig. 25.35** Histology of non-Hodgkin lymphoma. **A** (Low-grade) follicular or nodular pattern. **B** (High-grade) diffuse pattern.

(10%) disease. Other extranodal sites tend to be more common in high-grade disease, particularly CNS involvement. Compression syndromes may occur, including gut obstruction, ascites, superior vena cava obstruction and spinal cord compression.

The same staging system (see Box 25.55) is used for both HL and NHL, but NHL is more likely to be stage III or IV at presentation.

#### Investigations

These are as for HL, but in addition the following should be performed:

- *Bone marrow aspiration and trephine* to identify bone marrow involvement.
- *Immunophenotyping of surface antigens to distinguish T-cell from B-cell tumours*. This may be done on blood, marrow or nodal material.
- *Cytogenetic analysis to detect chromosomal translocations*, particularly rearrangements of the oncogene *c-MYC* and molecular testing for T-cell receptor or immunoglobulin gene rearrangements.
- *Immunoglobulin determination*. Some lymphomas are associated with IgG or IgM paraproteins, which serve as markers for treatment response.
- *Measurement of urate levels*. Some very aggressive high-grade NHLs are associated with very high urate levels, which can precipitate renal failure when treatment is started as a consequence of tumour lysis syndrome.
- *HIV testing*. HIV is a risk factor for some lymphomas and affects treatment decisions.
- *Hepatitis B and C testing*. This should be done prior to therapy with rituximab.

#### Management

##### Low-grade NHL

The majority of patients (80%) present with advanced stage disease and will run a relapsing and remitting course over several years. Overall survival has improved in recent years with more treatment options. Asymptomatic patients may not require therapy and are managed by 'watching and waiting'. Indications for treatment include marked systemic symptoms, lymphadenopathy causing discomfort or disfigurement,

bone marrow failure or compression syndromes. In follicular lymphoma, the options are:

- **Radiotherapy.** This can be used for localised stage I disease, which is rare. FDG PET-CT-confirmed stage I disease has a 70% cure rate with radiotherapy.
- **Chemotherapy.** Most patients will respond to oral therapy with chlorambucil, which is well tolerated, but not curative and is reserved nowadays for older/frail patients. More intensive intravenous chemotherapy in younger patients produces better quality of life through long periods of remission.
- **Monoclonal antibody therapy.** Humanised monoclonal antibodies ('biologic therapy'; p. 945) can be used to target surface antigens on tumour cells and to induce tumour cell apoptosis directly. The anti-CD20 antibody rituximab has been shown to induce durable clinical responses in up to 60% of patients when given alone, and acts synergistically when given with chemotherapy. Rituximab (R) in combination with cyclophosphamide, vincristine and prednisolone (R-CVP), cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (oncovin), prednisolone (R-CHOP) or bendamustine (R-bendamustine) is commonly used as first-line therapy. Two years of maintenance therapy with single-agent rituximab, following achievement of first or second response, especially if this is only a partial response, delays the time to next treatment. As yet, however, rituximab maintenance has not shown a survival benefit. New and more potent monoclonal antibodies are in development; a recent trial of obinutuzumab combined with chemotherapy showed longer progression-free survival compared to similar chemotherapy with rituximab.
- **Targeted therapy.** The PI3 kinase inhibitor idelalisib is approved for relapsed follicular lymphoma and ibrutinib (Fig. 25.30) is approved for relapsed mantle cell lymphoma (a poor-prognosis lymphoma with low-grade histology, but aggressive clinical behaviour) and for relapsed Waldenström's macroglobulinaemia (also known as lymphoplasmacytic lymphoma, see below). Newer targeted therapies are likely to become more widely used in low-grade lymphomas in the near future.
- **Transplantation.** High-dose chemotherapy and autologous HSCT can produce long remissions in patients with relapsed disease. Decisions on the timing of such treatment are complex in the context of rituximab maintenance and newer targeted therapies. However, younger patients with short first or second remissions or who relapse during rituximab maintenance should be considered.

### High-grade NHL

Patients with diffuse large B-cell NHL need treatment at initial presentation:

- **Chemotherapy.** The majority (>90%) are treated with intravenous combination chemotherapy, typically with the CHOP regimen (cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (oncovin) and prednisolone).
- **Monoclonal antibody therapy.** When combined with CHOP chemotherapy, rituximab (R) increases the complete response rates and improves overall survival. R-CHOP, 4–6 cycles, is currently recommended as first-line therapy for all relatively fit patients. Dose reduction (R-mini CHOP) is preferable in those over 80 years of age and replacement of doxorubicin with gemcitabine (R-GCVP) is considered in those with impaired cardiac function.
- **Radiotherapy.** Stage I patients without bulky disease are treated with four cycles of CHOP or R-CHOP, followed by involved site radiotherapy. Radiotherapy is also indicated for a residual localised site of bulk disease after chemotherapy and for spinal cord and other compression syndromes.
- **HSCT.** Autologous HSCT (p. 945) benefits patients with relapsed disease that is sensitive to salvage immunochemotherapy. As with HL, achieving a negative FDG PET-CT negativity to autologous transplantation is desirable.

- **CAR-T-cell therapy** (Fig. 25.17) is licensed for certain patients with multiply relapsed DLBCL or high-grade transformation of follicular lymphoma and can salvage patients from a desperate situation.

### Prognosis

Low-grade NHL runs an indolent remitting and relapsing course, with an overall median survival of 12 years. Transformation to a high-grade NHL occurs in 3% per annum and is associated with poor survival.

In diffuse large B-cell NHL treated with R-CHOP, some 75% of patients overall respond initially to therapy and 50% will have disease-free survival at 5 years. The prognosis for patients with high grade NHL is further refined according to the international prognostic index (IPI). For high-grade NHL, 5-year survival ranges from over 75% in those with low-risk scores (age <60 years, stage I or II, one or fewer extranodal sites, normal LDH and good performance status) to 25% in those with high-risk scores (increasing age, advanced stage, concomitant disease and a raised LDH).

Rearrangements of the *c-MYC* oncogene, either alone (more commonly Burkitt lymphoma) or with rearrangements of *BCL-2* and/or *BCL-6* (double or triple hit high-grade lymphomas) are recognised entities in WHO classification with poor prognoses and are increasingly treated more aggressively.

Relapse is associated with a poor response to further chemotherapy (<10% 5-year survival), but in patients under 65 years HSCT improves survival.

### Paraproteinaemias

A gammopathy refers to over-production of one or more classes of immunoglobulin. It may be polyclonal in association with acute or chronic inflammation, such as infection including HIV, sarcoidosis, autoimmune disorders or some malignancies. Alternatively, a monoclonal increase in a single immunoglobulin class may occur in association with normal or reduced levels of the other immunoglobulins. Such monoclonal proteins (also called M-proteins, paraproteins or monoclonal gammopathies) occur as a feature of myeloma, solitary plasmacytomas, lymphoma and amyloidosis, in connective tissue disease such as rheumatoid arthritis or polymyalgia rheumatica, in infection such as HIV and in solid tumours. In addition, they may be present with no underlying disease. Gammopathies are detected by plasma immunoelectrophoresis.

### Monoclonal gammopathy of uncertain significance

In monoclonal gammopathy of uncertain significance (MGUS, also known as benign monoclonal gammopathy), a paraprotein is present in the blood but there are no other features of myeloma, Waldenström macroglobulinaemia (see below), lymphoma or related disease. It is a common condition associated with increasing age; a paraprotein can be found in 1% of the population aged over 50 years, increasing to 5% over 80 years.

### Clinical features and investigations

Patients are usually asymptomatic and the paraprotein is found on blood testing for other reasons. The routine blood count and biochemistry are normal, the paraprotein is usually present in small amounts with no associated immune paresis and there are no lytic bone lesions. The bone marrow may have increased plasma cells, but these usually constitute less than 10% of nucleated cells.

### Prognosis

After follow-up of 20 years, only one-quarter of cases will progress to myeloma or a related disorder (i.e. around 1% per annum). There is no certain way of predicting progression in an individual patient. However, an abnormal ratio of kappa to lambda light chains (serum free light chain ratio, SFLR) increases the risk of progression. Patients with an abnormal ratio should be monitored for progression on an annual basis.

## Waldenström macroglobulinaemia

This is a low-grade lymphoplasmacytic lymphoma associated with an IgM paraprotein, causing clinical features of hyperviscosity syndrome. It is a rare tumour occurring in old age and more commonly affects males.

Patients classically present with features of hyperviscosity, such as nosebleeds, bruising, delirium and visual disturbance. However, presentation is more commonly with anaemia, systemic symptoms, splenomegaly or lymphadenopathy, or may be asymptomatic with an IgM paraprotein detected on routine screening. Patients are found on investigation to have an IgM paraprotein associated with a raised plasma viscosity. The bone marrow has a characteristic appearance, with infiltration of lymphoid cells, plasma cells and sometimes prominent mast cells. A high proportion of patients have a mutation in the *MYD88* gene.

### Management

If patients show symptoms of hyperviscosity and anaemia, plasmapheresis is required to remove IgM and make blood transfusion possible. Chemotherapy with alkylating agents, such as chlorambucil, has historically been the mainstay of treatment, controlling disease in over 50%. Fludarabine may be more effective in this disease, but has more side-effects. Rituximab in combination with chemotherapy, e.g bendamustine, is now most commonly used; ibrutinib is very effective and has recently been licensed for use. Rituximab alone can cause a rapid release of IgM and increase in viscosity. The median survival is 5 years.

## Multiple myeloma

This is a malignant proliferation of plasma cells. Normal plasma cells are derived from B cells and produce immunoglobulins that contain heavy and light chains. Normal immunoglobulins are polyclonal, which means that a variety of heavy chains are produced and each may be of kappa or lambda light chain type (Ch. 4). In myeloma, plasma cells produce immunoglobulin of a single heavy and light chain, a monoclonal protein commonly referred to as a paraprotein. In most cases an excess of light chain is produced and in some cases only light chain is produced; this appears in the urine as Bence Jones proteinuria and can be measured in the urine or serum as free light chain. The frequency of different isotypes of monoclonal protein in myeloma is shown in Box 25.58.

Although a small number of malignant plasma cells are present in the circulation, the majority are present in the bone marrow. The malignant plasma cells produce cytokines, which stimulate osteoclasts and result in net bone reabsorption. The resulting lytic lesions cause bone pain, fractures and hypercalcaemia. Marrow involvement can result in anaemia or pancytopenia.

### Clinical features and investigations

The incidence of myeloma is 4/100000 new cases per annum, with a male-to-female ratio of 2:1. The median age at diagnosis is 60–70 years and the disease is more common in people of African Caribbean origin. The clinical features are demonstrated in Fig. 25.37.

Diagnosis of myeloma requires two of the following criteria to be fulfilled:

- increased malignant plasma cells in the bone marrow
- serum and/or urinary M-protein
- skeletal lytic lesions.

Bone marrow aspiration, plasma and urine electrophoresis, and a skeletal survey are thus required; the latter is classically a series of plain X-rays, but more often now low-dose CT scan or whole-body MRI is performed. Normal immunoglobulin levels, i.e. the absence of immunoparesis, should cast doubt on the diagnosis. Paraproteinaemia can cause an elevated ESR, but this is a non-specific test; only approximately 5% of patients with a persistently elevated ESR above 100 mm/hr have underlying myeloma. Serum albumin and  $\beta_2$ -microglobulin are measured for prognostic purposes, along with a cytogenetic analysis of the tumour cells.

## 25.58 Classification of multiple myeloma

Type of monoclonal (M)-protein	Relative frequency (%)
IgG	55
IgA	21
Light chain only	22
Others (D, E, non-secretory)	2

### Management

If patients are asymptomatic with no evidence of end-organ damage (e.g. to kidneys, bone marrow or bone), treatment may not be required. So-called asymptomatic myeloma should be monitored closely for the development of end-organ damage.

### Immediate support

- High fluid intake to treat renal impairment and hypercalcaemia (p. 676)
- Analgesia for bone pain
- Bisphosphonates for hypercalcaemia and to delay other skeletal-related events (p. 1051)
- Allopurinol to prevent urate nephropathy
- Plasmapheresis, if necessary, for hyperviscosity
- Antibiotic prophylaxis with levofloxacin during the first 3 months of therapy.

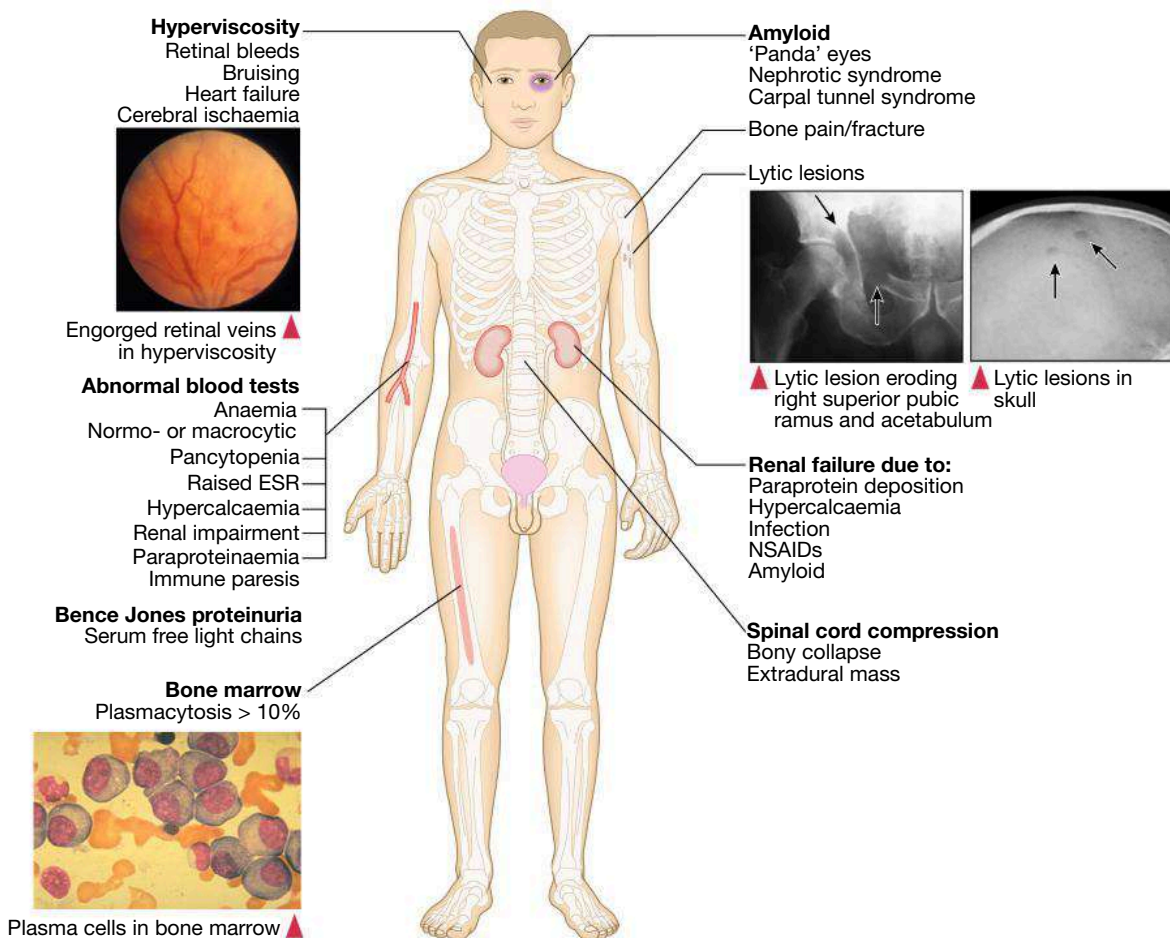

### Chemotherapy with or without HSCT

Patients are initially assessed for their fitness and eligibility for autologous HSCT and treatment pathways vary accordingly. Myeloma therapy has improved with the addition of novel agents, initially the immunomodulatory drug thalidomide and more recently the proteasome inhibitors bortezomib and carfilzomib, the second- and third-generation immunomodulatory drugs lenalidomide and pomalidomide and the anti-myeloma antibodies daratumumab and isatuximab, which binds to CD 38 on the malignant plasma cell (Fig. 25.38).

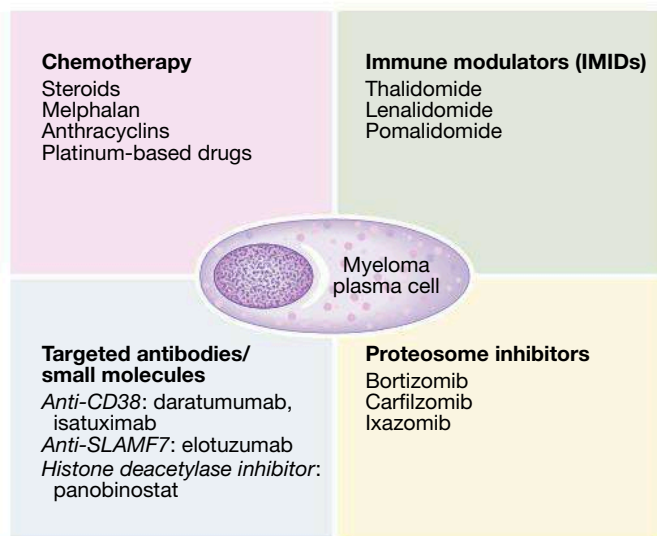

For first-line therapy in older patients who are unsuitable for transplant, thalidomide combined with the alkylating agent melphalan and prednisolone (MPT) has increased the median overall survival to more than 4 years. Lenalidomide is approved first-line treatment for patients not eligible for transplantation and who are intolerant of, or unsuitable for, thalidomide. Thalidomide and lenalidomide both have anti-angiogenic effects against tumour blood vessels and immunomodulatory effects. Both can cause somnolence, constipation, peripheral neuropathy and thrombosis, though lenalidomide has a better side-effect profile. It is vital that females of child-bearing age use adequate contraception, as thalidomide and lenalidomide are teratogenic. Treatment is administered until paraprotein levels have stopped falling. This is termed 'plateau phase' and can last for weeks or years.

In younger, fitter patients considered eligible for transplant, standard treatment includes first-line therapies, such as cyclophosphamide, thalidomide and dexamethasone (CTD) or bortezomib (Velcade), thalidomide and dexamethasone (VTD) to maximum response, and then autologous HSCT. This improves quality of life and prolongs survival, but does not cure myeloma. In all patients who have achieved maximal response, lenalidomide maintenance has been shown to prolong the response.

When myeloma progresses, treatment is given to induce a further plateau phase. In the UK, the proteasome inhibitor bortezomib and lenalidomide have been used as second- and third-line therapy, as appropriate. However, as they have been used more frequently in the first or second line with prognostic benefit, subsequent relapses are more difficult to treat. Pomalidomide, carfilzomib and daratumumab show promise in relapsed/refractory disease and are increasingly used. Patients who respond may benefit from a second autologous HSCT.

**Fig. 25.37** Clinical and laboratory features of multiple myeloma. (ESR = erythrocyte sedimentation rate; NSAIDs = non-steroidal anti-inflammatory drugs)

**Fig. 25.38** Myeloma therapy. The four main groups of drugs that may be used in the management of myeloma. (IMiDs = immunomodulatory imide drugs)

#### Radiotherapy

This is effective for localised bone pain not responding to simple analgesia and for pathological fractures. It is also useful for the emergency treatment of spinal cord compression complicating extradural plasmacytomas.

#### Bisphosphonates

Long-term bisphosphonate therapy reduces bone pain and skeletal events. These drugs protect bone and may cause apoptosis of malignant plasma cells. There is evidence that intravenous zoledronate in combination with anti-myeloma therapy confers a survival advantage over oral bisphosphonates. Osteonecrosis of the jaw may be associated with long-term use or poor oral hygiene and gum sepsis; regular dental review, including a check before starting therapy, is therefore important.

#### Prognosis

The international staging system (ISS) identifies poor prognostic features, including a high  $\beta_2$ -microglobulin and low albumin at diagnosis (ISS stage 3, median survival 29 months). Those with a normal albumin and a low  $\beta_2$ -microglobulin (ISS stage 1) have a median survival of 62 months. Increasingly, cytogenetic analysis is used to identify poor-risk patients, e.g. t(4;14), del(17/17p), t(14;16), t(14;20), non-hyperdiploidy and gain(1q). Use of autologous HSCT and advances in drug therapy with the newer agents have increased survival. Over one-third of patients are now surviving for 5 years, compared with only one-quarter 10 years ago. The outlook may improve further with new drugs and combinations of treatments.

Some general considerations regarding haematological malignancy in old age are summarised in [Box 25.59](#).

#### Solitary plasmacytomas

These are rare presentations of plasma cell malignancy in which an isolated tumour occurs in soft tissues or bone. Two-thirds of cases occur in soft tissues and are commonly centred around the upper aero-digestive tract, but can occur anywhere. Others present as bone tumours,

### 25.59 Haematological malignancy in old age

- **Median age:** approximately 70 years for most haematological malignancies.
- **Poor-risk biological features:** adverse cytogenetics or the presence of a multidrug resistance phenotype are more frequent.
- **Prognosis:** increasing age is an independent adverse variable in acute leukaemia and aggressive lymphoma.
- **Chemotherapy:** may be less well tolerated. Older people are more likely to have antecedent cardiac, pulmonary or metabolic problems, tolerate systemic infection less well and metabolise cytotoxic drugs differently.
- **Cure rates:** similar to those in younger patients, in those who do tolerate treatment.
- **Decision to treat:** should be based on the individual's biological status, the level of social support available, and the patient's wishes and those of the immediate family, but not on chronological age alone.

commonly in long bones and vertebrae. Patients present with pain, palpable lumps or compression symptoms, such as difficulty swallowing, shortness of breath or cord compression.

Diagnosis involves tissue biopsy, which demonstrates a solid tumour of monoclonal plasma cells, and staging to exclude disseminated multiple myeloma. Some cases are associated with a low-level paraprotein, but other features of myeloma are absent.

Primary treatment is usually with radiotherapy. This can be curative, especially in soft tissue plasmacytomas, which less frequently progress to myeloma. Plasmacytomas of bone have a high rate of progression to myeloma and must be monitored carefully or treated as myeloma from the outset. Rarely myeloma presents as multiple plasmacytomas of bone.

### Histiocytic disorders

These are a group of rare tissue infiltrating conditions affecting children and less commonly adults. Histiocytes are immune cells found in various tissues throughout the body whose functions include phagocytosis (tissue macrophages), activation of the immune system and promoting immune tolerance via antigen presentation to T cells (Fig. 25.39). Disorders resulting from pathological infiltration of tissues by histiocytes are shown in Box 25.60.

LCH is the commonest type and is caused by mutations in cell signalling known as the MAPKinase pathway. Key genes mutated in this pathway include *BRAF* (65%–70%) and *MAP2K* (20%). LCH can present with isolated painless lumps, e.g. of bone (eosinophilic granuloma) or with symptoms of disseminated tissue involvement including bone, lung, skin

### 25.60 Histiocytic disorders

- Langerhans cell histiocytosis (LCH)
- Cutaneous and mucocutaneous histiocytosis (C)
- Malignant histiocytosis (M)
- Rosai–Dorfman disease (RD)
- Haemophagocytic lymphohistiocytosis (HLH)

(e.g. persistent nappy rash), lymphadenopathy, splenomegaly and periodontal disease. Diagnosis can be difficult because of the rarity and multiple symptoms at presentation. Management includes surgical excision or radiotherapy of an isolated lesion or topical or systemic chemotherapy drugs, including methotrexate, etoposide and cladribine in disseminated LCH. The *BRAF* inhibitors, e.g. vemurafenib, have shown promising activity in relapsed LCH.

HLH results from mutations in immune genes, e.g. perforin. Presentation is predominantly in children with tissue infiltration by histiocytes and macrophages. Abnormal cytokine production, e.g. interferon-gamma and activation of complement, leads to hyperinflammation and associated haemophagocytosis of blood cells producing pancytopenia. Treatment is based around immunosuppression with glucocorticoids, chemotherapy or ciclosporin, all with the aim of proceeding to allogeneic stem cell transplantation. Newer treatments aimed at inhibiting cytokines or complement activation are being studied.

An acquired form of reactive haemophagocytosis called macrophage activation syndrome (MAS) or secondary HLH is associated with a range of conditions including rheumatological conditions, e.g. juvenile idiopathic arthritis, SLE and Kawasaki disease, acute viral infections, e.g. EBV, CMV and HHV6 and T-cell lymphomas. These diverse conditions generate a cytokine storm, which drives the MAS. Patients present very unwell with fever, severe pancytopenia, deranged coagulation tests, hepatomegaly and a very high ferritin level (often measured in the tens of thousands µg/L). Management includes supportive care, glucocorticoids or other immunosuppression, inhibition of IL-1 with anakinra and, if possible, treatment of the underlying condition.

### Aplastic anaemia

#### Primary idiopathic acquired aplastic anaemia

This is a rare disorder in Europe and North America, with 2–4 new cases per million population per annum. The disease is much more common

**Fig. 25.39 Histiocytic disorder.** [A] CT scan demonstrating bilateral histiocytic infiltration of the kidneys with typical 'hair on end' appearance of the renal cortex. The patient is an older woman with Langerhans cell histiocytosis involving kidneys, lymph nodes and skin. [B] PET scan of the same patient showing PET positivity in the renal cortex, most noticeable on the right. The intense PET signal relates to excretion of radioactive glucose in urine into the renal pelvis. Courtesy of Dr Mark Gandhi, Radiology Department, Aberdeen Royal Infirmary.

in certain other parts of the world, e.g. east Asia. The basic problem is failure of the pluripotent stem cells because of an autoimmune attack, producing hypoplasia of the bone marrow with a pancytopenia in the blood. The diagnosis rests on exclusion of other causes of secondary aplastic anaemia (see below) and rare congenital causes, such as Fanconi's anaemia.

### Clinical features and investigations

Patients present with symptoms of bone marrow failure, usually anaemia or bleeding, and less commonly, infections. An FBC demonstrates pancytopenia, low reticulocytes and often macrocytosis. Bone marrow aspiration and trephine reveal hypocellularity. The severity of aplastic anaemia is graded according to the Camitta criteria (Box 25.61).

### Management

All patients will require blood product support and aggressive management of infection. The prognosis of severe aplastic anaemia managed with supportive therapy only is poor and more than 50% of patients die, usually in the first year. The curative treatment for patients under 35 years of age with severe idiopathic aplastic anaemia is allogeneic HSCT if there is an available sibling donor (p. 945). Patients aged 35–50 may be candidates if they have no comorbidities. Those with a compatible sibling donor should proceed to transplantation as soon as possible; they have a 75%–90% chance of long-term cure. In older patients and those without a suitable donor, immunosuppressive therapy (IST) with anti-thymocyte globulin (ATG) and ciclosporin is the treatment of choice and gives 5-year survival rates of 75%. Unrelated donor allografts are considered for suitable patients who fail IST. The thrombopoietin receptor agonist eltrombopag has produced trilineage responses in patients who fail IST and is licensed for this indication. Non-transplanted patients may relapse or other clonal disorders of haematopoiesis may evolve, such as paroxysmal nocturnal haemoglobinuria (p. 959), myelodysplastic syndrome (p. 970) and AML (p. 964). Patients with aplastic anaemia must be followed up long-term.

## Secondary aplastic anaemia

Causes of this condition are listed in Box 25.62. It is not practical to list all the drugs that have been suspected of causing aplasia. It is important to check the reported side-effects of all drugs taken over the preceding months. In some instances, the cytopenia is more selective and affects only one cell line, most often the neutrophils. Frequently, this is an incidental finding, with no ill health. It probably has an immune basis, but this is difficult to prove.

The clinical features and methods of diagnosis are the same as for primary idiopathic aplastic anaemia. An underlying cause should be treated or removed, but otherwise management is as for the idiopathic form.

### 25.61 Camitta criteria

#### Severe AA (SAA)

- Marrow cellularity <25% (or 25%–50% with <30% residual haematopoietic cells), plus at least two of:  
Neutrophils <0.5 × 10<sup>9</sup>/L  
Platelets <20 × 10<sup>9</sup>/L  
Reticulocyte count <20 × 10<sup>9</sup>/L

#### Very severe AA (VSAA)

- As for SAA but neutrophils <0.2 × 10<sup>9</sup>/L

#### Non-severe AA (NSAA)

- AA not fulfilling the criteria for SAA or VSAA

### 25.62 Causes of secondary aplastic anaemia

- Drugs:
  - Cytotoxic drugs
  - Antibiotics – chloramphenicol, sulphonamides
  - Antirheumatic agents – penicillamine, gold, phenylbutazone, indometacin
  - Antithyroid drugs – carbimazole, propylthiouracil
  - Anticonvulsants
  - Immunosuppressants – azathioprine
- Chemicals:
  - Benzene, toluene solvent misuse – glue-sniffing
  - Insecticides – chlorinated hydrocarbons (DDT), organophosphates and carbamates (Ch. 10)
- Radiation
- Viral hepatitis
- Pregnancy
- Paroxysmal nocturnal haemoglobinuria

## Myeloproliferative neoplasms

These make up a group of chronic conditions characterised by clonal proliferation of marrow stem/precursor cells. Polycythaemia rubra vera (PRV), essential thrombocythaemia and myelofibrosis are the non-leukaemic myeloproliferative neoplasms. Although the majority of patients are classifiable as having one of these disorders, some have overlapping features and there is often progression from one to another, e.g. PRV to myelofibrosis. A mutation in the gene on chromosome 9 encoding the signal transduction molecule *JAK-2* (*JAK-2 V617F*) has been found in more than 90% of PRV cases and 50% of those with essential thrombocythaemia and myelofibrosis; less frequently, mutations may be identified in exon 12 of *JAK-2*. Mutations in the calreticulin gene (*CALR*), which produces a chaperone protein that protects proteins moving from the endoplasmic reticulum to the cytoplasm, have been found in a further 25% of patients with essential thrombocythaemia. Less commonly, mutations can be detected in the thrombopoietin receptor gene *MPL*.

### Myelofibrosis

In myelofibrosis, the marrow is initially hypercellular, with an excess of abnormal megakaryocytes that release growth factors, such as platelet-derived growth factor, to the marrow microenvironment, resulting in a reactive proliferation of fibroblasts. As the disease progresses, the marrow becomes fibrosed.

Most patients present over the age of 50 years, with lassitude, weight loss and night sweats. The spleen can be massively enlarged due to extramedullary haematopoiesis (blood cell formation outside the bone marrow), and painful splenic infarcts may occur.

The characteristic blood picture is leucoerythroblastic anaemia, with circulating immature red blood cells (increased reticulocytes and nucleated red blood cells) and granulocyte precursors (myelocytes). The red cells are shaped like teardrops (teardrop poikilocytes), and giant platelets may be seen in the blood. The white count varies from low to moderately high and the platelet count may be high, normal or low. Urate levels may be high due to increased cell breakdown, and folate deficiency is common. The marrow is often difficult to aspirate and a trephine biopsy shows an excess of megakaryocytes, increased reticulin and fibrous tissue replacement. The presence of a pathological *JAK-2* mutation supports the diagnosis.

### Management and prognosis

Median survival is 4 years from diagnosis, but ranges from 1 year to over 20 years. Treatment is directed at control of symptoms, e.g. red cell transfusions for anaemia. Folic acid should be given to prevent deficiency. Cytotoxic therapy with hydroxycarbamide may help control spleen size, the white cell count or systemic symptoms. Splenectomy

may be required for a grossly enlarged spleen or symptomatic pancytopenia secondary to splenic pooling of cells and hypersplenism. Allogeneic HSCT may be considered for younger patients. Ruxolitinib, an inhibitor of *JAK-2*, is effective at reducing systemic symptoms and splenomegaly and may improve life expectancy with longer-term use.

### Essential thrombocythaemia

Uncontrolled proliferation of megakaryocytes results in a raised level of circulating platelets that are often dysfunctional. Prior to a diagnosis of essential thrombocythaemia being made, reactive causes of thrombocytosis must be excluded (see [Box 25.15](#)). The presence of pathogenic *JAK-2 V617F*, *CALR* or, rarely, *MPL* mutations supports the diagnosis, but is not universal. Patients present at a median age of 60 years with vascular occlusion, acrocyanosis (painful discoloured finger tips) or bleeding, or with an asymptomatic isolated raised platelet count. A small percentage (around 5%) will transform to acute leukaemia and others to myelofibrosis.

It is likely that most patients with essential thrombocythaemia benefit from low-dose aspirin to reduce the risk of occlusive vascular events. Low-risk patients (age <40 years, platelet count <1500 × 10<sup>9</sup>/L and no bleeding or thrombosis) may not require treatment to reduce the platelet count. For those with a platelet count above 1500 × 10<sup>9</sup>/L, with symptoms, or with other risk factors for thrombosis such as diabetes or hypertension, treatment to control platelet counts should be given. Agents include oral hydroxycarbamide or anagrelide, an inhibitor of megakaryocyte maturation. Intravenous radioactive phosphorus (<sup>32</sup>P) may be useful in old age, but is rarely available nowadays, and interferon-alfa has a role in younger patients, including pregnant women and women planning to conceive.

### Polycythaemia rubra vera

PRV occurs mainly in patients over the age of 40 years and presents either as an incidental finding of a high haemoglobin, or with symptoms of hyperviscosity, such as lassitude, loss of concentration, headaches, dizziness, blackouts, pruritus and epistaxis. Some patients present with manifestations of peripheral arterial or cerebrovascular disease. Venous thromboembolism may also occur. Peptic ulceration is common, sometimes complicated by bleeding. Patients are often plethoric and many have a palpable spleen at diagnosis.

Investigation of polycythaemia is discussed on page 933. The diagnosis of PRV now rests on the demonstration of a high haematocrit and the presence of a pathogenic *JAK-2* mutation (positive in 95% of cases). In the occasional *JAK-2*-negative cases, a raised red cell mass and absence of causes of a secondary erythrocytosis must be established. The spleen may be enlarged and neutrophil and platelet counts are frequently raised, an abnormal karyotype may be found in the marrow and in vitro culture of the marrow can be used to demonstrate autonomous growth in the absence of added growth factors.

### Management and prognosis

Aspirin reduces the risk of thrombosis. Venesection gives prompt relief of hyperviscosity symptoms. Between 400 and 500 mL of blood (less if the patient is in old age) are removed and the venesection is repeated every 5–7 days until the haematocrit is reduced to below 45%. Less frequent, regular venesection will maintain this level until the haemoglobin remains reduced because of iron deficiency.

Suppression of marrow proliferation with hydroxycarbamide or interferon-alfa may reduce the risk of vascular occlusion, control spleen size and reduce transformation to myelofibrosis. The *JAK-2* inhibitor ruxolitinib is licensed for patients whose disease is not controlled by hydroxycarbamide. Median survival after diagnosis in treated patients exceeds 10 years. Some patients survive more than 20 years; however, cerebrovascular or coronary events occur in up to 60% of patients. The disease may convert to another myeloproliferative disorder, with about 15% developing acute leukaemia or myelofibrosis.

## Bleeding disorders

### Disorders of primary haemostasis

The initial formation of the platelet plug (see [Fig. 25.6A](#); also known as 'primary haemostasis') may fail in thrombocytopenia (p. 938), von Willebrand disease (p. 984), and also in platelet function disorders and diseases affecting the vessel wall.

### Vessel wall abnormalities

Vessel wall abnormalities may be:

- congenital, such as hereditary haemorrhagic telangiectasia
- acquired, as in a vasculitis ([Ch. 26](#)) or scurvy.

### Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) is a dominantly inherited condition caused by mutations in the genes encoding endoglin and activin receptor-like kinase, which are endothelial cell receptors for transforming growth factor-beta (TGF-β), a potent angiogenic cytokine. Telangiectasia and small aneurysms are found on the fingertips, face and tongue, and in the nasal passages, lung and gastrointestinal tract. A significant proportion of these patients develop larger pulmonary arteriovenous malformations (PAVMs) that cause arterial hypoxaemia due to a right-to-left shunt. These predispose to paradoxical embolism, resulting in stroke or cerebral abscess. All patients with HHT should be screened for PAVMs and cerebral AVMs; if these are found, ablation by embolisation should be considered.

Patients present either with recurrent bleeds, particularly epistaxis, or with iron deficiency due to occult gastrointestinal bleeding. Treatment can be difficult because of the multiple bleeding points, but regular iron therapy often allows the marrow to compensate for blood loss. Local cautery or laser therapy may prevent single lesions from bleeding. A variety of medical therapies have been tried but none has been found to be universally effective.

### Ehlers–Danlos disease

Vascular Ehlers–Danlos syndrome (type 4) is a rare autosomal dominant disorder (1/100 000) caused by a defect in type 3 collagen that results in fragile blood vessels and organ membranes, leading to bleeding and organ rupture. Classical joint hypermobility ([Ch. 26](#)) is often limited in this form of the disease, but skin changes and facial appearance are typical. The diagnosis should be considered when there is a history of bleeding with normal laboratory tests.

### Scurvy

Vitamin C deficiency affects the normal synthesis of collagen and results in a bleeding disorder characterised by perifollicular and petechial haemorrhage, bruising and subperiosteal bleeding. The key to diagnosis is the dietary history ([Ch. 22](#)).

### Platelet function disorders

Bleeding may result from thrombocytopenia (see [Box 25.14](#)) or from congenital or acquired abnormalities of platelet function. The most common acquired disorders are iatrogenic, resulting from the use of aspirin, clopidogrel, ticagrelor, dipyridamole and the glycoprotein IIb/IIIa inhibitors to prevent arterial thrombosis (see [Box 25.26](#)). Inherited platelet function abnormalities are relatively rare. Congenital abnormalities may be due to deficiency of the membrane glycoproteins, e.g. Glanzmann's thrombasthenia (IIb/IIIa) or Bernard–Soulier syndrome (Ib), or due to the presence of defective platelet granules, e.g. a deficiency of dense (delta) granules (see [Fig. 25.7](#)) giving rise to storage pool disorders. The congenital macrothrombocytopathies that are due to mutations in the myosin heavy chain gene *MYH-9* are characterised by large platelets, inclusion bodies

in the neutrophils (Döhle bodies) and a variety of other features, including sensorineural deafness and renal abnormalities. Other familial thrombocytopathies are important, as they can be associated with somatic features (TAR; thrombocytopenia with absent radii (TAR)), and some are associated with a propensity for development of bone marrow failure or dysplasia (e.g. mutations in *RUNX-1* and *ANKRD 26*).

Apart from Glanzmann's thrombasthenia, these conditions are mild disorders, with bleeding typically occurring after trauma or surgery, but rarely spontaneous. Glanzmann's thrombasthenia is an autosomal recessive condition associated with a variable, but often severe bleeding disorder. These conditions are usually managed by local mechanical measures, but antifibrinolytics, such as tranexamic acid, may be useful and, in severe bleeding, platelet transfusion may be required. Recombinant VIIa is licensed for the treatment of resistant bleeding in Glanzmann's thrombasthenia.

## Thrombocytopenia

Thrombocytopenia occurs in many disease processes, as listed in [Box 25.14](#), many of which are discussed elsewhere in this chapter.

### Idiopathic thrombocytopenic purpura

Idiopathic thrombocytopenic purpura (ITP) is immune-mediated with involvement of autoantibodies, most often directed against the platelet membrane glycoprotein IIb/IIIa, which sensitise the platelet, resulting in premature removal from the circulation by cells of the reticulo-endothelial system. It is not a single disorder; some cases occur in isolation while others are associated with underlying immune dysregulation in conditions such as connective tissue diseases, HIV infection, B-cell malignancies, pregnancy and certain drug therapies. The clinical presentation and pathogenesis are similar, whatever the cause of ITP.

#### Clinical features and investigations

The presentation depends on the degree of thrombocytopenia. Spontaneous bleeding typically occurs only when the platelet count is below  $20 \times 10^9/L$ . At higher counts, the patient may complain of easy bruising or sometimes epistaxis or menorrhagia. Many cases with counts of more than  $50 \times 10^9/L$  are discovered by chance.

In adults, ITP more commonly affects females and may have an insidious onset. Unlike ITP in children, it is unusual for there to be a history of a preceding viral infection. The development of ITP in the context of COVID-19 infection has been documented. Symptoms or signs of a connective tissue disease may be apparent at presentation or emerge several years later. Patients aged over 65 years should be considered for a bone marrow examination to look for an accompanying B-cell malignancy and appropriate autoantibody testing performed if a diagnosis of connective tissue disease is suspected. HIV testing should be considered because a positive result will have major implications for appropriate therapy. The peripheral blood film is normal, apart from a greatly reduced platelet number, while the bone marrow reveals an obvious increase in megakaryocytes.

#### Management

Many patients with stable compensated ITP and a platelet count of more than  $30 \times 10^9/L$  do not require treatment to raise the platelet count, except at times of increased bleeding risk, such as surgery and biopsy. First-line therapy for patients with spontaneous bleeding is with high doses of glucocorticoids, either prednisolone (1 mg/kg daily) or dexamethasone (40 mg daily for 4 days), to suppress antibody production and inhibit phagocytosis of sensitised platelets by reticulo-endothelial cells. Administration of intravenous immunoglobulin can raise the platelet count by blocking antibody receptors on reticulo-endothelial cells and is combined with glucocorticoid therapy if there is severe haemostatic failure, especially with evidence of significant mucosal bleeding or a slow response to glucocorticoids alone. Persistent or potentially life-threatening bleeding should be treated with platelet transfusion in addition to the other therapies.

The condition may become chronic, with remissions and relapses. Relapses should be treated by re-introducing glucocorticoids. If a patient has two relapses or primary refractory disease, second-line therapies are considered. The options for second-line therapy include the thrombopoietin receptor agonists (TPO-RA) eltrombopag and romiplostim (which stimulate new platelet formation), the splenic tyrosine kinase inhibitor fostamatinib, splenectomy and immunosuppression. Where splenectomy is considered, the precautions shown in [Box 25.37](#) need to be in place. Splenectomy produces complete remission in about 70% of patients and improvement in a further 20%–25% in favourable cases. The TPO-RAs induce response in around 75% of cases, usually within 10–14 days. Low-dose glucocorticoid therapy and immunosuppressants such as rituximab, ciclosporin, mycophenolate and tacrolimus may also produce remissions. The order in which therapies should be used is not entirely clear, although the TPO-RAs and fostamatinib are licensed for this indication, while the immunosuppressive agents are not.

## Coagulation disorders

Normal coagulation is explained in [Figure 25.6](#) and the effects of age are discussed in [Box 25.63](#). Coagulation factor deficiency may be congenital or acquired and may affect one or several of the coagulation factors ([Box 25.64](#)). Inherited disorders are almost uniformly related to decreased synthesis, as a result of mutation in the gene encoding a key protein in coagulation. Von Willebrand disease is the most common inherited bleeding disorder. Haemophilia A and B are the most common single coagulation factor deficiencies, but inherited deficiencies of all the other coagulation factors are seen. Acquired disorders may be due to under-production (e.g. in liver failure), increased consumption (e.g. in DIC) or inhibition of function of coagulation factors (such as heparin therapy or immune inhibitors of coagulation, e.g. acquired haemophilia A).

### Haemophilia A

Factor VIII deficiency resulting in haemophilia A affects 1/10 000 individuals. It is the most common congenital coagulation factor deficiency. Factor VIII is primarily synthesised by the liver and endothelial cells and has a half-life of about 12 hours. It is protected from proteolysis in the circulation by binding to von Willebrand factor (vWF).

#### Genetics

The factor VIII gene is located on the X chromosome. Haemophilia is associated with a range of mutations in the factor VIII gene; these include major inversions, large deletions and missense, nonsense and splice site abnormalities. As the factor VIII gene is on the X chromosome, haemophilia A is a sex-linked disorder ([Ch. 3](#)). Thus all daughters of a patient with haemophilia are obligate carriers and they, in turn, have a 1 in 4 chance of each pregnancy resulting in the birth of an affected male baby, a normal male baby, a carrier female or a normal female. Antenatal diagnosis by chorionic villous sampling is possible in families with a known mutation.

Haemophilia 'breeds true' within a family; all members have the same factor VIII gene mutation and a similarly severe or mild phenotype. Female carriers of haemophilia may have reduced factor VIII levels because of random inactivation of their normal X chromosome in the developing fetus. This can result in a mild bleeding disorder; thus all known or suspected carriers of haemophilia A should have their factor VIII level measured.

#### Clinical features

The extent and patterns of bleeding are closely related to residual factor VIII levels ([Box 25.65](#)). Patients with severe haemophilia (factor VIII levels  $<0.01$  U/mL) present with spontaneous bleeding into skin, muscle and joints. Retroperitoneal and intracranial bleeding is also a feature. Babies with severe haemophilia have an increased risk of intracranial haemorrhage and, although there is insufficient evidence to recommend routine

**25.63 Haemostasis and thrombosis in old age**

- **Thrombocytopenia:** reasonably common because of the rising prevalence of disorders in which it may be a secondary feature and also because of the greater use of drugs that can cause it.
- **'Senile' purpura:** presumed to be due to an age-associated loss of subcutaneous fat and the collagenous support of small blood vessels, making them more prone to damage from minor trauma.
- **Thrombosis:** incidence of thromboembolic disease rises with increasing age. This may be due to stasis and concurrent illness, to which older people are prone. Some studies show increased platelet aggregation with age and others age-associated hyperactivity of the haemostatic system, which could contribute to a prothrombotic state.
- **Thromboprophylaxis:** should be considered in all older patients who are immobile as a result of acute illness. Prophylaxis is not required in chronic immobility without a medical cause, as there is no associated increase in thromboembolism.
- **Anticoagulation:** older patients are more sensitive to the anticoagulant effects of warfarin, partly due to the concurrent use of other drugs and the presence of other pathology. Life-threatening or fatal bleeds on warfarin are significantly more common in those over 80 years.

**25.64 Causes of coagulopathy****Congenital****X-linked**

- Haemophilia A and B

**Autosomal**

- Von Willebrand disease
- Factor II, V, VII, X, XI and XIII deficiencies
- Combined II, VII, IX and X deficiency
- Combined V and VIII deficiency
- Hypofibrinogenaemia
- Dysfibrinogenaemia

**Acquired****Under-production**

- Liver failure
- Vitamin K deficiency

**Increased consumption**

- Coagulation activation:
  - Disseminated intravascular coagulation (DIC)
- Immune-mediated:
  - Acquired haemophilia and von Willebrand syndrome
- Others:
  - Acquired factor X deficiency (in amyloid)
  - Acquired von Willebrand syndrome in Wilms' tumour
  - Acquired factor VII deficiency in sepsis

**Drug-induced**

- Inhibition of function:
  - Heparins
  - Argatroban
  - Bivalirudin
  - Fondaparinux
  - Rivaroxaban
  - Apixaban
  - Dabigatran
  - Edoxaban
- Inhibition of post-translational modification:
  - Warfarin

caesarean section for these births, it is appropriate to avoid head trauma and to perform cranial imaging of the newborn within the first 24 hours of life. Individuals with moderate and mild haemophilia (factor VIII levels 0.01–0.4 U/mL) present with the same pattern of bleeding, but usually after trauma or surgery when bleeding is disproportionate to the severity of the insult.

**25.65 Severity of haemophilia (ISTH criteria)**

Severity	Factor VIII or IX level	Clinical presentation
Severe	<0.01 U/mL	Spontaneous haemarthroses and muscle haematomas
Moderate	0.01–0.05 U/mL	Mild trauma or surgery causes bleeding
Mild	>0.05–0.4 U/mL	Major injury or surgery results in excess bleeding

(ISTH = International Society on Thrombosis and Haemostasis)

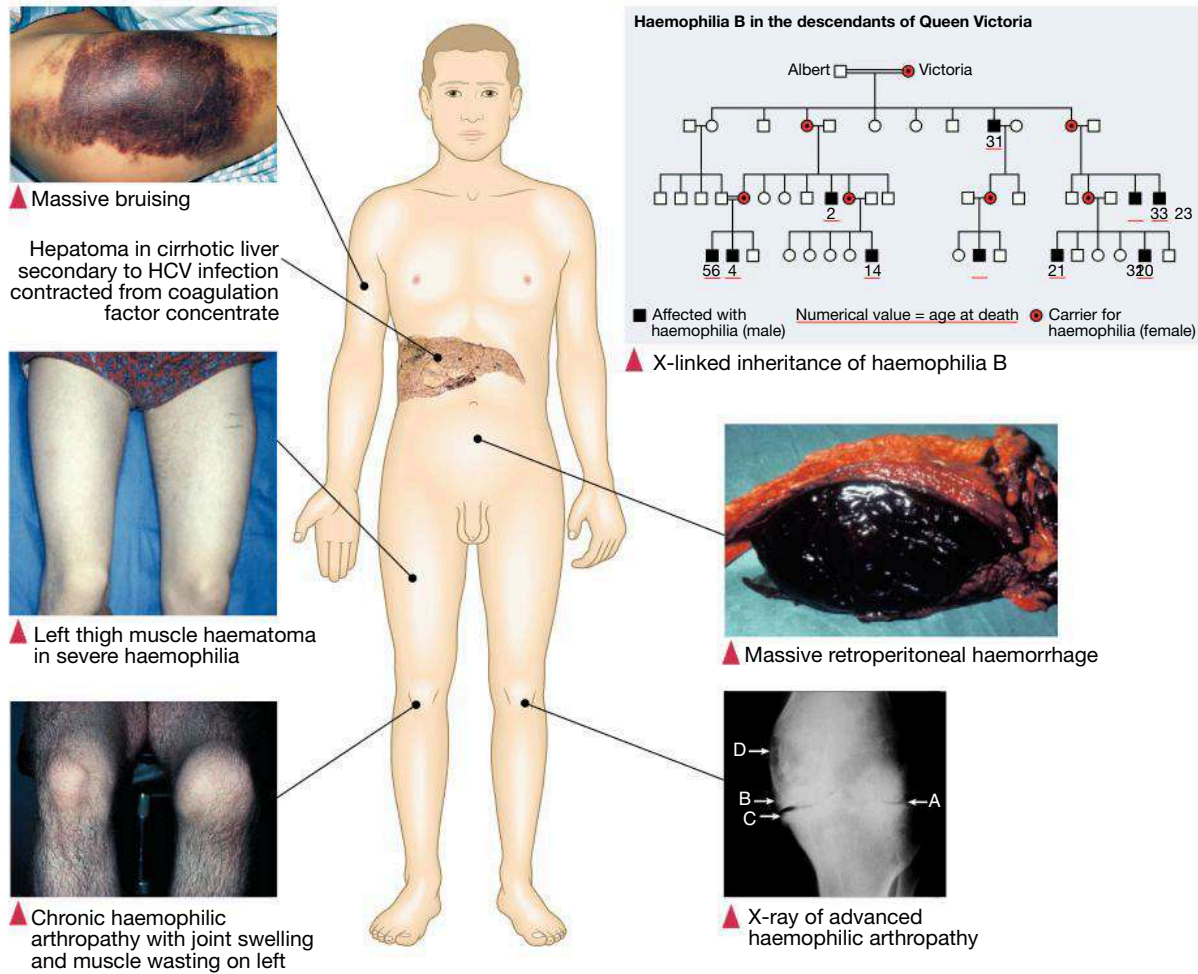

The major morbidity of recurrent bleeding in severe haemophilia is musculoskeletal. Bleeding is typically into large joints, especially knees, elbows, ankles and hips. Muscle haematomas are also characteristic, most commonly in the calf and psoas muscles. If early treatment is not given to arrest bleeding, a hot, swollen and very painful joint or muscle haematoma develops. Recurrent bleeding into joints leads to synovial hypertrophy, destruction of the cartilage and chronic haemophilic arthropathy (Fig. 25.40). Complications of muscle haematomas depend on their location. A large psoas bleed may extend to compress the femoral nerve; calf haematomas may increase pressure within the inflexible fascial sheath, causing a compartment syndrome with ischaemia, necrosis, fibrosis, and subsequent contraction and shortening of the Achilles tendon.

**Management**

The aim of management of severe haemophilia A (and B; see below) in high-income countries is to render patients 'bleed free'. This can be achieved by prophylaxis using coagulation factor concentrates or, in haemophilia A, by a bispecific monoclonal antibody called emicizumab that mimics factor VIII activity. Emicizumab binds to both activated factor IX and factor X to allow the formation of the tenase complex that results in thrombin and clot formation (Fig. 25.41). Prophylaxis using concentrates aims to achieve trough levels of factor VIII or IX that protect the patient against spontaneous bleeding. There is debate about optimal trough values needed to achieve this aim. Prophylaxis can be provided in many different ways: daily, on alternate days, or on information from pharmacokinetic studies that inform on the best way of scheduling prophylaxis. Practice in haemophilia A and B is also changing due to the introduction of recombinant factor concentrates that have been manipulated to alter their half-life. In addition to standard half-life recombinant factor VIII and IX, there are new products produced by Fc fusion and pegylation/glycopegylation that extend the half-life of the coagulation factor to the degree that it can be used to alter dosing schedules for prophylaxis.

The alternative approach, which still needs to be used in low- and middle-income countries, is to treat on demand. In severe haemophilia A, bleeding episodes should be treated by raising the factor VIII level, usually by intravenous infusion of factor VIII concentrate. Factor VIII concentrates are freeze-dried and stable at 4°C and can therefore be stored in domestic refrigerators, allowing patients to treat themselves at home at the earliest indication of bleeding. Coagulation factor concentrates prepared from blood donor plasma are now screened for many blood-borne pathogens including HBV, HCV and HIV, and undergo two separate virus inactivation or removal processes during manufacture; these preparations have a good safety record. However, factor concentrates prepared by recombinant technology are now widely available and, although more expensive, are perceived as being safer than those derived from human plasma in relation to infection risk. In addition to raising factor VIII or IX concentrations, resting of the bleeding site with either bed rest or a splint reduces continuing haemorrhage. Once bleeding has settled, the patient should be mobilised and physiotherapy used to restore strength to the surrounding muscles. All non-immune potential recipients of pooled blood products should be offered hepatitis A and B immunisation.

**Fig. 25.40 Clinical manifestations of haemophilia.** On the knee X-ray, repeated bleeds have led to broadening of the femoral epicondyles, and there is no cartilage present, as evidenced by the close proximity of the femur and tibia (A); sclerosis (B), osteophyte (C) and bony cysts (D) are present. (HCV = hepatitis C virus) *Inset (Massive bruising)* From Hoffbrand VA. *Color atlas of clinical hematology*, 3rd edn. Philadelphia: Mosby, Elsevier Inc.; 2000.

**Fig. 25.41 Mechanism of action of novel agents in haemostasis and thrombosis.** Emicizumab is a bispecific antibody that acts in a similar manner to Factor VIIIa by binding to factor IXa and factor X and so can be used in haemophilia A. Caplacizumab inhibits the A1 domain on von Willebrand factor (vWF), preventing binding to platelets and subsequent platelet aggregation. It is increasingly used in the treatment of thrombotic thrombocytopenic purpura (TTP).

The vasopressin receptor agonist desmopressin raises the vWF and factor VIII levels 3–4-fold, which is useful in arresting bleeding in patients with mild or moderate haemophilia A. The dose required for this purpose is higher than that used in diabetes insipidus, usually 0.3 µg/kg, and is given intravenously or subcutaneously. Alternatively, the same effect can be achieved by intranasal administration of a 300 µg dose. Following repeated administration of desmopressin, patients need to be monitored for evidence of water retention, which can result in significant hyponatraemia. Desmopressin is contraindicated in patients with a history of severe arterial disease, because of a propensity to provoke a thrombotic event, and in young children where hyponatraemia can result in fits.

**Complications of coagulation factor therapy**

Before 1986, coagulation factor concentrates from human plasma were not fully virus-inactivated and many patients became infected with HIV and HBV/HCV. Concern that the infectious agent that causes variant Creutzfeldt–Jakob disease (vCJD) (Ch. 28) might be transmissible by blood and blood products has been confirmed in recipients of red cell transfusion (p. 940), and in one recipient of factor VIII. Another serious complication of factor VIII treatment is the development of anti-factor VIII antibodies, which arise in about 25% of those with severe haemophilia. These antibodies rapidly neutralise therapeutic infusions, making treatment relatively ineffective. Infusions of activated clotting factors, e.g.

VIIa or factor VIII inhibitor bypass activity (FEIBA), may stop bleeding. Emicizumab has a major role in the treatment of patients with haemophilia A who have developed inhibitory antibodies.

### Haemophilia B (Christmas disease)

Aberrations of the factor IX gene, which is also present on the X chromosome, result in a reduction of the plasma factor IX level, giving rise to haemophilia B. This disorder is clinically indistinguishable from haemophilia A, but is less common. The frequency of bleeding episodes is related to the severity of the deficiency of the plasma factor IX level. Treatment is with a factor IX concentrate, used in much the same way as factor VIII for haemophilia A. The new extended half-life recombinant factor IX products made by Fc fusion, albumin fusion and pegylation offer the possibility of prophylaxis on a once-weekly or even two-weekly schedule. Although factor IX concentrates shared the problems of virus transmission seen with factor VIII, they do not commonly induce inhibitory antibodies (<1% patients); when this does occur, however, it may be heralded by the development of a severe allergic-type reaction.

### Von Willebrand disease

Von Willebrand disease is a common and usually mild bleeding disorder caused by a quantitative (types 1 and 3) or qualitative (type 2) deficiency of von Willebrand factor (vWF). This protein is synthesised by endothelial cells and megakaryocytes, and is involved in both platelet function and coagulation. It normally forms a multimeric structure that is essential for its interaction with subendothelial collagen and platelets (see Figs. 25.6 and 25.7). vWF acts as a carrier protein for factor VIII, to which it is non-covalently bound; deficiency of vWF lowers the plasma factor VIII level. vWF also forms bridges between platelets and subendothelial components (e.g. collagen; see Fig. 25.6B), allowing platelets to adhere to damaged vessel walls; deficiency of vWF therefore leads to impaired platelet plug formation. Blood group antigens (A and B) are expressed on vWF, reducing its susceptibility to proteolysis; as a result, people with blood group O have lower circulating vWF levels than individuals with non-O groups.

Most patients with von Willebrand disease have a type 1 disorder, characterised by a quantitative decrease in a normal functional protein. This usually arises through reduced synthesis or increased clearance of vWF. Patients with type 2 disorders inherit vWF molecules that are functionally abnormal. The type of abnormality depends on the site of the mutation in the vWF gene and how it affects binding to platelets, collagen and factor VIII. Patients with type 2A disease have abnormalities in vWF-dependent platelet adhesion; those with mutations in the platelet glycoprotein Ib binding site, resulting in increased affinity for glycoprotein 1b, have type 2B disease; those with mutations in the factor VIII binding site have type 2N disease; and those with other abnormalities in platelet binding, but with normal vWF multimeric structure, have type 2M disease. The patterns of laboratory abnormality accompanying these types are described in Box 25.66. The gene for vWF is located on chromosome 12 and the disease is usually autosomal dominantly inherited, except in type 2N and type 3, where inheritance is autosomal recessive.

#### Clinical features

Patients present with haemorrhagic manifestations similar to those in individuals with reduced platelet function. Superficial bruising, epistaxis, menorrhagia and gastrointestinal haemorrhage are common. Bleeding episodes are usually much less frequent than in severe haemophilia, and excessive haemorrhage may be observed only after trauma or surgery. Within a single family, the disease has variable penetrance, so that some members may have quite severe and frequent bleeds, whereas others are relatively asymptomatic.

#### Investigations

The disorder is characterised by reduced activity of vWF and factor VIII. The disease can be classified using a combination of assays that include functional and antigenic measures of vWF, multimeric analysis of the

### 25.66 Classification of von Willebrand disease

Type	Defect	Inheritance	Investigations/patterns
1	Partial quantitative	AD	Parallel decrease in vWF:Ag, RiCoF and VIII:c
2A	Qualitative	AD	Absent HWM of vWF Ratio of vWF activity to antigen <0.7
2B	Qualitative	AD	Reduced HWM of vWF Enhanced platelet agglutination (RIPA)
2M	Qualitative	AD	Ratio of vWF activity to antigen <0.7 Normal multimers of vWF Abnormal vWF/platelet interactions
2N	Qualitative	AR	Defective binding of vWF to VIII Low VIII
3	Severe quantitative	AR or CH	Very low vWF and VIII:c activity Absent multimers

(AD = autosomal dominant; AR = autosomal recessive; CH = compound heterozygote; HWM = high-weight multimers of vWF; RiCoF = ristocetin co-factor; RIPA = ristocetin-induced platelet agglutination; VIII:c = coagulation factor VIII activity in functional assay; vWF = von Willebrand factor; vWF:Ag = vWF antigen measured by ELISA)

protein, and specific tests of function to determine binding to platelet glycoprotein Ib (RIPA) and factor VIII (see Box 25.66). In addition, analysis for mutations in the vWF gene can be informative.

#### Management

Many episodes of mild haemorrhage can be successfully treated by local means or with desmopressin, which raises the vWF level, resulting in a secondary increase in factor VIII. Tranexamic acid may be useful in mucosal bleeding. For more serious or persistent bleeds, haemostasis can be achieved with selected factor VIII concentrates, which contain considerable quantities of vWF in addition to factor VIII. Pure plasma-derived and recombinant vWF concentrates are now available, improving the options and the perceived safety of treatment. Young children and patients with severe arterial disease should not receive desmopressin, and patients with type 2B disease develop thrombocytopenia that may be troublesome following desmopressin. Bleeding in type 3 patients responds only to factor VIII/vWF concentrate.

### Rare inherited bleeding disorders

Severe deficiencies of factor VII, X and XIII occur as autosomal recessive disorders. They are rare, but are associated with severe bleeding. Typical features include haemorrhage from the umbilical stump and intracranial haemorrhage. Factor XIII deficiency in women is typically associated with recurrent fetal loss.

Factor XI deficiency may occur in heterozygous or homozygous individuals. Bleeding is very variable and is not accurately predicted by coagulation factor levels. In general, severe bleeding is confined to patients with levels below 15% of normal.

### Acquired bleeding disorders

DIC is an important cause of bleeding that begins with exaggerated and inappropriate intravascular coagulation. It is discussed later under thrombotic disorders.

#### Liver disease

Although, traditionally, severe parenchymal liver disease is associated with an excess of bleeding, it is now clear that these patients also have an increased risk of venous thrombosis. The description of end-stage liver

disease as a state of auto-anticoagulation is misleading. Although there is reduced hepatic synthesis of procoagulant factors, this is balanced to a degree by the reduced production of natural anticoagulant proteins and reduced fibrinolytic activity in patients with advanced liver disease. In severe parenchymal liver disease, bleeding may arise from many different causes. Major bleeding, is often from structural abnormalities such as oesophageal varices or peptic ulcer, and sepsis and volume overload are common precipitants of bleeding. There is reduced hepatic synthesis, for example, of factors V, VII, VIII, IX, X, XI, prothrombin and fibrinogen. Clearance of plasminogen activator is reduced. Thrombocytopenia may occur secondary to hypersplenism in the presence of portal hypertension and due to reduced production and activity of thrombopoietin in advanced liver disease. In cholestatic jaundice, there is reduced vitamin K absorption, leading to deficiency of factors II, VII, IX and X, but also of proteins C and S. Treatment with plasma products or platelet transfusion should be reserved for acute bleeds or to cover interventional procedures such as liver biopsy. Vitamin K deficiency can be readily corrected with parenteral administration of vitamin K.

### Renal failure

The severity of the haemorrhagic state in renal failure is proportional to the plasma urea concentration. Bleeding manifestations are those of platelet dysfunction, with gastrointestinal haemorrhage being particularly common. The causes are multifactorial and include anaemia, mild thrombocytopenia and the accumulation of low-molecular-weight waste products, normally excreted by the kidney, that inhibit platelet function. Treatment is by dialysis to reduce the urea concentration. Rarely, in severe or persistent bleeding, platelet concentrate infusions and red cell transfusions are indicated. Increasing the concentration of vWF, either by cryoprecipitate or by desmopressin, may promote haemostasis. Patients with significant renal impairment have an increased risk of anticoagulant-related bleeding, particularly with drugs that are at least partially renally excreted.

## Thrombotic disorders

### Venous thromboembolic disease (venous thromboembolism)

While the most common presentations of venous thromboembolism (VTE) are deep vein thrombosis (DVT) of the leg (p. 188) and/or pulmonary embolism (PE; see also p. 546), similar management principles apply to rarer manifestations such as jugular vein thrombosis, upper limb DVT, cerebral sinus thrombosis (p. 1186) and intra-abdominal venous thrombosis (e.g. Budd–Chiari syndrome; p. 909).

VTE has an annual incidence of approximately 1:1000 in Western populations. The relative incidence of DVT:PE is approximately 2:1. Mortality 30 days after DVT is approximately 10%, compared to 15% for PE. All forms of VTE are increasingly common with age and many of the deaths are related to coexisting medical conditions, such as active cancer or inflammatory disease, which predispose the patient to thrombosis in the first place. Risk factors for VTE are often present (Box 25.67) and it is appropriate to seek evidence of these risk factors in determining the long-term management strategy. Figure 25.42 illustrates some of the causes and consequences of VTE. The diagnosis of DVT and PE are discussed on pages 188 and 546, respectively.

### Management of VTE

The mainstay of treatment for all forms of VTE is anticoagulation. This can be achieved in several ways. One option is to use LMWH followed by a coumarin anticoagulant, such as warfarin. Treatment of acute VTE with LMWH should continue for a minimum of 5 days. Patients treated with warfarin should achieve a target INR of 2.5 (range 2–3; pp. 930 and Box 25.25) with LMWH continuing until the INR is above 2. Alternatively, patients may be treated with a DOAC. Rivaroxaban and apixaban may be used immediately from diagnosis without the need for LMWH, while

### 25.67 Factors predisposing to venous thrombosis

#### Patient factors

- Increasing age
- Obesity
- Varicose veins
- Previous deep vein thrombosis
- Family history, especially of unprovoked venous thromboembolism when young
- Transient additional risk factors:
  - Pregnancy/puerperium
  - Oestrogen-containing oral contraceptives and hormone replacement therapy
  - Immobility, e.g. long-distance travel (>4 hrs)
  - Intravenous drug use involving the femoral vein
  - Surgery (see below)
  - Medical illnesses (see below)

#### Surgical conditions

- Major surgery, especially if >30 mins' duration
- Abdominal or pelvic surgery, especially for cancer
- Major lower limb orthopaedic surgery, e.g. joint replacement and hip fracture surgery

#### Medical conditions

- Myocardial infarction/heart failure
- Inflammatory conditions: inflammatory bowel disease, connective tissue disorders and vasculitis
- Malignancy (anti-cancer chemotherapy increases the risk of venous thromboembolism compared with cancer alone)
- Nephrotic syndrome
- Chronic obstructive pulmonary disease
- Severe infection, bacterial or viral
- Neurological conditions associated with immobility, e.g. stroke, paraplegia, Guillain–Barré syndrome
- Any high-dependency admission

#### Haematological disorders

- Polycythaemia rubra vera
- Essential thrombocythaemia
- Deficiency of natural anticoagulants: antithrombin, protein C, protein S
- Paroxysmal nocturnal haemoglobinuria
- Gain-of-function prothrombotic mutations: factor V Leiden, prothrombin gene *G20210A*
- Myelofibrosis

#### Antiphospholipid syndrome

the licences for dabigatran and edoxaban include initial treatment with LMWH for a minimum of 5 days before commencing the DOAC (see Fig. 25.41). In patients with active cancer and VTE, maintenance anticoagulation with LMWH is associated with a lower recurrence rate than warfarin. The use of DOACs in cancer-associated thrombosis is under study. Small studies suggest a possible role for apixaban and rivaroxaban in this context. Patients who have had VTE and have a strong contraindication to anticoagulation and those who continue to have new pulmonary emboli despite therapeutic anticoagulation should have an inferior vena cava (IVC) filter inserted to prevent life-threatening PE.

The optimal *initial* period of anticoagulation is between 6 weeks and 6 months. Patients with a provoked VTE in the presence of a temporary risk factor, which is then removed, can usually be treated for short periods (e.g. 3 months), and indeed anticoagulation for more than 6 months does not alter the rate of recurrence following discontinuation of therapy. If there are ongoing risk factors that cannot be alleviated, such as active cancer, long-term anticoagulation is usually recommended, provided that the risk of bleeding is not deemed excessive.

For patients with unprovoked VTE, the optimum duration of anticoagulation can be difficult to establish. Recurrence of VTE is about 2%–3% per annum in patients who have a temporary medical risk factor at presentation and about 7%–10% per annum in those with apparently unprovoked VTE. This plateaus at around 30%–40% recurrence at 5 years. As such, many patients who have had unprovoked episodes of VTE will benefit from long-term anticoagulation. Several factors predict risk of recurrence following an episode of unprovoked VTE. The strongest

**Fig. 25.42** Causes and consequences of venous thromboembolic disease and its treatment. (DVT = deep vein thrombosis; IVC = inferior vena cava)

predictors of recurrence are male sex and a positive D-dimer assay measured 1 month after stopping anticoagulant therapy. These factors are incorporated into scoring systems to predict recurrence such as the DASH score, HERDOO2 score and the Vienna prediction model.

The management of DVT of the leg should also include elevation and analgesia; in limb-threatening DVT, thrombolysis may also be considered. Thrombolysis for PE is discussed in [Chapter 17](#). Post-thrombotic syndrome is due to damage of venous valves by the thrombus. It occurs in around 30% of patients who sustain a proximal lower limb DVT and results in persistent leg swelling, heaviness and discoloration. The most severe complication of this syndrome is ulceration around the medial malleolus (see [Fig. 25.42](#)). Use of elastic compression stockings following a DVT does not reduce the incidence of post-thrombotic syndrome.

### Prophylaxis of VTE

All patients admitted to hospital should be assessed for their risk of developing VTE and appropriate prophylactic measures should be put in place. Both medical and surgical patients are at increased risk. A summary of the risk categories is given in [Box 25.68](#). Early mobilisation of patients is important to prevent DVT and those at medium or high risk require additional antithrombotic measures; these may be pharmacological or mechanical. There is increasing evidence in high-risk groups, such as patients who have had major lower limb orthopaedic surgery and abdominal or pelvic cancer surgery, for protracted thromboprophylaxis

for as long as 30 days or so after the procedure. Particular care should be taken with the use of pharmacological prophylaxis in patients with a high risk of bleeding or with specific risks of haemorrhage related to the site of surgery or the use of spinal or epidural anaesthesia.

### Inherited and acquired thrombophilia and prothrombotic states

Several inherited conditions predispose to VTE (see [Box 25.67](#)), and have several points in common that are worth noting:

- None of them is strongly associated with arterial thrombosis.
- All are associated with a slightly increased incidence of adverse outcome of pregnancy, including recurrent early fetal loss, but there are no data to indicate that any specific intervention changes that outcome.
- Apart from antithrombin deficiency and homozygous factor V Leiden, most carriers of these genes will never have an episode of VTE; if they do, it will be associated with the presence of an additional temporary risk factor.
- There is little evidence that detection of these abnormalities predicts recurrence of VTE over and above the validated scoring systems mentioned above.

## 25.68 Antithrombotic prophylaxis

### Indications

Patients in the following categories should be considered for specific antithrombotic prophylaxis:

#### Moderate risk of DVT

- Major surgery:
  - In patients >40 years or with other risk factor for VTE
- Major medical illness, e.g.:
  - Heart failure
  - Myocardial infarction with complications
  - Sepsis
  - Inflammatory conditions, including inflammatory bowel disease
  - Active malignancy
  - Nephrotic syndrome
  - Stroke and other conditions leading to lower limb paralysis

#### High risk of DVT

- Major abdominal or pelvic surgery for malignancy or with history of DVT or known thrombophilia (see [Box 25.4](#))
- Major hip or knee surgery
- Neurosurgery

### Methods of VTE prophylaxis

#### Mechanical

- Intermittent pneumatic compression
- Graduated compression stockings
- Mechanical foot pumps

#### Pharmacological

- LMWHs
- Rivaroxaban
- Unfractionated heparin
- Apixaban
- Fondaparinux
- Warfarin
- Dabigatran

(DVT = deep vein thrombosis; VTE = venous thromboembolism)

- None of these conditions per se requires treatment with anticoagulants. Patients with thrombosis should receive anticoagulation, as discussed earlier. Patients who are deemed to be at high risk of thrombosis, e.g. those with antithrombin deficiency in pregnancy, should receive treatment or prophylactic doses of unfractionated or LMW heparin to cover the period of risk only.

### Antithrombin deficiency

Antithrombin (AT) is a serine protease inhibitor (SERPIN) that inactivates the activated coagulation factors IIa, IXa, Xa and XIa. Heparins and fondaparinux achieve their therapeutic effect by potentiating the activity of AT. Familial deficiency of AT is inherited in an autosomal dominant manner; homozygosity for mutant alleles is not compatible with life. Around 70% of affected individuals will have an episode of VTE before the age of 60 years and the relative risk for thrombosis compared with the background population is 10–20-fold. Pregnancy is a high-risk period for VTE and this requires fairly aggressive management with doses of LMWH that are greater than the usual prophylactic doses ( $\geq 100$  U/kg/day). AT concentrate (either plasma-derived or recombinant) is available; this is required for cardiopulmonary bypass and may be used as an adjunct to heparin in surgical prophylaxis and in the peripartum period.

### Protein C and S deficiencies

Protein C and its co-factor protein S are vitamin K-dependent natural anticoagulants involved in switching off coagulation factor activation (factors Va and VIIIa) and so thrombin generation (see [Fig. 25.6F](#)). Inherited deficiency of either protein C or S results in a prothrombotic state with a 5-fold relative risk of VTE compared with the background population.

### Factor V Leiden

Factor V Leiden results from a gain-of-function, single-base-pair mutation, which prevents the cleavage and hence inactivation of activated

factor V. This results in a relative risk of venous thrombosis of 5 in heterozygotes and 50 or more in rare homozygotes. The mutation is found in about 5% of Northern Europeans, 2% of Hispanics, 1.2% of African Americans, 0.5% of Asian Americans and 1.25% of Indigenous Americans, and is rare in Chinese and Malay people.

### Prothrombin G20210A

This gain-of-function mutation in the non-coding 3' end of the prothrombin gene is associated with an increased plasma level of prothrombin. It is present in about 2% of Northern Europeans, but is rare in native populations of Korea, China, India and Africa. In the heterozygous state, it is associated with a 2–3-fold increase in risk of VTE compared with the background population.

## Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is a clinicopathological entity in which a constellation of clinical conditions, alone or in combination, is found in association with a persistently positive test for an antiphospholipid antibody. The antiphospholipid antibodies are heterogeneous and typically are directed against proteins that bind to phospholipids ([Box 25.69](#)). Although causal roles for these antibodies have been proposed, the mechanisms underlying the clinical features of APS are not clear. In clinical practice, two types of test are used, which detect:

- antibodies that bind to negatively charged phospholipid on an ELISA plate (called an anticardiolipin antibody test); these assays usually contain  $\beta_2$ -glycoprotein 1 ( $\beta_2$ -GP1)
- those that interfere with phospholipid-dependent coagulation tests like the APTT or the dilute Russell viper venom time (DRVVT; called a lupus anticoagulant test).

The term antiphospholipid antibody encompasses both a lupus anticoagulant and an anticardiolipin antibody/anti- $\beta_2$ -GP1; individuals may be positive for one, two or all three of these activities. It has been shown that patients who are 'triple positive' have an increased likelihood of thrombotic events compared with single or double positives.

### Clinical features and management

APS may present in isolation (primary APS) or in association with one of the conditions shown in [Box 25.69](#), most typically systemic lupus erythematosus (secondary APS). Most patients present with a single manifestation and APS is now most frequently diagnosed in women with

## 25.69 Antiphospholipid syndrome (APS)

### Clinical manifestations

- Adverse pregnancy outcome
  - Recurrent first trimester abortion ( $\geq 3$ )
  - Unexplained death of morphologically normal fetus after 10 weeks' gestation
  - Severe early pre-eclampsia
- Venous thromboembolism
- Arterial thromboembolism
- Livedo reticularis, catastrophic APS, transverse myelitis, skin necrosis, chorea

### Conditions associated with secondary APS

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Systemic sclerosis
- Behçet's disease
- Temporal arteritis
- Sjögren syndrome

### Targets for antiphospholipid antibodies

- $\beta_2$ -glycoprotein 1
- Protein C
- Annexin V
- Prothrombin (may result in haemorrhagic presentation)

adverse outcomes of pregnancy. It is extremely important to make the diagnosis in patients with APS, whatever the manifestation, because it affects the prognosis and management of arterial thrombosis, VTE and pregnancy.

Arterial thrombosis, typically stroke, associated with APS should probably be treated with anti-coagulation, as opposed to anti-platelet therapy. APS-associated VTE is one of the situations in which the predicted recurrence rate is high enough to indicate long-term anti-coagulation after a first event. Recent evidence suggests that patients with APS presenting with thrombotic events should receive warfarin as opposed to a DOAC as anticoagulant of choice. In women with obstetric presentations of APS, intervention with heparin and aspirin is almost routinely prescribed, although there is little evidence from clinical trials that it is an effective therapy in increasing the chance of a successful pregnancy outcome.

## Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) may complicate a range of illnesses (Box 25.70). It is characterised by systemic activation of the pathways involved in coagulation and its regulation. This may result in the generation of intravascular fibrin clots causing multi-organ failure, with simultaneous coagulation factor and platelet consumption, causing bleeding. The systemic coagulation activation is induced either through cytokine pathways, which are activated as part of a systemic inflammatory response, or by the release of procoagulant substances such as tissue factor. In addition, suboptimal function of the natural anticoagulant pathways and dysregulated fibrinolysis contribute to DIC. There is consumption of platelets, coagulation factors (notably factors V and VIII) and fibrinogen. The lysis of fibrin clot results in production of fibrin degradation products (FDPs), including D-dimers.

25.70 Disseminated intravascular coagulation (DIC)	
<b>Underlying conditions</b>	
<ul style="list-style-type: none"> <li>• Infection/sepsis</li> <li>• Trauma</li> <li>• Obstetric, e.g. amniotic fluid embolism, placental abruption, pre-eclampsia</li> <li>• Severe liver failure</li> <li>• Malignancy, e.g. solid tumours and leukaemias</li> <li>• Tissue destruction, e.g. pancreatitis, burns</li> <li>• Vascular abnormalities, e.g. vascular aneurysms, liver haemangiomas</li> <li>• Toxic/immunological, e.g. ABO incompatibility, snake bites, recreational drugs</li> </ul>	
<b>ISTH scoring system for diagnosis of DIC</b>

<b>Total score</b>	
$\geq 5 =$ Compatible with overt DIC $< 5 =$ Repeat monitoring over 1–2 days	
(ISTH = International Society for Thrombosis and Haemostasis)	

## Investigations

DIC should be suspected when any of the conditions listed in Box 25.70 are met. Measurement of coagulation times (APTT and PT; see Box 25.3) along with fibrinogen, platelet count and FDPs, helps in the assessment of prognosis and aids clinical decision-making with regard to both bleeding and thrombotic complications.

## Management

Therapy is primarily aimed at the underlying cause. These patients will often require intensive care to deal with concomitant issues, such as acidosis, dehydration, renal failure and hypoxia. Blood component therapy, such as fresh frozen plasma, cryoprecipitate and platelets, should be given if the patient is bleeding or to cover interventions with a high bleeding risk, but should not be prescribed routinely based on coagulation tests and platelet counts alone. Prophylactic doses of heparin should be given, unless there is a clear contraindication. Established thrombosis should be treated cautiously with therapeutic doses of unfractionated heparin, unless clearly contraindicated. Patients with DIC should not, in general, be treated with antifibrinolytic therapy, e.g. tranexamic acid.

## Thrombotic thrombocytopenic purpura

Like DIC and also heparin-induced thrombocytopenia (p. 937), thrombotic thrombocytopenic purpura (TTP) is a disorder in which thrombosis is accompanied by paradoxical thrombocytopenia. TTP is characterised by a pentad of findings, although few patients have all five components:

- thrombocytopenia
- microangiopathic haemolytic anaemia
- neurological sequelae
- fever
- renal impairment.

It is an acute autoimmune disorder mediated by antibodies against ADAMTS-13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif).

This enzyme normally cleaves vWF multimers to produce normal functional units, and its deficiency results in large vWF multimers that cross-link platelets. The features are of microvascular occlusion by platelet thrombi affecting key organs, principally brain and kidneys. It is a rare disorder (1 in 750 000 per annum), which may occur alone or in association with drugs (ticlopidine, ciclosporin), HIV, shiga toxins (Ch. 13) and malignancy. It should be treated by emergency plasma exchange. Glucocorticoids, aspirin and rituximab also have a role in management. Caplacizumab, a monoclonal antibody directed against the A domain of vWF, is associated with improved outcomes, less relapse and faster time to recovery in patients with acquired TTP. Untreated mortality rates are 90% in the first 10 days, and even with appropriate therapy, the mortality rate is 20%–30% at 6 months.

## Multiple Choice Questions

25.1. Which of the following is not true of emicizumab?

- A. It emulates the role of factor VIII by allowing formation of the tenase complex
- B. It is useful in the management of haemophilia A
- C. It is useful in the management of haemophilia A patients with inhibitors
- D. It is a bispecific monoclonal antibody
- E. It is given intravenously three times weekly to provide prophylaxis

Answer: E.

Emicizumab is a bispecific monoclonal antibody which replicates the action of factor VIII in making the tenase complex. This results in downstream activation of factor X and subsequently thrombin and clot generation. Emicizumab can therefore be used in all categories of haemophilia A and has had its greatest effect on patients with inhibitors. Its great clinical advantage is that it is a subcutaneous preparation

25.2. A 20-year-old woman who has sustained an apparently unprovoked pulmonary embolism has a positive test for a lupus anticoagulant on admission. Both anticardiolipin and anti-beta<sub>2</sub> glycoprotein-1 antibodies are negative. She has no history of SLE or any connective tissue disease. Which of the following best describes the diagnosis and management?

- A. She has antiphospholipid syndrome and she should be anticoagulated indefinitely with low molecular weight heparin which is the drug of choice in APS
- B. She does not have antiphospholipid syndrome because aCL and anti-B2 GP-1 are both negative
- C. She has antiphospholipid syndrome and she should be anticoagulated indefinitely with warfarin which is the drug of choice in APS
- D. She may have APS but only if she has a repeated positive LA 12 weeks after the first positive
- E. She does not have proven APS and should be anticoagulated indefinitely with rivaroxaban

Answer: D.

APS is a clinicopathological entity comprising a clinical event (thrombosis in arterial or venous circulation or adverse outcome of pregnancy) accompanied by a persistent positive antiphospholipid antibody test (any) on two occasions at least 12 weeks apart. Recent data from the TRAPs study has resulted in the regulatory bodies indicating that warfarin is the optimal anticoagulant for patients with VTE associated with APS.

25.3. A 7-year-old Italian boy attends the local hospital. He has been unwell for 5 days with a mild fever, low energy and poor appetite. On examination he is listless with conjunctival pallor. His cheeks appear flushed. A widespread, fine erythematous rash over the trunk and limbs is noted. Bloods show:  
WBC  $14.9 \times 10^9/L$  (4–11)  
Hb 51 g/L (113–141)  
MCV 72 fL (80–100)  
Reticulocytes  $12 \times 10^9/L$  (25–85)  
Bilirubin 62  $\mu\text{mol/L}$  (3–21)  
Blood film: many spherocytes and atypical lymphocytes

What is the most likely diagnosis?

- A. Hereditary spherocytosis with acute haemolytic crisis
- B. Infectious mononucleosis
- C. Hereditary spherocytosis with megaloblastic crisis
- D. Hereditary elliptocytosis with acute haemolytic crisis
- E. Hereditary spherocytosis with aplastic crisis

Answer: E.

Parvovirus B19 (erythrovirus) will precipitate an aplastic crisis in hereditary spherocytosis. There is a characteristic 'flushed cheeks' rash. The virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count. An elevated MCV is associated with a megaloblastic crisis and an acute haemolytic crisis where a reticulocytosis will also be prominent. Elliptocytes are found in hereditary elliptocytosis. Infectious mononucleosis presents with sore throat, lymphadenopathy and atypical mononuclear cells on the blood film in the absence of spherocytes.

25.4. A 55-year-old man presents with further relapse of diffuse large B-cell non-Hodgkin lymphoma (DLBL) having failed previous treatments with R-CHOP chemotherapy and R-DHAP chemotherapy followed by autologous stem cell transplantation. In considering further treatment with CAR-T-cell therapy which of the following statements is true?

- A. The patient must achieve a negative FDG PET-CT prior to CAR-T-cell therapy
- B. CAR-T cells can be prepared and delivered within one week
- C. The T cells are most commonly provided by an unrelated donor
- D. A chimeric antigen receptor (CAR) is composed of part antibody molecule and part T-cell receptor
- E. The treatment works by exhausting cytotoxic T-cell function

Answer: D.

The patient fulfils one of the currently licensed indications for CAR-T-cell therapy of multiply relapsed DLBCL. The patient does not have to be in remission but the disease needs to be controlled enough for the patient to be fit enough for the procedure. The process of preparing CAR-T cells is complex and takes about 8 weeks in total. Current CAR-T cells use autologous T cells taken from the patient. Future CAR-T-cell products may be prepared from donor T cells as so-called 'off the shelf CAR-T cells'. The CAR-T cells work by enhanced recognition and killing of lymphoma cells by the modified T cells. T-cell exhaustion is a process by which tumours protect themselves. Checkpoint inhibitors reverse this process.

25.5. A 40-year-old woman presents with a persistent blocked nose associated with swelling of the left cheek. A CT scan shows a mass in the post-nasal space and involving the left maxillary sinus. A biopsy confirms plasmacytoma. Which of the following is in keeping with a diagnosis of solitary plasmacytoma?

- A. Multiple lytic bone lesions on an MRI scan
- B. 20% plasma cells in a bone marrow sample taken from the posterior iliac crest
- C. Pancytopenia
- D. Hypercalcaemia associated with acute renal failure
- E. Low-level IgG paraprotein

Answer: E.

Extramedullary solitary plasmacytomas most commonly occur in the upper aero-digestive tract. They present as isolated tumours of plasma cells and other features of disseminated myeloma including multiple lytic lesions, hypercalcaemia, widespread marrow involvement and cytopenias are absent. A low-level intact paraprotein is commonly seen.

**General Assessment of Locomotor System (GALS) and Schöber's test**

**1 Gait**

Ask patient to walk for a few steps, then come back. Look for pain or limp

**2 Arms**

<p>Inspect hands for swelling or deformity</p> 	<p>Press over supraspinatus (tests for hyperalgesia)</p> 	
<p>Ask patient to make a fist and open and close fingers (tests hand function)</p> 		<p>Ask patient to put hands behind head (tests shoulder movements)</p>
<p>Squeeze metacarpals (tests for inflammation)</p> 	<p>Patient turns palms up and down with elbows at side (tests supination and pronation of wrists and elbow)</p>	 <p>Patient flexes elbows to touch shoulder (tests elbow flexion)</p>

**3 Legs**

<p>Flex each hip with hand on knee. Rotate hips internally and externally (tests hip movements and detects knee crepitus)</p> 	<p>Palpate each knee for warmth and swelling (tests for synovitis and effusion)</p> 	 <p>Inspect ankles and feet. Squeeze forefoot (tests for metatarsophalangeal synovitis)</p>
--	---	--

**4 Spine**

 <p>Patient looks at ceiling and then puts chin on chest (tests flexion and extension cervical spine)</p>	 <p>Ask patient to try to put ear on shoulder (tests lateral flexion cervical spine)</p>	 <p>Patient slides hand down leg to knee (tests lateral spine flexion)</p>	 <p>Inspect spine from behind and side, looking for scoliosis, kyphosis or localised deformity. Ask patient to touch toes</p>
--	---	---	--

**5 Schöber's test**

<p>Mark skin with pen in midline about 4 cm below superior iliac crest. Make another mark in midline 10 cm above first. Ask patient to bend forwards. Normally, distance between marks should increase to 15 cm</p> 	<p>Stand behind patient and hold their pelvis. Ask them to turn from side to side without moving their feet (tests thoracolumbar rotation)</p> 
---	--

Disorders of the musculoskeletal system affect all ages and ethnic groups. In the UK, about 25% of new consultations in general practice are for musculoskeletal symptoms. Musculoskeletal diseases may arise from processes affecting bones, joints, muscles, or connective tissues such as skin and tendon. The principal manifestations are pain and impairment of locomotor function.

Diseases of the musculoskeletal system tend to be more common in women and most increase in frequency with increasing age. They are the most common cause of physical disability in older people and account for one-third of physical disability at all ages.

## Functional anatomy and physiology

The musculoskeletal system is responsible for movement of the body, provides a structural framework to protect internal organs and acts as a reservoir for storage of calcium and phosphate in the regulation of mineral homeostasis. The main components of the musculoskeletal system are depicted in Figure 26.1.

### Bone

Bones fall into two main types, based on their embryonic development. Flat bones, such as the skull, develop by intramembranous ossification, in which embryonic fibroblasts differentiate directly into bone within condensations of mesenchymal tissue during early fetal life. Long bones, such as the femur and radius, develop by endochondral ossification from a cartilage template. During development, the cartilage is invaded by vascular tissue containing osteoprogenitor cells and is gradually replaced

by bone from centres of ossification situated in the middle and at the ends of the bone. A thin remnant of cartilage called the growth plate or epiphysis remains at each end of long bones and chondrocyte proliferation here is responsible for skeletal growth during childhood and adolescence. At the end of puberty, the increased levels of sex hormones halt cell division in the growth plate. The cartilage remnant then disappears as the epiphysis fuses and longitudinal bone growth ceases.

Two types of bone tissue are present in the normal skeleton (Fig. 26.1). Cortical bone is formed from Haversian systems, comprising concentric lamellae of bone tissue surrounding a central canal that contains blood vessels. Cortical bone is dense and forms a hard envelope around the long bones. Trabecular or cancellous bone fills the centre of the bone and consists of an interconnecting meshwork of trabeculae, separated by spaces filled with bone marrow. Important cell types in bone are:

- **Osteoclasts:** multinucleated cells of haematopoietic origin, responsible for bone resorption.
- **Osteoblasts:** mononuclear cells derived from marrow stromal cells responsible for bone formation.
- **Osteocytes:** cells that differentiate from osteoblasts that become embedded in bone matrix during bone formation. They are responsible for sensing and responding to mechanical stimuli and for coordinating osteoclast and osteoblast activity by producing receptor activator of nuclear factor kappa B ligand (RANKL) and sclerostin (SOST).
- **Bone marrow stromal cells:** cells that produce RANKL and macrophage colony-stimulating factor (M-CSF), which act together to stimulate osteoclast formation, and other cytokines that support haematopoiesis.
- **Bone lining cells:** flattened cells lining the bone surface that differentiate from osteoblasts when bone formation is complete.

Fig. 26.1 Structure of the major musculoskeletal tissues.

## Bone matrix and mineral

The most abundant protein of bone is type I collagen, which is formed from two  $\alpha 1$  peptide chains and one  $\alpha 2$  chain wound together in a triple helix. Type I collagen is proteolytically processed inside the cell before being laid down in the extracellular space, releasing propeptide fragments that can be used as biochemical markers of bone formation. Subsequently, the collagen fibrils become 'cross-linked' to one another

**Fig. 26.2** The bone remodelling cycle. Bone is renewed and repaired by the process of bone remodelling. This begins by removal of old and damaged bone by osteoclasts during the phase of bone resorption. After about 10 days, the osteoclasts undergo programmed cell death (apoptosis) and during the reversal phase are replaced by osteoblasts, which begin to fill in the resorbed area with new bone matrix, heralding the start of bone formation. The bone matrix is initially uncalcified (osteoid) but then becomes mineralised to form mature bone.

by pyridinium molecules, a process that enhances bone strength. When bone is broken down by osteoclasts, the cross-links are released into the circulation. These can be measured biochemically and are sometimes used clinically to assess levels of bone resorption. Bone is normally laid down in an orderly fashion, but when bone turnover is high, as in Paget's disease or severe hyperparathyroidism, it is laid down in a chaotic pattern, giving rise to 'woven bone' that is mechanically weak. Bone matrix also contains growth factors, other structural proteins and proteoglycans, thought to be involved in helping bone cells attach to bone matrix and in regulating bone cell activity. The other major component of bone is mineral, comprised of calcium and phosphate crystals deposited between the collagen fibrils in the form of hydroxyapatite [ $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ ]. Mineralisation is essential for bone rigidity and strength, but over-mineralisation causes bone to become brittle. In clinical practice, increased mineralisation can occur in some types of osteogenesis imperfecta and in response to long-term bisphosphonate therapy.

## Bone remodelling

Bone remodelling is required for renewal and repair of the skeleton throughout life. This is a cyclical process that has four phases: quiescence, resorption, reversal and formation, as illustrated in Figure 26.2. Remodelling starts with the attraction of osteoclast precursors in peripheral blood to the target site, probably by local release of chemotactic factors from areas of microdamage. The osteoclasts resorb bone and, after about 10 days, undergo programmed cell death (apoptosis), heralding the start of the reversal phase when osteoblast precursors are recruited to the resorption site. The osteoblast precursors differentiate into mature osteoblasts and form new bone during the formation phase. Initially, the matrix is unmineralised (osteoid) but eventually becomes mineralised to form mature bone. Some osteoblasts become trapped in bone matrix and differentiate into osteocytes, which play a key regulatory role in coordinating bone formation and resorption, whereas others differentiate into bone-lining cells.

The cellular and molecular mediators of this bone remodelling are shown in more detail in Figure 26.3. Osteoclast precursors are derived from haematopoietic stem cells and differentiate into mature osteoclasts

**Fig. 26.3** Cellular and molecular regulators of bone remodelling. Osteoclast precursors are derived from haematopoietic stem cells. They differentiate into mature osteoclasts in response to the receptor activator of nuclear factor kappa B ligand (RANKL), which is produced by osteocytes, bone marrow stromal cells and activated T cells (not shown), and macrophage colony-stimulating factor (M-CSF), which is produced by bone marrow stromal cells. Osteoprotegerin (OPG) is also produced in the bone microenvironment, where it inhibits osteoclastic bone resorption by blocking the effect of RANKL. Osteoblasts, which are derived from bone marrow stromal cells, are responsible for bone formation. Osteoblast activity is stimulated by signalling molecules in the Wnt family but inhibited by sclerostin (SOST), which is produced by osteocytes. In addition to their role in regulating osteoclast and osteoblast activity, osteocytes have an endocrine function in regulating phosphate homeostasis by producing fibroblast growth factor 23 (FGF23), which acts on the kidney to promote phosphate excretion.

26.1 Key regulators of bone remodelling			
Mediator	Source	Main effects	Comment
<b>RANKL</b>	Osteocytes Stromal cells Activated T cells	Stimulates bone resorption	Activates RANK
<b>Osteoprotegerin</b>	Stromal cells Lymphocytes	Inhibits bone resorption	Acts as decoy receptor for RANKL
<b>Wnt</b>	Stromal cells	Stimulates bone formation	Activates LRP receptors
<b>Sclerostin</b>	Osteocytes	Inhibits bone formation	Blocks effect of Wnt on LRP receptors
<b>Parathyroid hormone</b>	Parathyroid glands	Increases bone resorption and formation	
<b>Thyroid hormone</b>	Thyroid gland	Increases bone resorption and formation	
<b>Oestrogen</b>	Ovary	Inhibits bone resorption	
<b>Glucocorticoid</b>	Adrenal gland Exogenous	Inhibits bone formation	

(LRP = lipoprotein receptor-related protein; RANKL = receptor activator of nuclear factor kappa B ligand)

in response to M-CSF, produced by bone marrow stromal cells, and RANKL, produced by both osteocytes and bone marrow stromal cells. The RANKL binds to and activates a receptor called RANK (receptor activator of nuclear factor kappa B) on osteoclast precursors, promoting osteoclast differentiation and bone resorption. This effect is blocked by osteoprotegerin (OPG), which is a decoy receptor for RANKL that inhibits osteoclast formation. Once formed, mature osteoclasts attach to the bone surface by a tight sealing zone and secrete hydrochloric acid and proteolytic enzymes, including cathepsin K, into the space underneath, which is known as the Howship's lacuna. The acid dissolves the mineral and cathepsin K degrades collagen. Osteocytes also produce sclerostin (SOST), which is a potent inhibitor of bone formation. Under conditions of mechanical loading, sclerostin production by osteocytes is inhibited, allowing bone formation to proceed, stimulated by members of the Wnt family of signalling proteins. The Wnt molecules stimulate bone formation by activating members of the lipoprotein receptor-related protein (LRP) family, the most important of which are LRP4, LRP5 and LRP6. Sclerostin antagonises the effects of Wnt family members by blocking their interaction with LRP family members. Finally, osteocytes play a critical role in phosphate homeostasis by producing the hormone FGF23, which regulates renal tubular phosphate reabsorption. Key regulators of bone remodelling are summarised in [Box 26.1](#).

Mineralisation of bone is critically dependent on the enzyme alkaline phosphatase (ALP), which is produced by osteoblasts and degrades pyrophosphate, an inhibitor of mineralisation. Bone remodelling is predominantly regulated at a local level but can be influenced by circulating hormones or mechanical loading, which can up-regulate or down-regulate remodelling across the whole skeleton ([Box 26.1](#)).

## Joints

There are three main types of joint: fibrous, fibrocartilaginous and synovial ([Box 26.2](#)).

### Fibrous and fibrocartilaginous joints

These comprise a simple bridge of fibrous or fibrocartilaginous tissue joining two bones together where there is little requirement for movement such as the symphysis pubis. The intervertebral disc is a special type of fibrocartilaginous joint in which an amorphous area, called the nucleus pulposus, lies in the centre of the fibrocartilaginous bridge. The nucleus has a high water content and acts as a cushion to improve the disc's shock-absorbing properties.

26.2 Types of joint		
Type	Range of movement	Examples
<b>Fibrous</b>	Minimal	Skull sutures
<b>Fibrocartilaginous</b>	Limited	Symphysis pubis Costochondral junctions Intervertebral discs Sacroiliac joints
<b>Synovial</b>	Large	Most limb joints Temporomandibular Costovertebral

### Synovial joints

These are complex structures containing several cell types. They are found where a wide range of movement is needed ([Fig. 26.4](#)).

#### Articular cartilage

This avascular tissue covers the bone ends in synovial joints. Cartilage cells (chondrocytes) are responsible for synthesis and turnover of cartilage, which consists of a mesh of type II collagen fibrils that extend through a hydrated 'gel' of proteoglycan molecules. The most important proteoglycan is aggrecan, which consists of a core protein to which several glycosaminoglycan (GAG) side chains are attached ([Fig. 26.5](#)). The GAGs are polysaccharides that consist of long chains of disaccharide repeats comprising one normal sugar and an amino sugar. The most abundant GAGs in aggrecan are chondroitin sulphate and keratan sulphate. Hyaluronan is another important GAG that binds to aggrecan molecules to form very large complexes with a total molecular weight of more than 100 million. Aggrecan has a strong negative charge and avidly binds water molecules to assume a shape that occupies the maximum possible volume available. The expansive force of the hydrated aggrecan, combined with the restrictive strength of the collagen mesh, gives articular cartilage excellent shock-absorbing properties.

With ageing, the concentration of chondroitin sulphate decreases, whereas that of keratan sulphate increases, resulting in reduced water content and shock-absorbing properties. These changes differ from those found in osteoarthritis, where there is abnormal chondrocyte division, loss of proteoglycan from matrix and an increase in water content.

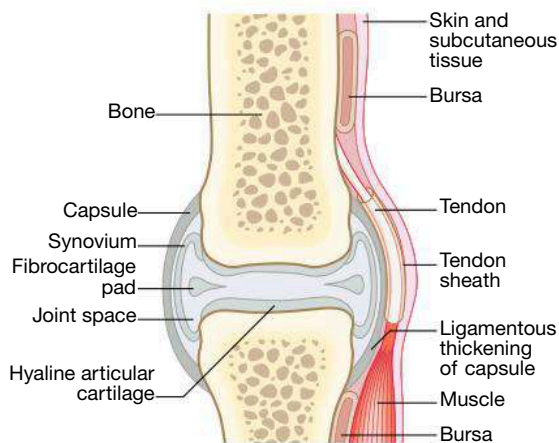

Fig. 26.4 Structure of a synovial joint.

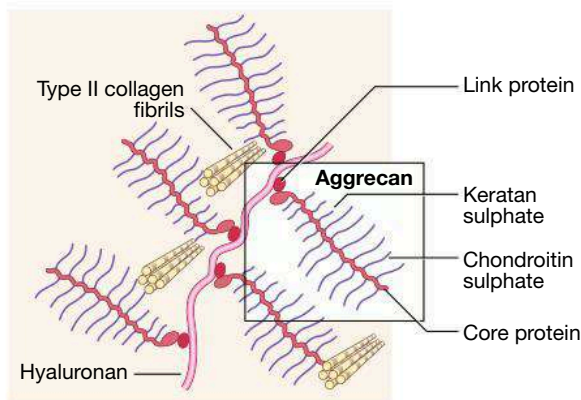

Fig. 26.5 Ultrastructure of articular cartilage.

Cartilage matrix is constantly turning over and in health there is a perfect balance between synthesis and degradation. Degradation of cartilage matrix is carried out by aggrecanases and matrix metalloproteinases, responsible for the breakdown of proteins and proteoglycans, and by glycosidases, responsible for the breakdown of GAGs. Pro-inflammatory cytokines, such as interleukin (IL)-1 and tumour necrosis factor (TNF), which are released during inflammation, stimulate production of aggrecanase and metalloproteinases, causing cartilage degradation.

### Synovial fluid

The surfaces of articular cartilage are separated by a space filled with synovial fluid (SF), a viscous liquid that lubricates the joint. It is an ultrafiltrate of plasma, into which synovial cells secrete hyaluronan and proteoglycans.

### Intra-articular discs

Some joints contain fibrocartilaginous discs within the joint space that act as shock absorbers. The most clinically important are the menisci of the knee. These are avascular structures that remain viable because of diffusion of oxygen and nutrients from the SF.

### Synovial membrane, joint capsule and bursae

The bones of synovial joints are connected by the joint capsule, a fibrous structure richly supplied with blood vessels, nerves and lymphatics which encases the joint. Ligaments are discrete, regional thickenings of the capsule that act to stabilise joints (see Fig. 26.4). The inner surface of the joint capsule is the synovial membrane, comprising an outer layer of blood vessels and loose connective tissue that is rich in type I collagen,

and an inner layer 1–4 cells thick consisting of two main cell types. Type A synoviocytes are phagocytic cells derived from the monocyte/macrophage lineage and are responsible for removing particulate matter from the joint cavity; type B synoviocytes are fibroblast-like cells that secrete SF. Most inflammatory and degenerative joint diseases are associated with thickening of the synovial membrane and infiltration by lymphocytes, polymorphs and macrophages.

Bursae are hollow sacs lined with synovium and contain a small amount of SF. They help tendons and muscles move smoothly in relation to bones and other articular structures.

## Skeletal muscle

Skeletal muscles are responsible for body movements and respiration. Muscle consists of bundles of cells (myocytes) embedded in fine connective tissue containing nerves and blood vessels. Myocytes are large, elongated, multinucleated cells formed by fusion of mononuclear precursors (myoblasts) in early embryonic life. The nuclei lie peripherally and the centre of the cell contains actin and myosin molecules, which interdigitate with one another to form the myofibrils that are responsible for muscle contraction. The molecular mechanisms of skeletal muscle contraction are the same as for cardiac muscle (p. 389). Myocytes contain many mitochondria that provide the large amounts of adenosine triphosphate (ATP) necessary for muscle contraction and are rich in the protein myoglobin, which acts as a reservoir for oxygen during contraction.

Individual myofibrils are organised into bundles (fasciculi) that are bound together by a thin layer of connective tissue (the perimysium). The surface of the muscle is surrounded by a thicker layer of connective tissue, the epimysium, which merges with the perimysium to form the muscle tendon. Tendons are tough, fibrous structures that attach muscles to a point of insertion on the bone surface called the enthesis. Enthuses transmit tensile load from soft tissues to bone and are composed of either fibrous tissue or fibrocartilage, depending on the local needs of the tissue in adapting to physical stress. The entheses are particularly affected by inflammation in patients with spondyloarthritis, as discussed later in this chapter.

## Investigation of musculoskeletal disease

Clinical history and examination usually provide sufficient information for the diagnosis and management of many musculoskeletal diseases. Investigations are helpful in confirming the diagnosis, assessing disease activity and indicating prognosis. Investigations that are commonly used in musculoskeletal disease are discussed in more detail below

### Joint aspiration

Joint aspiration with examination of SF is pivotal in patients with suspected septic arthritis, crystal arthritis or intra-articular bleeding. It should be carried out in all individuals with acute monoarthritis and samples should be sent for microbiology and clinical chemistry.

It is possible to obtain SF by aspiration from most peripheral joints and only a small amount is required for diagnostic purposes. Normal SF is present in small volume, is clear and either colourless or pale yellow, and has a high viscosity. It contains few cells. With joint inflammation, the volume increases, the cell count and the proportion of neutrophils rise (causing turbidity), and the viscosity reduces (due to enzymatic degradation of hyaluronan and aggrecan). Turbid fluid with a high neutrophil count occurs in septic arthritis, crystal arthritis and reactive arthritis. High concentrations of urate crystals or cholesterol can make SF appear white. Non-uniform blood-staining usually reflects needle trauma to the synovium. Uniform blood-staining is most commonly due to a bleeding diathesis, trauma or pigmented villonodular synovitis, but can also occur in severe inflammatory synovitis. A lipid layer floating above blood-stained

**Fig. 26.6** Compensated polarised light microscopy of synovial fluids ( $\times 400$ ).

**A** Monosodium urate crystals show bright negative birefringence under polarised light and needle-shaped morphology. **B** Calcium pyrophosphate crystals show weak positive birefringence under polarised light and are few in number. They are more difficult to detect than urate crystals.

fluid is diagnostic of intra-articular fracture and is caused by release of bone marrow fat into the joint.

Crystals can be identified by compensated polarised light microscopy of fresh SF (to avoid crystal dissolution and post-aspiration crystallisation). Urate crystals are long and needle-shaped, and show a strong light intensity and negative birefringence (Fig. 26.6A). Calcium pyrophosphate crystals are smaller, rhomboid in shape and usually less numerous than urate crystals; they have weak intensity and positive birefringence (Fig. 26.6B).

## Imaging

### Plain X-rays

X-rays show structural changes that are of value in the differential diagnosis and monitoring of many bone and joint diseases (Box 26.3).

They are of diagnostic value in osteoarthritis (OA), where they demonstrate joint space narrowing that tends to be focal rather than widespread (as seen in inflammatory arthritis). Other features of OA detected on X-rays include osteophytes, subchondral sclerosis, bone cysts and calcified loose bodies within the synovium (see Fig. 26.18). Erosions and sclerosis of the sacroiliac joints and syndesmophytes in the spine may be observed in spondyloarthritis (SpA; see Fig. 26.41). Erosions, associated with new bone formation and periosteal reaction, also occur in peripheral joints and at entheses in SpA. In tophaceous gout, well-defined punched-out erosions may occur (see Fig. 26.27). Calcification of cartilage, tendons and soft tissues or muscle occurs mainly in chondrocalcinosis (see Fig. 26.28), calcium-containing crystal diseases, tumoral calcinosis and autoimmune connective tissue diseases.

X-rays are of limited value in the diagnosis of rheumatoid arthritis (RA) because features such as erosions, joint space narrowing and periarticular osteoporosis may be detectable only after several months or even years. The main indication for X-rays in RA is in the assessment of disease over time when structural damage to the joints is suspected.

### Radionuclide bone scintigraphy

Radionuclide bone scintigraphy is mainly used in the diagnosis of metastatic bone disease and Paget's disease of bone. Abnormalities may also be observed in primary bone tumours, complex regional pain syndrome, OA and different types of inflammatory arthritis, but the changes are non-specific and other imaging modalities are more commonly used. Bone scintigraphy involves gamma-camera imaging following an intravenous injection of  $^{99m}\text{Tc}$ -labelled bisphosphonate. Early post-injection images reflect blood flow and can show increased perfusion of inflamed synovium, Pagetic bone or primary or secondary bone tumours. Delayed images taken a few hours later reflect bone remodelling as the

## 26.3 Radiographic abnormalities in selected rheumatic diseases

### Rheumatoid arthritis

- Periarticular osteoporosis
- Marginal joint erosions
- Joint subluxation
- Joint space narrowing

### Osteoporosis

- Osteopenia
- Vertebral fractures
- Non-vertebral fractures
- Cortical thinning

### Paget's disease

- Bone expansion
- Abnormal trabecular pattern
- Osteosclerosis and lysis
- Pseudofractures

### Psoriatic arthritis

- Sacroiliitis
- Syndesmophytes
- Bone sclerosis
- Proliferative enthesitis erosions
- Enthesophytes
- Juxta-articular new bone

### Osteoarthritis

- Joint space narrowing
- Osteophytes
- Subchondral sclerosis
- Joint deformity
- Subchondral cysts

## 26.4 Conditions detected by magnetic resonance imaging

- Osteonecrosis
- Intervertebral disc disease
- Nerve root entrapment
- Spinal cord compression
- Spinal stenosis
- Infection
- Complex regional pain syndrome
- Malignancy
- Fractures
- Meniscal disease
- Synovitis
- Sacroiliitis and enthesitides
- Inflammatory myositis
- Rotator cuff tears, bursitis and tenosynovitis

$^{99m}\text{Tc}$ -labelled bisphosphonate localises to sites of active bone turnover. Single photon emission computed tomography (SPECT) combines radionuclide imaging with computed tomography. Bone radionuclide SPECT can provide accurate anatomical localisation of abnormalities within bone and is of particular value in the assessment of patients with chronic low back and pelvic pain where standard scintigraphy has yielded inconclusive results.

## Magnetic resonance imaging

Magnetic resonance imaging (MRI) gives detailed information on anatomy, allowing three-dimensional visualisation of bone and soft tissues that cannot be adequately assessed by plain X-rays. The technique is valuable in the assessment and diagnosis of many musculoskeletal diseases (Box 26.4). T1-weighted sequences are useful for defining anatomy, whereas T2-weighted sequences are useful for assessing tissue water content, which is often increased in synovitis and other inflammatory disorders (Fig. 26.7). MRI sequences that suppress signal from fat, such as short T1 inversion recovery (STIR), are helpful when evaluating inflammatory disease. Contrast agents, such as gadolinium, can be administered to increase sensitivity in detecting erosions and synovitis.

## Ultrasonography

Ultrasonography is a useful investigation for confirmation of small joint synovitis and erosions, for anatomical location of periarticular lesions, for characterisation of tendon lesions and for guided injection of joints and bursae. Ultrasonography is more sensitive than clinical examination for the detection of early synovitis and can be helpful in the diagnosis and assessment of patients with suspected inflammatory arthritis. In addition to locating synovial thickening and effusions, ultrasound can detect

**Fig. 26.7** Magnetic resonance image showing joint synovitis. Coronal post-contrast T1-weighted image shows extensive enhancement consistent with synovitis (white areas, arrowed) in both wrists, at the second metacarpophalangeal joint and proximal interphalangeal joints of the right hand. *Courtesy of Dr I. Beggs.*

**Fig. 26.8** Ultrasound image showing synovitis. Lateral image of a metacarpophalangeal joint in inflammatory arthritis. The periosteum (P) of the phalanx shows as a white line. The dark, hypo-echoic area indicates an effusion. The coloured areas demonstrated by power Doppler indicate increased vascularity. The inset shows a transverse image of the same joint. *Courtesy of Dr N. McKay.*

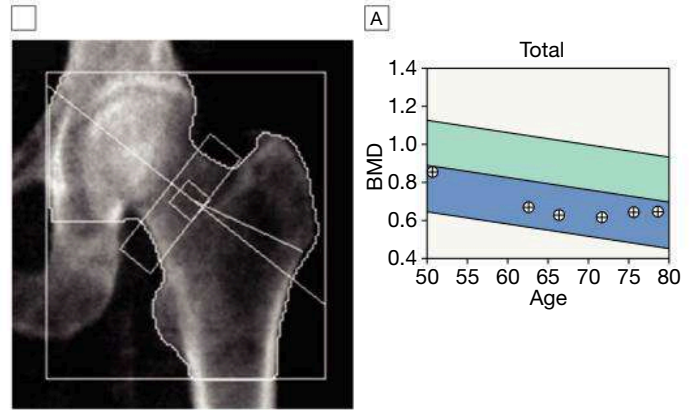

increased blood flow within synovium using power Doppler imaging, an option that is available on most modern ultrasound machines (Fig. 26.8). Ultrasound is also used in the differential diagnosis of giant cell arteritis (GCA) to look for evidence of thickening of the vessel wall in the temporal or axillary arteries.

### Computed tomography

Computed tomography (CT) is used selectively for assessing patients with bone and joint disease. CT may be used when skeletal anatomy needs defining, when calcific lesions are being assessed, when MRI is contraindicated, or when articular regions are being evaluated in which an adjacent joint replacement creates signal artefacts on MRI (using specific metal artefact reduction algorithms).

### Dual X-ray absorptiometry

Dual X-ray absorptiometry (DXA) is used to measure bone mineral density (BMD) and has a key role in the diagnosis and management of osteoporosis. Measurements at lumbar spine, hip and sometimes forearm are obtained. DXA works on the principle that calcium in bone attenuates passage of X-rays through the tissue in proportion to the amount of mineral present: the more bone mineral present, the higher the BMD value. The results are presented in terms of BMD (in grams of hydroxyapatite per cm<sup>2</sup>)

Scan date	Age	BMD	T-score	BMD change vs baseline	BMD change vs previous
11.01.2021	78	0.648	-2.4	-24.5%#	0.5%
03.01.2018	75	0.645	-2.4	-24.8%#	3.9%
21.01.2014	71	0.620	-2.6	-27.7%#	-1.6%
05.09.2008	66	0.630	-2.6	-26.5%#	-5.7%*
13.12.2004	62	0.668	-2.2	-22.1%#	-22.1%#
21.01.1993	50	0.857	-0.7		

\*Statistically significant change since the previous scan results.

#Statistically significant change since baseline data in 1993.

**Fig. 26.9** Left hip dual X-ray absorptiometry (DXA) scan. **A** The regions of interest (ROI) of the hip that are scanned. **B** Graph showing the changes in bone mineral density (BMD) of the total hip ROI over time. The extent of the blue panels above and below the central line represents  $\pm 2$  standard deviations from the average BMD of the reference population for age. Data panel: BMD estimates, corresponding T-scores (see text for explanation) and changes in BMD over time (and with ageing) are shown. By 2008 this patient had become osteoporotic (T-score  $< -2.5$ ). Since 2014 (age 71 years) the patient has been benefitting from effective osteoporosis treatment and BMD has increased.

and as the T-score, which reflect the number of standard deviations by which the patient's BMD value differs from that in a young healthy control (Fig. 26.9). Osteoporosis is defined to be present when the T-score is  $-2.5$  or below; osteopenia is defined to be present when the T-score lies between  $-1.0$  and  $-2.5$ ; and normal BMD is defined to be present when the T-score lies between  $-1.0$  and below  $+2.5$ . T score values above  $+2.5$  indicate high bone density. It is important to recognize that T-score values fall with age in the whole population as bone density falls, meaning that many people aged 60 and above have osteopenia or osteoporosis based on T-score, even though the BMD results are in the 'normal range' for that age group. Bone density needs to be interpreted carefully taking into account coexisting conditions, such as aortic calcification, vertebral fractures, degenerative disc disease and OA, all of which can cause high BMD results even in the presence of osteoporosis. Radiographic correlation is helpful in these circumstances.

### Blood tests

#### Haematology

Abnormalities in the full blood count (FBC) often occur in inflammatory rheumatic diseases, but changes are usually non-specific. Examples include neutrophilia in crystal arthritides and septic arthritis neutropenia in systemic lupus erythematosus (SLE) and lymphopenia in autoimmune rheumatic and connective tissue diseases. Reduced levels of

### 26.5 Typical biochemical features in various bone diseases

	Calcium	Phosphate	ALP	PTH	FGF23	25(OH)D
Osteoporosis	N	N	N (↑ after fracture)	N or ↑	N	N or ↓
Paget's disease	N	N	↑↑	N or ↑	N	N or ↓
Renal osteodystrophy	N or ↓	↑	↑	↑↑	↑↑	N or ↓
Vitamin D-deficient osteomalacia	N or ↓	N or ↓	↑	↑↑	N or ↓	↓↓
Hypophosphataemic rickets	N	↓↓	↑	N or ↑	↑↑	N or ↓
Primary hyperparathyroidism	↑/↑↑	N or ↓	N or ↑	↑/↑↑	N or ↑	N or ↓

(N = normal; single arrow = increased or decreased; double arrow = greatly increased or decreased; ALP = alkaline phosphatase; FGF23 = fibroblast growth factor 23; 25(OH)D = 25 hydroxy-vitamin D; PTH = parathyroid hormone)

### 26.6 Causes of an elevated serum creatinine phosphokinase (CPK)

- Inflammatory myositis ± vasculitis
- Muscular dystrophy
- Motor neuron disease
- Alcohol, drugs (especially statins)
- Myocardial infarction\*
- Trauma, strenuous exercise, prolonged immobilisation after a fall
- Hypothyroidism, metabolic myopathy
- Viral myositis

\*The CK-MB cardiac-specific isoform is disproportionately elevated compared with total CPK.

haemoglobin and raised platelets are a common and important finding in active inflammatory diseases. Some disease-modifying anti-rheumatic drugs (DMARDs) and biologics can cause marrow toxicity and require regular monitoring of the FBC. Additional tests that are useful in assessing rheumatic diseases include the direct antiglobulin test (which can indicate intravascular haemolysis in SLE).

## Biochemistry

Routine biochemistry is useful for assessing metabolic bone disease, muscle diseases and gout, and is essential in monitoring DMARDs and biologic drugs (renal and hepatic function). Several bone diseases, including Paget's disease, renal bone disease and osteomalacia, give a characteristic pattern that can be helpful diagnostically (Box 26.5). Serum levels of uric acid are usually raised in gout, but a normal level does not exclude it, especially during an acute attack when uric acid levels temporarily fall. Equally, an elevated serum uric acid does not confirm the diagnosis, since most hyperuricaemic people never develop gout. Levels of C-reactive protein (CRP) are a useful marker of infection and inflammation, and are more specific than the erythrocyte sedimentation rate (ESR). An exception is in autoimmune connective tissue diseases, such as SLE and systemic sclerosis, where CRP may be normal but the ESR raised in active disease. Accordingly, an elevated CRP in a patient with SLE or systemic sclerosis suggests an intercurrent illness, such as sepsis, rather than active disease. Serum creatine phosphokinase (CK) levels are useful in the diagnosis of myopathy or myositis, but specificity and sensitivity are poor and raised levels may occur in other conditions (Box 26.6).

## Immunology

Autoantibody tests are widely used in the diagnosis of rheumatic diseases. Whatever test is used, the results must be interpreted in light of the clinical picture and the different detection and assay systems used in different hospitals.

### Rheumatoid factor

Rheumatoid factor (RF) is an antibody directed against the Fc fragment of human immunoglobulin. In routine clinical practice, immunoglobulin M

### 26.7 Conditions associated with a positive rheumatoid factor\*

Condition	Approximate frequency (%)
Rheumatoid arthritis with nodules and extra-articular manifestations	100
Rheumatoid arthritis (overall)	70
Primary Sjögren syndrome	90
Mixed essential cryoglobulinaemia	90
Primary biliary cholangitis	50
Infective endocarditis	40
Systemic lupus erythematosus	30
Tuberculosis	15
Age >65 years	20

\*Normal healthy people can be positive for rheumatoid factor.

(IgM) RF is usually measured. About 70% of patients with RA test positive for RF, but the specificity for RA is poor (Box 26.7). High RF titres in RA are associated with more severe disease and extra-articular features.

### Anti-citrullinated peptide antibodies

Anti-citrullinated peptide antibodies (ACPA) recognise peptides in which the amino acid arginine has been converted to citrulline by peptidylarginine deiminase, an enzyme abundant in inflamed synovium and in a variety of mucosal structures. Like RF, ACPA is positive in around 70% of people with RA, but specificity is higher (>95%) and consequently ACPA has largely superseded RF in the diagnosis of RA. Like RF, ACPA positivity is associated with more severe disease and extra-articular features. It is important to emphasise that ACPA positivity does not equate to a diagnosis of RA since a proportion of people in the normal population are ACPA positive. These individuals are at increased risk of developing RA at some point in life, but may never do so. The pathogenic role of ACPAs is still debated but they may amplify the synovial response to an inflammatory stimulus.

### Antinuclear antibodies

Antinuclear antibodies (ANAs) are directed against one or more components of the cell nucleus, including nucleic acids and the proteins that process DNA or RNA. They occur in many inflammatory rheumatic diseases, but are also found at low titre in normal individuals and in other diseases (Box 26.8). ANAs are not associated with disease severity or activity. The most common indication for ANA testing is in patients suspected of having SLE or other autoimmune connective tissue diseases. ANA has high sensitivity for SLE (100%), but low specificity (10%–40%). A negative ANA virtually excludes SLE but a positive result does not confirm it.

### 26.8 Conditions associated with a positive antinuclear antibody\*

Condition	Approximate frequency (%)
Systemic lupus erythematosus	100
Systemic sclerosis	90–95
Sjögren syndrome	40–70
Dermatomyositis or polymyositis	30–80
Mixed connective tissue disease	100
Autoimmune hepatitis	100
Rheumatoid arthritis	30–50
Autoimmune thyroid disease	30–50
Malignancy	Varies widely
Infectious diseases	Varies widely

\*Low-titre positive antinuclear antibody can occur in people without autoimmune disease, without obvious clinical consequences, particularly in older adults.

Anti-DNA antibodies bind to double-stranded DNA (dsDNA). They are useful in SLE monitoring as high titres are associated with more severe disease and an increase in antibody titre may precede relapse. Most commonly, testing for anti-DNA antibodies is performed by enzyme-linked immunosorbent assay (ELISA) but immunofluorescent staining of DNA from the microorganism *Crithidia luciliae* is also used and has a much higher specificity than dsDNA ELISA for the diagnosis of SLE. It is primarily used in patients where the clinical suspicion of SLE is high but where standard dsDNA tests have yielded equivocal results.

It is also possible to screen for antibodies to various extractable nuclear antigens (ENA). These act as biomarkers for certain subtypes of autoimmune connective tissue diseases and some complications of SLE, but for most disorders their sensitivity and specificity are poor (Box 26.9).

#### Antiphospholipid antibodies

These antibodies can be detected in patients with SLE and in the antiphospholipid syndrome (see Box 25.69). In clinical practice the most commonly used tests are for antibodies to cardiolipin/beta<sub>2</sub>-glycoprotein 1 (β<sub>2</sub>GP1) and the dilute Russell viper venom test, which is a functional assay for antibodies that interfere with the clotting mechanism in vitro.

#### Antineutrophil cytoplasmic antibodies

Antineutrophil cytoplasmic antibodies (ANCA) are IgG antibodies directed against the cytoplasmic constituents of neutrophils and are useful in the diagnosis and monitoring of systemic vasculitis. Two common patterns are described by immunofluorescence: cytoplasmic fluorescence (c-ANCA), which is caused by antibodies to proteinase-3 (PR3); and perinuclear fluorescence (p-ANCA), which is caused by antibodies to myeloperoxidase (MPO) and other proteins, such as lactoferrin and elastase. These antibodies are not specific for vasculitis and positive results may be found in autoimmune liver disease, malignancy, infection (bacterial and human immunodeficiency virus, HIV), inflammatory bowel disease (IBD), RA, SLE and pulmonary fibrosis.

#### Complement and complement component antibodies

Low complement C3 is an indicator of active SLE and some forms of vasculitis owing to consumption of complement by immune complexes (see Fig. 4.4). Low C4 is less specific for SLE activity. High C3 and functional measures of complement activation are non-specific features of inflammation. It is possible to screen for autoantibodies directed against a variety of other complement components. Some have clinical utility. For example, anti-C1q antibodies are associated with SLE, but also occur in hypocomplementemic urticarial vasculitis syndrome (HUVS).

### 26.9 Conditions associated with antibodies to extractable nuclear antigens

Antibody (target/other name)	Disease association
Anti-centromere antibody	Localised cutaneous systemic sclerosis (sensitivity 60%, specificity 98%)
Anti-histone antibody	Drug-induced lupus (80%)
Anti-Jo-1 (anti-histidyl-tRNA synthetase)	Polymyositis, dermatomyositis or polymyositis–systemic sclerosis overlap (20%–30%) Particularly associated with interstitial lung disease
Anti-La antibody (anti-SS-B)	Sjögren syndrome (60%) SLE (20%–60%)
Anti-ribonucleoprotein antibody (anti-RNP)	Mixed connective tissue disease (100%) SLE (25%–50%), usually in conjunction with anti-Sm antibodies
Anti-Ro antibody (anti-SS-A)	SLE (35%–60%): associated with photosensitivity, thrombocytopenia and subacute cutaneous lupus Maternal anti-Ro antibodies associated with neonatal lupus and congenital heart block Sjögren syndrome (40%–80%)
Anti-RNA polymerase	Diffuse systemic sclerosis (15%)
Anti Sm (anti-Smith antibody)	SLE (15%–30%); associated with renal disease
Anti-Scl-70 (anti-topoisomerase I antibody)	Diffuse systemic sclerosis (15%); associated with more severe organ involvement, including pulmonary fibrosis

(SLE = systemic lupus erythematosus)

#### Approach to autoantibody testing and interpretation

Testing for autoantibodies should only be performed to gain support for the diagnosis when clinical assessment suggests there may be an underlying autoimmune disease. They are not screening tests for the presence of autoimmune disease since they have limited sensitivity and specificity (see Box 26.9). Routine re-testing of autoantibody profiles is seldom helpful unless the clinical features of the disease change or evolve with time.

#### Tissue biopsy

Tissue biopsy is useful in confirming the diagnosis in certain musculoskeletal diseases.

Synovial biopsy can be useful in selected patients with chronic inflammatory monoarthritis or tenosynovitis to rule out chronic infectious causes, especially mycobacterial infections. Synovial biopsy can be obtained arthroscopically or by using ultrasound guidance under local anaesthetic.

Temporal artery biopsy can be of value in patients suspected of having giant cell arteritis.

Biopsies of affected tissues, such as skin, lung, nasopharynx, gut, kidney and muscle, are of value in confirming a diagnosis of systemic vasculitis.

Muscle biopsy is important in the investigation of myopathy and inflammatory myositis. It is usually taken from the quadriceps or deltoid through a small skin incision under local anaesthetic. Since myositis can be patchy in nature, MRI is sometimes used to localise the best site for biopsy. Immunohistochemical staining, together with plain histology, gives information on primary and secondary muscle and neuromuscular

disease. Repeat biopsies are sometimes used to monitor the response to treatment.

Bone biopsy is occasionally required in patients with infiltrative disorders of bone, renal bone disease, suspected chronic infection or malignancy and rarely to confirm or exclude the presence of osteomalacia. For focal lesions, the biopsy should be taken under X-ray guidance or at open surgery, from an affected site. If a systemic bone disease or disorder of mineralisation is suspected, biopsies are usually taken from the iliac crest using a large-diameter (8 mm) trephine needle under local anaesthetic and processed without demineralisation.

## Electromyography

Electromyography is of value in the investigation of suspected myopathy and inflammatory myositis, when it shows the diagnostic triad of:

- spontaneous fibrillation
- short-duration action potentials in a polyphasic disorganised outline
- repetitive bouts of high-voltage oscillations on needle contact with diseased muscle.

## Presenting problems in musculoskeletal disease

The pattern of joint involvement and time-course can often provide valuable clues to the underlying diagnosis. The most common clinical presentations of musculoskeletal disease are discussed in this section.

### Monoarthritis

This refers to pain and swelling affecting a single joint. The most common causes are crystal arthritis, sepsis, reactive arthritis and oligoarticular juvenile idiopathic arthritis. Other potential causes are shown in [Box 26.10](#).

#### Clinical assessment

The clinical history, pattern of joint involvement, speed of onset, and age and gender of the patient all give clues to the most likely diagnosis. A very rapid onset (6–12 hours) is suggestive of either gout or acute calcium pyrophosphate arthritis (CPPA), which is also known as pseudogout. Both may be triggered by an intercurrent illness, dehydration or surgery. Gout classically affects younger men and particularly targets the first metatarsophalangeal (MTP) joint, whereas CPPA tends to affect older women, often with pre-existing OA or calcium pyrophosphate deposition (CPPD) disease. Reactive arthritis can also develop acutely and may be preceded by a diarrhoeal illness or genital infection. Septic arthritis develops more slowly and continues to progress until treated. Haemarthrosis usually follows an injury and may be associated with a large effusion,

in the absence of periarticular swelling or skin change. Pigmented villonodular synovitis also presents with synovial swelling and a large effusion, affecting a single joint but with a gradual onset. Rheumatoid arthritis seldom presents with monoarthritis, but psoriatic arthritis (PsA) can present this way, although the onset is usually more gradual in both conditions. Osteoarthritis can present with pain affecting a single joint, but the onset is gradual. Although there may be bony swelling of joints affected by OA, synovitis and effusions are uncommon.

#### Investigations

Aspiration of the affected joint is mandatory in patients with sudden onset of a hot swollen joint. The fluid should be sent for culture and Gram stain to seek the presence of organisms and should be checked by polarised light microscopy for crystals. Blood cultures should also be taken in patients suspected of having septic arthritis. CRP and ESR should be measured. While values are raised with both infection and inflammation, serial measurements can be useful in assessing the response to treatment. Serum uric acid measurements are of limited value since urate is a negative acute phase reactant and values can fall to within the normal range in acute gout. If investigations suggest CPPA, an elevated serum calcium may suggest underlying primary hyperparathyroidism.

#### Management

If there is any suspicion of septic arthritis, intravenous antibiotics should be given promptly, pending the results of cultures (see [Box 26.50](#)). Patients with suspected crystal-induced arthritis or reactive arthritis may be given intra-articular glucocorticoid injections to help the pain and swelling, but only if Gram stain is negative and synovial fluid culture has been negative for 48 hours. Longer-term management should be directed towards the underlying cause.

### Polyarthritis

This term is used to describe pain and swelling affecting five or more joints or joint groups. The possible causes are listed in [Box 26.11](#) and extra-articular features are listed in [Box 26.12](#).

#### Clinical assessment

The hallmarks of an inflammatory polyarthritis are early-morning stiffness and worsening of symptoms with inactivity, along with synovial swelling and tenderness on examination.

The pattern of involvement can be helpful in reaching a diagnosis ([Fig. 26.10](#)). In RA there is typically symmetrical involvement targeting the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands and wrists as well as the ankles and metatarsophalangeal (MTP) and PIP joints of the feet. Other large joints may also be affected. In psoriatic arthritis (PsA), the PIP and distal interphalangeal (DIP) joints of the hands are usually affected, often in an asymmetrical pattern and accompanied by nail pitting or early onycholysis. Large joints may also be affected, and psoriasis may or may not be present. In SLE there may be a polyarthritis, but this more usually causes polyarthralgia and tenosynovitis, mainly of distal limb joints and tendons. OA has a similar pattern of involvement to PsA in the hands, but can usually be distinguished by the presence of Heberden's and Bouchard's nodes and lack of synovitis and other features of PsA.

#### Investigations

Blood samples should be taken for routine haematology, biochemistry, ESR, CRP, viral serology and an immunological screen, including ANA and ACPA (or RF). If there is clinical suspicion of an inflammatory arthritis, but clinical signs of synovitis are absent, ultrasound examination or MRI may be helpful in confirming the diagnosis.

#### Management

Management should be tailored to the underlying diagnosis. While investigations are in progress non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics may be considered for symptom control. While

26.10 Causes of monoarthritis	
<b>Common</b>	
<ul style="list-style-type: none"> <li>• Gout</li> <li>• Pseudogout</li> <li>• Trauma</li> <li>• Haemarthrosis</li> </ul>	<ul style="list-style-type: none"> <li>• Spondyloarthritis</li> <li>• Psoriatic arthritis</li> <li>• Reactive arthritis</li> <li>• Enteropathic arthritis</li> </ul>
<b>Less common</b>	
<ul style="list-style-type: none"> <li>• Rheumatoid arthritis</li> <li>• Juvenile idiopathic arthritis</li> <li>• Pigmented villonodular synovitis</li> <li>• Foreign body reaction</li> </ul>	<ul style="list-style-type: none"> <li>• Tuberculosis</li> <li>• Leukaemia*</li> <li>• Gonococcal infection</li> <li>• Osteomyelitis*</li> </ul>
*In children, both leukaemia and osteomyelitis may present with monoarthritis.	

26.11 Common causes of polyarthritis	
Cause	Characteristics
<b>Rheumatoid arthritis</b>	Symmetrical, small and large joints, upper and lower limbs
<b>Viral arthritis</b>	Symmetrical, small joints; may be associated with rash and prodromal illness; self-limiting
<b>Osteoarthritis</b>	Symmetrical, targets PIP, DIP and first CMC joints in hands, knees, hips, back and neck; associated with Heberden's and Bouchard's nodes
<b>Psoriatic arthritis</b>	Tends to be asymmetrical, affecting PIP and DIP joints in the hands but large joints may also be affected; often associated with nail pitting/onycholysis, dactylitis and enthesitis
<b>Axial spondyloarthritis and enteropathic arthritis</b>	Tends to affect mid-size and large joints and entheses, lower more than upper limbs; history of inflammatory back pain
<b>Systemic lupus erythematosus</b>	Symmetrical, typically affecting small joints; clinical evidence of synovitis unusual
<b>Juvenile idiopathic arthritis</b>	Various patterns including: polyarticular, oligoarticular and systemic but also enthesitis-predominant
<b>Chronic gout</b>	Affects distal more than proximal joints; history of acute attacks
<b>Chronic sarcoidosis</b>	Small and large joints, often involves ankles
<b>Poncet's disease</b>	A reactive arthritis often affecting large joints associated with tuberculosis
<b>Calcium pyrophosphate arthritis</b>	Chronic polyarthritis with involvement of wrists, ankles, knees and oligoarticular small hand joints

(CMC = carpometacarpal; DIP = distal interphalangeal; PIP = proximal interphalangeal)

glucocorticoids can be helpful in treating symptoms of inflammatory arthritis they should generally be avoided until a definitive diagnosis has been made.

## Fracture

Fractures are a common presenting symptom of osteoporosis, but they also occur in other bone diseases, in osteopenia and in some people with a normal skeleton where there has been a high trauma injury.

### Clinical assessment

The presentation is with localised bone pain, which is worsened by movement of the affected limb or region. There is usually a history of trauma, but spontaneous fractures can occur in the absence of trauma in severe osteoporosis. Fractures can be divided into several subtypes, based on the precipitating event and presence or absence of an underlying disease (Box 26.13). The main differential diagnosis is soft tissue injury, but fracture should be suspected when there is marked pain and swelling, abnormal movement of the affected limb, crepitus or deformity. Femoral neck fractures typically produce a shortened, externally rotated leg that is painful to move. The pain from vertebral fracture is variable and a high index of suspicion is key to making the diagnosis by imaging, as discussed below.

### Investigations

X-rays of the affected site should be taken in at least two planes and examined for discontinuity of the cortical outline (Box 26.14). In addition to demonstrating the fracture, X-rays may also show evidence of an

26.12 Extra-articular features of inflammatory arthritis	
Clinical feature	Disease association
<b>Skin, nails and mucous membranes</b>	
Psoriasis, nail pitting and dystrophy	Psoriatic arthritis
Raynaud's phenomenon	Systemic sclerosis, antiphospholipid syndrome, SLE
Photosensitivity	SLE
Livedo reticularis	SLE, antiphospholipid syndrome
Splinter haemorrhages, nail-fold infarcts, purpuric lesions	Vasculitis
Urticaria and erythemas	SLE, adult-onset Still's disease, systemic JIA, rheumatic fever
Oral ulcers	SLE, reactive arthritis, Behçet's disease
Nodules	RA (mainly extensor surfaces), gout (tophi; eccentric, white deposits within), rheumatic fever
Xerostomia, dry skin, various rashes	Primary Sjögren syndrome
<b>Eyes</b>	
Uveitis	SpA, sarcoid, JIA, Behçet's disease
Conjunctivitis	Reactive arthritis
Episcleritis, scleritis	RA, vasculitis
<b>Heart, lungs</b>	
Pleuro-pericarditis	SLE, RA, rheumatic fever
Aortic valve/root disease	HLA-B27-related SpA
Interstitial lung disease	RA, SLE, primary Sjögren syndrome
<b>Abdominal organs</b>	
Hepatosplenomegaly	RA, SLE
Haematuria, proteinuria	SLE, vasculitis, systemic sclerosis
Urethritis	Reactive arthritis and SpA (sterile)
Fever, lymphadenopathy	Infection, systemic JIA, rheumatic fever

(HLA = human leucocyte antigen; JIA = juvenile idiopathic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SpA = spondyloarthritis)

underlying disorder, such as osteoporosis, Paget's disease or osteomalacia. If the X-ray fails to show evidence of a fracture, but clinical suspicion remains high, MRI should be obtained. In many countries patients with low trauma fractures above the age of 50 are referred for a DXA scan to screen for osteoporosis. DXA is also indicated in those under 50 with very strong clinical risk factors for osteoporosis.

### Management

Management of fracture in the acute stage requires adequate pain relief, with opiates if necessary, reduction of the fracture to restore normal anatomy and immobilisation of the affected limb to promote healing. This can be achieved either by the use of an external cast or splint, or by internal fixation. Femoral neck fractures present a special management problem since non-union and osteonecrosis are common. This is especially true with intracapsular hip fractures, which should be treated by joint replacement surgery. Following the fracture, rehabilitation is required with physiotherapy and a supervised exercise programme. If the DXA scan shows evidence of osteoporosis or other metabolic bone disease, this should be treated appropriately as described later in this chapter.

## Generalised musculoskeletal pain

### Clinical assessment

There are a variety of causes of generalised pain, as summarised in Box 26.15. Relentlessly progressive pain occurring in association with weight loss suggests malignant disease with bone metastases. Generalised bone pain may also arise in osteomalacia, primary

**Fig. 26.10** Patterns of joint involvement in different forms of polyarthritis. **A** Rheumatoid arthritis typically targets the metacarpophalangeal and proximal interphalangeal joints of the hands and metatarsophalangeal joints of the feet, as well as other joints, in a symmetrical pattern. **B** Psoriatic arthritis targets proximal and distal interphalangeal joints of the hands, entheses and larger joints in an asymmetrical pattern. Sacroiliitis (often asymmetrical) may occur. **C** Axial spondyloarthritis/ankylosing spondylitis targets the spine, sacroiliac joints, entheses and large peripheral joints in an asymmetrical pattern. **D** Osteoarthritis targets the proximal and distal interphalangeal joints of the hands, first carpometacarpal joint at the base of the thumb, knees, hips, lumbar and cervical spine.

26.13 Characteristics of different fracture types		
Fracture type	Precipitation factor	Disease
<b>Fragility fracture</b>	Fall from standing height or less	Osteoporosis Osteopenia
<b>Vertebral fracture</b>	Bending, lifting, falling	Osteoporosis
<b>Stress fracture</b>	Running, excessive training	Normal
<b>High-energy fracture</b>	Major trauma	Normal
<b>Pathological fracture</b>	Spontaneous, minimal trauma	Malignancy Paget's disease Osteomalacia

26.14 How to investigate a suspected fracture	
<ul style="list-style-type: none"> <li>• Order X-rays in two projections at right-angles to one another</li> <li>• Include the whole bone and the joints at either end (this may reveal an additional unsuspected fracture)</li> <li>• Check for evidence of displacement</li> <li>• Check for a break in the cortex</li> <li>• In suspected vertebral fracture, check for depression of the end plate</li> <li>• If clinical suspicion is high but no fracture is seen, request magnetic resonance imaging</li> </ul>	

hyperparathyroidism and polyostotic Paget's disease. An important common cause is fibromyalgia (FM) syndrome, which presents with generalised pain that particularly affects the trunk, back and neck. Accompanying features include fatigue, poor concentration and focal areas of hyperalgesia. Widespread pain may also occur in association with Ehlers–Danlos syndrome hypermobility subtype (hEDS). Pain is a prominent feature in patients with polymyalgia rheumatica and GCA, but this tends to be localised to the pelvic and shoulder girdle. Similarly, pain is also a common feature of inflammatory arthritis and OA but tends to be localised to affected joints. Widespread pain can occur in PsA if there is extensive enthesitis.

26.15 Some common causes of generalised pain	
<ul style="list-style-type: none"> <li>• Myositis</li> <li>• Psoriatic arthritis (enthesopathic)</li> <li>• Fibromyalgia</li> <li>• Ehlers–Danlos syndrome, hypermobility type</li> <li>• Parvovirus arthromyalgia</li> <li>• Rheumatic fever/post-streptococcal infection</li> <li>• Metastatic cancer</li> <li>• Severe osteomalacia</li> </ul>	

### Investigations

Bone scintigraphy is of value in patients with suspected bone metastases or Paget's disease and can also reveal evidence of stress fractures in osteomalacia. FBC, ESR and CRP may be abnormal in the presence of inflammatory disease and myeloma. Plasma and urine protein electrophoresis should be performed to screen for myeloma, and if abnormalities are detected further imaging should be considered with X-ray, low-dose CT or MRI. Routine biochemistry, vitamin D and parathyroid hormone (PTH) should be measured if osteomalacia is suspected. In Paget's disease, the typical picture is of an elevation in ALP with otherwise normal biochemistry. Investigations are unremarkable in patients with FM and hEDS.

### Management

Management should be directed towards the underlying cause. Chronic pain of unknown cause and that associated with FM respond poorly to analgesics and NSAIDs, but may respond partially to antineuropathic agents, such as amitriptyline, duloxetine, gabapentin and pregabalin.

### Muscle weakness

Muscle weakness can arise from a variety of causes, as shown in Box 26.16. It is important to distinguish between a subjective feeling of generalised weakness occurring with fatigue, and an objective weakness with loss of muscle power and function. The former is a non-specific manifestation of many systemic conditions.

## 26.16 Causes of proximal muscle weakness

### Inflammatory

- Polymyositis
- Dermatomyositis
- Other autoimmune connective tissue disease
- Inclusion body myositis
- Sarcoid
- Myasthenia gravis

### Endocrine (Ch. 20)

- Hypothyroidism
- Hyperthyroidism
- Cushing's syndrome
- Addison's disease

### Metabolic (Ch. 19)

- Myophosphorylase deficiency
- Phosphofructokinase deficiency
- Hypokalaemia
- Carnitine deficiency
- Osteomalacia
- Hypercalcaemia

### Genetic

- Muscular dystrophy
- Mitochondrial disease

### Drugs/toxins

- Alcohol
- Cocaine
- Glucocorticoids
- Statins and fibrates
- Tumour necrosis factor inhibitors
- Zidovudine

### Infections (Ch. 13)

- Viral (HIV, cytomegalovirus, rubella, Epstein–Barr, echovirus)
- Parasitic (schistosomiasis, cysticercosis, toxoplasmosis)
- Bacterial (*Clostridium perfringens*, staphylococci, tuberculosis, *Mycoplasma*)

### Clinical assessment

Clinical examination should document the presence, pattern and severity of muscle weakness assessed using the Medical Research Council (MRC) scale (no power (0) to full power (5)). Proximal muscle weakness suggests the presence of a myopathy or myositis, which typically causes difficulty in standing from a seated position, walking up steps, squatting and lifting overhead. Worsening of symptoms on exercise and post-exertional cramps suggest a metabolic myopathy, such as glycogen storage disease. A strong family history and onset in childhood or early adulthood suggest muscular dystrophy. Alcohol excess can cause an inflammatory myositis and atrophy of type 2 muscle fibres. Proximal myopathy may be a complication of Cushing's syndrome, glucocorticoid therapy and osteomalacia. Myopathy and myositis can also occur in association with many drugs (see Box 26.78) and viral infections, including HIV; in the latter case, it may be due to HIV itself or to treatment with zidovudine. Polymyositis and dermatomyositis in adults are frequently associated with an occult malignancy, emphasising the importance of a thorough general examination of patients with this presentation.

### Investigations

Investigations should include routine biochemistry and haematology, ESR, CRP, creatine kinase, serum 25(OH)-vitamin D, PTH, parvovirus, hepatitis B/C, HIV and streptococcus serology, serum and urine protein electrophoresis, serum ACE, ANAs/ENAs, RF, complement and myositis-specific autoantibodies such as Jo-1. Open muscle biopsy (site-guided by MRI detection of abnormal muscle) and electromyography (EMG) are usually required to make the diagnosis. Genetic testing may be of value in patients where an inherited disorder is suspected. Patients suspected to have myositis should be screened for malignancy. Initially this involves a CT scan of the chest, abdomen and pelvis followed by upper gastrointestinal endoscopy and colonoscopy if necessary.

### Management

Management is determined by the underlying cause, but all patients with muscle disease should be referred for physiotherapy and graded exercises to maximise muscle function while specific treatment is introduced.

## 26.17 Causes of low back pain

- Mechanical (soft-tissue lesion) back pain
- Intervertebral disc disease (degenerative or annulus tear and prolapse)
- Facet joint disease (osteoarthritis, psoriatic arthritis)
- Vertebral fracture
- Paget's disease
- Axial spondyloarthritis
- Discitis (infective or inflammatory ['spondylodiscitis'])
- Bone metastases
- Spondylolisthesis

## Regional musculoskeletal pain

Regional musculoskeletal pain is a common presenting complaint, usually occurring as the result of age-related degenerative disease of tendons and ligaments, OA and trauma.

### Back pain

Back pain is a common symptom that affects 60%–80% of people at some time in their lives. Although the prevalence has not increased, reported disability from back pain has risen significantly in the last 30 years. In Western countries, back pain is the most common cause of sickness-related work absence. In the UK, 7% of adults consult their GP each year with back pain. Globally, low back pain is thought to affect about 9% of the population. The most important causes of low back pain are summarised in Box 26.17.

### Clinical assessment

The main purpose of clinical assessment is to differentiate the self-limiting disorder of acute mechanical back pain from serious spinal pathology, as summarised in Figure 26.11. Mechanical back pain is the most common cause of acute back pain in people aged 20–55. This accounts for more than 90% of episodes, is usually acute and associated with lifting or bending. It is exacerbated by activity and is generally relieved by rest (Box 26.18). It is usually confined to the lumbar–sacral region, buttock or thigh, is asymmetrical and does not radiate beyond the knee (which would imply nerve root irritation). On examination, there may be asymmetric local paraspinal muscle spasm and tenderness, with painful restriction of some, but not all, movements. Low back pain is more common in manual workers, particularly those in occupations that involve heavy lifting and twisting. The prognosis is generally good. After 2 days, 30% are better and 90% have recovered by 6 weeks. Recurrences of pain may occur and about 10%–15% of patients go on to develop chronic back pain that may be difficult to treat. Psychological elements, such as job dissatisfaction, depression and anxiety, are important risk factors for the transition to chronic pain and disability.

Back pain secondary to serious spinal pathology has different characteristics (Box 26.19). If there is clinical evidence of spinal cord or nerve root compression, or a cauda equina lesion, then urgent investigation is needed. Spinal stenosis presents insidiously with leg discomfort on walking that is relieved by rest, bending forwards or walking uphill. Patients may adopt a characteristic simian posture, with a forward stoop and slight flexion at hips and knees. The most common cause is the gradual development of coexisting contributing lesions such as facet joint arthritis, ligament flavum thickening or degenerative spondylolisthesis.

Degenerative disc disease and osteoarthritis is a common cause of chronic low back pain in middle-aged and older adults. Prolapse of an intervertebral disc presents when discs are still well hydrated (in young and early middle age) with nerve root pain, which can be accompanied by characteristic features such as sensory deficit, motor weakness and asymmetrical reflexes (Box 26.20). Examination may reveal a positive sciatic or femoral stretch test. About 70% of patients improve by 4 weeks. Inflammatory back pain (IBP) due to axial spondyloarthritis (axSpA) or

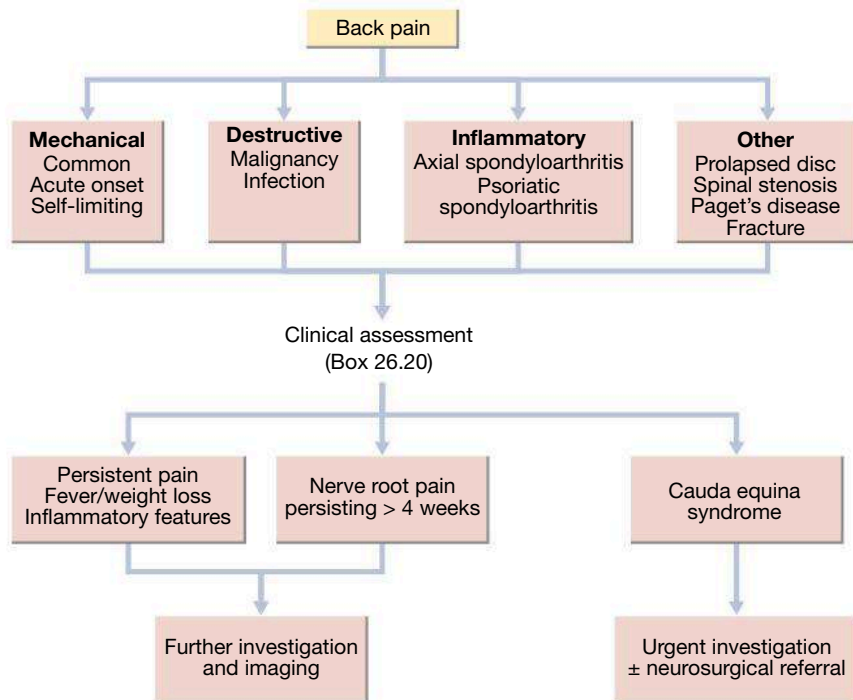

Fig. 26.11 Initial triage assessment of back pain.

i	26.18 Features of mechanical low back pain
	<ul style="list-style-type: none"> <li>• Pain varies with physical activity (improved with rest)</li> <li>• Onset often sudden and precipitated by lifting or bending</li> <li>• Recurrent episodes</li> <li>• Pain limited to back or upper leg</li> <li>• No clear-cut nerve root distribution</li> <li>• No systemic features</li> <li>• Self-limiting with recovery at 6 weeks in 90%</li> </ul>

i	26.19 Red flags for possible spinal pathology
	<p><b>History</b></p> <ul style="list-style-type: none"> <li>• Age &lt; 20 years or &gt; 55 years at presentation</li> <li>• Character: constant, progressive pain unrelieved by rest</li> <li>• Location: thoracic pain</li> <li>• Past medical history: carcinoma, tuberculosis, HIV, systemic glucocorticoid use, osteoporosis</li> <li>• Constitutional: systemic upset, sweats, weight loss</li> <li>• Major trauma</li> </ul> <p><b>Examination</b></p> <ul style="list-style-type: none"> <li>• Painful spinal deformity</li> <li>• Severe/symmetrical spinal deformity</li> <li>• Saddle anaesthesia</li> <li>• Progressive neurological signs/muscle-wasting</li> <li>• Multiple levels of root signs</li> </ul>

PsA has a gradual onset and almost always occurs before the age of 40. It is associated with morning stiffness and improves with movement. Spondylolithesis may cause back pain that is typically aggravated by standing and walking. Occasionally, diffuse idiopathic skeletal hyperostosis (DISH) can cause back pain, but this is not a prominent feature. Arachnoiditis is a rare cause of chronic severe low back pain. It is caused by chronic inflammation of the nerve root sheaths in the spinal canal and can complicate meningitis, spinal surgery or myelography with oil-based contrast agents.

i	26.20 Clinical features of radicular pain
	<p><b>Nerve root pain</b></p> <ul style="list-style-type: none"> <li>• Unilateral leg pain worse than low back pain</li> <li>• Pain radiates beyond knee</li> <li>• Paraesthesia in same distribution</li> <li>• Nerve irritation signs (reduced straight leg raising that reproduces leg pain)</li> <li>• Motor, sensory or reflex signs (limited to one or adjacent nerve roots)</li> <li>• Often self-limiting, with 50% recovery at 6 weeks</li> </ul> <p><b>Cauda equina syndrome</b></p> <ul style="list-style-type: none"> <li>• Difficulty with micturition</li> <li>• Loss of anal sphincter tone or faecal incontinence</li> <li>• Saddle anaesthesia</li> <li>• Gait disturbance</li> <li>• Pain, numbness or weakness affecting one or both legs</li> </ul>

### Investigations

Investigations are not required in patients with acute mechanical back pain. Those with persistent pain (> 6 weeks) or red flags (see Box 26.19) should undergo further investigation. MRI is the investigation of choice because it can demonstrate spinal stenosis, cord compression or nerve root compression, as well as inflammatory changes in axSpA, malignancy and sepsis. Plain X-rays can be of value in patients suspected of having vertebral compression fractures, OA and degenerative disc disease. If metastatic disease is suspected, bone scintigraphy or CT should be considered. Additional investigations that may be required include routine biochemistry and haematology, ESR and CRP (to screen for infection and inflammatory disease), protein and urine electrophoresis (for myeloma), human leucocyte antigen (HLA)-B27 for axSpA and prostate-specific antigen for prostate carcinoma.

### Management

Education is important in patients with mechanical back pain. It should emphasise the self-limiting nature of the condition and the fact that exercise is helpful rather than damaging. Regular analgesia and/or NSAIDs may be required to improve mobility and facilitate exercise. Return to

## 26.21 Causes of neck pain

### Mechanical

- Postural
- Whiplash injury
- Cervical spondylosis

### Inflammatory

- Infections
- Axial spondyloarthritis
- Psoriatic arthritis
- Rheumatoid arthritis
- Polymyalgia rheumatica
- Discitis

### Metabolic

- Axial CPPD disease
- Fibrous dysplasia
- Paget's disease

### Neoplastic

- Metastases
- Myeloma
- Lymphoma
- Intrathecal tumours

### Other

- Fibromyalgia
- Torticollis

### Referred

- Pharynx
- Cervical lymph nodes
- Dental disease
- Angina pectoris
- Aortic aneurysm
- Pancoast tumour
- Diaphragm

(CPPD = calcium pyrophosphate deposition)

work and normal activity should take place as soon as possible. Bed rest is not helpful and may increase the risk of chronic disability. Referral for physiotherapy should be considered if a return to normal activities has not been achieved by 6 weeks. Low-dose tricyclic antidepressant drugs may help pain, sleep and mood.

Other treatment modalities that are occasionally used include epidural and facet joint injection, traction and lumbar supports, though there is limited randomised controlled trial evidence to support their use. Malignant disease, osteoporosis, Paget's disease and SpAs require specific treatment of the underlying condition.

Surgery is required in less than 1% of patients with low back pain, but may be needed in progressive spinal stenosis, in spinal cord compression and in some patients with nerve root compression.

## Neck pain

Neck pain is a common symptom that can occur following an injury or falling asleep in an awkward position, as a result of stress or in association with OA of the spine. The causes are shown in [Box 26.21](#). Most cases resolve spontaneously or with a short course of NSAIDs or analgesics and some exercise therapy. Patients with persistent pain that follows a nerve root distribution and those with upper or lower limb neurological signs should be investigated by MRI and, if necessary, referred for a neurosurgical opinion.

## Shoulder pain

Shoulder pain is a common complaint over the age of 40 ([Box 26.22](#)). Varying pain patterns associated with common lesions are shown in [Figure 26.12](#). For most shoulder lesions, general management is with analgesics, NSAIDs, local glucocorticoid injections and physiotherapy aimed at restoring normal movement and function. Surgery may be required in patients who have debilitating or persistent symptoms in association with rotator cuff lesions or severe acromioclavicular joint arthritis. If there is subacromial impingement, without evidence of a rotator cuff tear on MRI, subacromial glucocorticoid injection and physiotherapy constitute a reasonable first step. Calcific supraspinatus tendonitis unresponsive to glucocorticoid injection can be treated with barbotage (needle disruption of deposit under ultrasound guidance).

## 26.22 Clinical findings in shoulder pain

### Rotator cuff and subacromial lesions

- Pain reproduced by resisted active movement:
  - Abduction: supraspinatus
  - External rotation: infraspinatus, teres minor
  - Internal rotation: subscapularis

### Acromioclavicular joint

- Pain on full abduction and adduction (at 90° of forward elevation)

### Bicipital (long head) tendinitis

- Tenderness over bicipital groove
- Pain reproduced by resisted active wrist supination or elbow flexion

**Fig. 26.12** Pain patterns around the shoulder. The dark shading indicates sites of maximum pain.

Complete rotator cuff tears in people under 40 years of age may respond well to full surgical repair, but results are less good in older people. Adhesive capsulitis (frozen shoulder) presents with pain associated with marked restriction of elevation and external rotation. Adhesive capsulitis is commonly associated with diabetes mellitus and neck/radicular lesions. Treatment in the early stage is with analgesia, intra- and extracapsular glucocorticoid injection, and regular 'pendulum' exercises of the arm to mobilise. Complete recovery sometimes takes up to 2 years. For severe or persistent symptoms, joint distension and manipulation under anaesthesia are surgical options.

## Elbow pain

The most common causes are repetitive trauma causing lateral epicondylitis (tennis elbow) and medial epicondylitis (golfer's elbow) ([Box 26.23](#)). SpAs, including psoriatic disease, can present with the same symptoms (tendon insertion enthesitis). Management is by rest, analgesics and topical or systemic NSAIDs. Local glucocorticoid injections may be required in resistant cases. Olecranon bursitis can also follow local repetitive trauma, but other causes include infections and gout.

## Hand and wrist pain

Pain from hand or wrist joints is well localised to the affected joint, except for pain from the first carpometacarpal (CMC) joint, commonly targeted by OA or PsA; although maximal at the thumb base, the pain often radiates down the thumb and to the radial aspect of the wrist. Non-articular causes of hand pain include:

26.23 Common local causes of elbow pain		
Lesion	Pain	Examination findings
<b>Lateral humeral epicondylitis</b> (traumatic 'tennis elbow' or SpA-related enthesitis)	Lateral epicondyle  Radiation to extensor forearm	Tenderness over epicondyle Pain reproduced by resisted active wrist extension
<b>Medial humeral epicondylitis</b> (traumatic 'golfer's elbow' or SpA-related enthesitis)	Medial epicondyle  Radiation to flexor forearm	Tenderness over epicondyle Pain reproduced by resisted active wrist flexion
<b>Olecranon bursitis</b> (gout, rheumatoid arthritis or infection)	Olecranon	Tender swelling

(SpA = spondyloarthritis)

**Fig. 26.13** Pain patterns of hip disease and trochanteric pain syndrome. The dark shading indicates sites of maximum pain.

- *Tenosynovitis*: affects flexor or extensor digital tendons. Pain and tenderness are well localised to the tendon lesions. There is often early-morning 'claw-like' digit stiffness. De Quervain's tenosynovitis involves the tendon sheaths of abductor pollicis longus and extensor pollicis brevis. It produces pain maximal over the radial aspect of the distal forearm and wrist and marked pain on forced ulnar deviation of the wrist with the thumb held across the patient's palm (Finkelstein's sign). This test is not specific for this lesion alone.
- *Raynaud's phenomenon*: digital vasospasm triggered mostly by cold.
- *C6, C7 or C8 radiculopathy*.
- *Carpal tunnel syndrome*: hand position-dependent and/or nocturnal pain, numbness and paraesthesia of thumb and second to fourth digits.

## Hip pain

Pain from the hip joint is usually felt deep in the groin, with variable radiation to the buttock, anterolateral thigh or knee (Fig. 26.13). A lay person's description of their 'hip pain' will often locate the pain to the greater trochanter area. A common cause in older people is OA, which should be suspected if the pain is worse on weight bearing. Paget's disease can also enter into the differential diagnosis. Occasionally, inflammatory disease secondary to axSpA or PsA can present with groin, greater trochanter area or hip pain. Greater trochanter pain syndrome is usually due to either gluteus medius insertional tendonitis/enthesitis, trochanteric bursitis or referred pain (Box 26.24). Pain at this site may also be referred from the lumbosacral spine. Other less common causes of pain in the hip/groin area include inguinal hernia, adductor tendonitis and enthesitis of anterior superior/inferior iliac spines.

## Knee pain

In middle and older age, the most common cause of knee pain is OA, the features of which are described later in this chapter. Pain that is associated with locking of the knee (sudden painful inability to extend fully) is usually due to a meniscal tear or osteochondritis dissecans. Referred pain from the hip may present at the knee and is reproduced by hip, not knee, movement. Pain from periarticular lesions is well localised to the involved structure (Box 26.25). Anterior knee pain may be due to patellar ligament or retinacular lesions (enthesitis, tendonitis, fat-pad syndrome) occurring typically from overuse and/or axSpA. Anterior knee pain is relatively common in adolescents and may be the result of patellar articular cartilage or ligament insertion osteochondritis.

26.24 Local causes of hip pain		
Lesion	Pain	Examination findings
<b>Osteoarthritis</b>	Groin pain, worse on weight bearing	Limited range of movement and/or pain on examination of hip
<b>Gluteus medius enthesitis</b>	Upper lateral thigh, worse on lying on that side at night	Tenderness over greater trochanter
<b>Trochanteric bursitis</b>	As above	As above
<b>Adductor tendonitis</b> (SpA-related enthesitis or sports-related trauma)	Upper inner thigh	Tenderness over adductor origin/tendon/muscle Pain reproduced by resisted active hip adduction
<b>Ischiogluteal enthesitis/bursitis</b>	Buttock, worse on sitting	Tenderness over ischial prominence
<b>Pubic symphysisitis</b> (can mimic intra-articular hip lesions)	Medial groin pain, can radiate to inner or even outer upper thighs	Tenderness over symphysis joint If pain is worse on trunk curl/rectus activation under symphysis-resting hand, it may be insertional rectus enthesitis (SpAs)

(SpA = spondyloarthritis)

26.25 Local causes of knee pain		
Lesion	Pain	Examination findings
Osteoarthritis	Weight bearing or on ascending and descending stairs	Enlargement of knee joint, tenderness at joint margins, crepitus on flexion, small effusions, quadriceps wasting
Pre-patellar bursitis	Over patella	Tender fluctuant swelling in front of patella
Superficial and deep infrapatellar bursitis and fat-pad syndrome	Anterior knee, inferior to patella	Tenderness in front of (superficial) or behind (deep) patellar tendon Pain on full flexion
Anserine bursitis/ enthesitis	Upper medial tibia	Tenderness ( $\pm$ swelling) over upper medial tibia
Medial collateral ligament lesions (injury or enthesitis)	Upper medial tibia	Localised tenderness of upper medial tibia Pain reproduced by valgus stress on partly flexed knee
Popliteal cyst (Baker's cyst)	Popliteal fossa	Tender swelling of popliteal fossa
Patellar ligament enthesopathy	Anterior upper tibia	Tenderness over tibial tubercle
Osteochondritis of patellar ligament (Osgood–Schlatter disease)	Anterior upper tibia	Pain on resisted active knee extension

## Ankle and foot pain

Pain from the ankle (tibiotalar) joint due to OA or osteochondral defect is felt between the malleoli and is worse on weight-bearing. Pain from the subtalar joint (from the same lesions) is also worse on weight-bearing. Inflammatory arthritis of either of these joints (RA, PsA, CPPD arthritis or gout) often worsens and swells with rest. These diagnoses can be associated with hindfoot tenosynovitis (peroneal or posterior tibial). Pain under the heel is typically due to plantar fasciitis. This can occur as the result of overuse, in which case it may respond to rest, padded footwear and local glucocorticoid injections, but can also arise in SpA as a manifestation of enthesitis. Pain affecting the back of the heel may be due to Achilles tendinitis or enthesitis. The MTP joints of the feet are commonly involved symmetrically in RA. The presentation is with pain on walking felt below the metatarsal heads, often described as 'walking on marbles'. Patients with active inflammation of the MTP joints have pain when the forefoot is squeezed. Involvement of the first MTP joint is common in OA or PsA and is associated, respectively, with hallux valgus and dactylitis. The hallux is also a classical target in acute gout. Morton's neuroma is a neuropathy of an interdigital nerve and is usually located between the third and fourth metatarsal heads. Women are most commonly affected (tight shoes can be to blame). Local sensory loss and a palpable tender swelling between the metatarsal heads may be detected. Footwear adjustment often helps, with or without a local glucocorticoid injection, but surgical decompression may be required if symptoms persist.

## Principles of management

The management of rheumatological disorders should be tailored to the underlying diagnosis. Certain aspects are common to many disorders,

26.26 Interventions for patients with rheumatic diseases	
<b>Core interventions</b>	
<ul style="list-style-type: none"> <li>• Education</li> <li>• Aerobic conditioning</li> <li>• Muscle strengthening</li> <li>• Simple analgesics</li> <li>• Disease-modifying therapy</li> </ul>	<ul style="list-style-type: none"> <li>• Reduction of adverse mechanical factors</li> <li>• Pacing of activities</li> <li>• Appropriate footwear</li> <li>• Weight reduction if obese</li> </ul>
<b>Other options</b>	
<ul style="list-style-type: none"> <li>• Other analgesic drugs:               <ul style="list-style-type: none"> <li>• Oral non-steroidal anti-inflammatory drugs</li> <li>• Topical agents</li> <li>• Opioid analgesics</li> <li>• Amitriptyline</li> <li>• Gabapentin/pregabalin</li> </ul> </li> </ul>	<ul style="list-style-type: none"> <li>• Local glucocorticoid injections</li> <li>• Physical treatments:               <ul style="list-style-type: none"> <li>• Heat, cold, aids, appliances</li> </ul> </li> <li>• Surgery</li> <li>• Coping strategies (see Box 26.27)</li> </ul>

however, and the general principles are discussed here. The therapeutic aims are:

- to educate patients about their disease so as to enhance self-management
- to control pain, if it is present
- to optimise function
- to modify the disease process where this is possible
- to identify and treat comorbidity.

These aims are interrelated and success in one area often benefits others. Successful management requires careful assessment of the person as a whole. The management plan should be individualised and patient-centred, should involve relevant members of the multidisciplinary team, and should be agreed and understood by both the patient and all the practitioners that are involved. It must also take into account:

- the patient's activity requirements and occupational and recreational aspirations
- risk factors that may influence the disease
- the patient's perceptions and knowledge of the condition
- medications and coping strategies that have already been tried
- comorbid disease and its therapy
- the availability, costs and logistics of appropriate evidence-based interventions.

Generally, the simplest and safest interventions should be tried first. Symptoms and signs may change with time, so the management plan for most patients requires regular review and re-adjustment.

Core interventions that should be considered for everyone with a painful musculoskeletal condition are listed in Box 26.26. There are also other non-pharmacological and drug options, the choice of which depends on the nature and severity of the diagnosis.

## Education and lifestyle interventions

### Education

Patients must always be informed about the nature of their condition and its investigation, treatment and prognosis, since education can improve outcome. Information and therapist contact can reduce pain and disability, improve self-efficacy and reduce the health-care costs of many musculoskeletal conditions, including OA and RA. The mechanisms are unclear, but in part may result from improved adherence. Benefits are modest, but potentially long-lasting, safe and cost-effective. Education can be provided through one-to-one discussion, written literature, patient-led group education classes and interactive computer programs. Inclusion of the patient's partner or carer is often appropriate;

this is essential for childhood conditions but also helps in many chronic adult conditions.

For children and adolescents with chronic diseases such as JIA, education and support of the whole family, schooling and psychological support is essential and best delivered through a multidisciplinary team.

Patient-run charitable organisations provide a wealth of information and support to patients (see 'Further information'). The detail of the educational materials and services that organisations can provide should be known to the multidisciplinary team and organisation contact details should be made available to patients.

## Exercise

Several types of exercise can be prescribed:

- *Aerobic fitness training* can produce long-term reduction in pain and disability. It improves well-being, encourages restorative sleep and benefits common comorbidity, such as obesity, diabetes, chronic heart failure and hypertension.
- *Local strengthening exercise* for muscles that act over compromised joints also reduces pain and disability, with improvements in the reduced muscle strength, proprioception, coordination and balance that associate with chronic arthritis. 'Small amounts often' of strengthening exercise are better than protracted sessions performed infrequently.
- *Weight-bearing exercise* is of value in osteoporosis, where it can result in modest increases in bone density and slow bone loss.

## Joint protection

Excessive impact-loading and adverse repetitive use of a compromised joint or periarticular tissue can worsen symptoms in patients with arthritis. This can be mitigated by cessation of contact sports and by pacing of activities by dividing physical tasks into shorter segments with brief breaks in between. Other strategies include adaptations to machinery or tools at the workplace; the use of shock-absorbing footwear with thick soft soles, which can reduce impact-loading through feet, knees, hips and back; and the use of a walking stick on the contralateral side to a painful hip, knee or foot.

## Non-pharmacological interventions

### Physical and occupational therapy

Local heat, ice packs, wax baths and other local external applications can induce muscle relaxation and provide temporary relief of symptoms in a range of rheumatic diseases.

Hydrotherapy and balneotherapy (immersion in a bath) induce muscle relaxation and facilitate movement in a warm, pain-relieving environment without the restraints of gravity and normal load-bearing. Various manipulative techniques may also help improve restricted movement.

Splints can give temporary rest and support for painful joints and periarticular tissues, and can prevent harmful involuntary postures during sleep. Prolonged rest must be avoided. Orthoses are more permanent appliances used to reduce instability and excessive abnormal movement and provide support and comfort. They include working wrist splints, knee braces, iron and T-straps to control ankle instability and a multitude of (often custom made) foot insole supports to offload painful or deformed foot structures. Orthoses are particularly suited to severely disabled patients in whom a surgical option is inappropriate and often need to be custom-made for the individual.

Aids and appliances can provide dignity and independence for patients with respect to activities of daily living. Common examples are a raised toilet seat, raised chair height, extended handles on taps, a shower instead of a bath, thick-handled cutlery and extended 'hands' to pull on tights and socks. Full assessment and advice from an occupational therapist maximise the benefits of these aids.

## 26.27 Self-help and coping strategies

- Yoga, Pilates and relaxation techniques to reduce stress
- Avoidance of negative situations or activities that produce stress and increase in pleasant activities that give satisfaction
- Information and discussion to alter beliefs about and perspectives on disease
- Reduction or avoidance of catastrophising and maladaptive pain behaviour
- Imagery and distraction techniques for pain
- Expansion of social contact and better use of social services

## Self-help and coping strategies

These plans help patients to cope better with, and adjust to, chronic pain and disability. They may be useful at any stage but are particularly beneficial for patients with incurable problems who have tried all available treatment options. The aim is to increase self-management through self-assessment and problem-solving, so that patients can recognise negative, but potentially remediable, aspects of their mood (stress, frustration, anger or low self-esteem) and their situation (physical, social, financial). These may then be addressed by changes in attitude and behaviour, as shown in [Box 26.27](#).

Involvement of the spouse or partner in mutual goal-setting can improve partnership adjustment. Such approaches are often an element of group education classes and pain clinics, but may require more formal clinical psychological input.

Tailored multidisciplinary approaches are required for patients with juvenile idiopathic arthritis (JIA) and other chronic childhood diseases, dependent on age and maturity. Adolescents and young adults have specific demands, different to those of young children and adults, which are influenced by many issues in their lives impinging on the disease process, its impact and their ability to cope with it.

## Weight control

Obesity aggravates pain at most sites through increased mechanical strain and is a risk factor for progression of joint damage in patients with OA and other types of arthritis. Obesity may contribute, through its metabolic and inflammatory effects, to amplifying symptoms of rheumatic disease and in certain scenarios has been linked with poorer immunotherapy responses (e.g. anti-TNF- $\alpha$  in PsA). This should be explained to obese patients and strategies offered on how to lose and maintain an appropriate weight. By contrast, excessive weight loss is also detrimental and low weight (body mass index (BMI)  $<20$  kg/m<sup>2</sup>) is associated with an increased risk of fractures. Patients should therefore be advised to maintain BMI within the 20–25 kg/m<sup>2</sup> range.

## Surgery

A variety of surgical interventions can relieve pain and conserve or restore function in patients with bone, joint and periarticular disease ([Box 26.28](#)). Soft tissue release and tenosynovectomy can reduce inflammatory symptoms, improve function and prevent or retard tendon damage for variable periods, sometimes indefinitely. Synovectomy does not prevent disease progression, but may be indicated for pain relief when drugs, physical therapy and intra-articular injections have provided insufficient relief. The main approaches for damaged joints are osteotomy (cutting bone to alter joint mechanics and load transmission), excision arthroplasty (removing part or all of the joint), joint replacement (insertion of prosthesis in place of the excised joint) and arthrodesis (joint fusion). Surgical fixation of fractures is frequently required in patients with osteoporosis and other bone diseases.

The main aims of surgery are to provide pain relief and improve function and quality of life. If surgery is to be successful, the aims and consequences of each operation should be considered as part of an integrated programme of management and rehabilitation by multidisciplinary teams of surgeons, allied health professionals and physicians, and carefully explained to the patient. Assessment of motivation, social support and

## 26.28 Surgical procedures in rheumatological and bone diseases

Procedure	Indication
<b>Soft tissue release</b>	
Carpal tunnel	Median nerve compression
Tarsal tunnel	Posterior tibial nerve entrapment
Flexor tenosynovectomy	Relief of 'trigger' fingers
Ulnar nerve transposition	Ulnar nerve entrapment at elbow
Fasciotomy	Severe Dupuytren's contracture
<b>Tendon repairs and transfers</b>	
Hand extensor tendons	Extensor tendon rupture
Thumb and finger flexor tendons	Flexor tendon rupture
<b>Synovectomy</b>	
Wrist and extensor tendon sheath (+ excision of radial head)	Pain relief and prevention of extensor tendon rupture in RA, resistant inflammatory synovitis
Knee synovectomy	Resistant inflammatory synovitis
<b>Osteotomy</b>	
Femoral osteotomy	Early OA of hip
Tibial osteotomy	Uni-compartmental knee OA Deformed tibia in OA or Paget's disease
<b>Excision arthroplasty</b>	
First metatarsophalangeal joint (Keller's procedure)	Painful hallux valgus
Radial head	Painful distal radio-ulnar joint
Lateral end of clavicle	Painful acromioclavicular joint
Metatarsal head	Painful subluxed metatarsophalangeal joints
<b>Joint replacement arthroplasty</b>	
Knee, hip, shoulder, elbow	Painful damaged joints in OA and RA
<b>Arthrodesis</b>	
Wrist	Damaged joint: pain relief, improvement of grip
Ankle/subtalar joints	Damaged joint: pain relief, stabilisation of hindfoot
<b>Fracture repair</b>	
Hip arthroplasty	Fractured neck of femur
External fixation	Multiple fractures, open fractures
Intramedullary nailing	Tibial and femur fractures
Screw, plating and wiring	Wrist and other fractures
<b>Other procedures</b>	
Nerve root decompression	Spinal stenosis, nerve entrapment
Vertebroplasty and kyphoplasty	Painful vertebral fracture (evidence base for efficacy poor)

(OA = osteoarthritis; RA = rheumatoid arthritis)

environment is no less important than careful consideration of patients' general health, their risks for major surgery, the extent of disease in other joints, and their ability to mobilise following surgery. For some severely compromised people, pain relief and functional independence are better served by provision of a suitable wheelchair, home adjustments and social services than by surgery that is technically successful, but following which the patient cannot mobilise.

## Pharmacological treatment

### Analgesics

Paracetamol (1 g up to 4 times daily) is the oral analgesic of first choice for mild to moderate pain. It is thought to work by inhibiting prostaglandin

synthesis in the brain while having little effect on peripheral prostaglandin production. It is well tolerated and has few adverse effects and drug interactions. An increased risk of gastrointestinal events and cardiovascular disease has been reported with chronic usage in observational studies, but this may be due to channelling of patients at higher risk of these events for treatment with paracetamol rather than an NSAID. Paracetamol can be combined with codeine (co-codamol) or dihydrocodeine (co-dydramol). These compound analgesics are more effective than paracetamol, but have more side-effects, including constipation, headache and delirium (especially in older adults). The centrally acting opioid analgesics tramadol and meptazinol may be useful for temporary control of severe pain unresponsive to other measures, but can cause nausea, bowel upset, dizziness and somnolence, and withdrawal symptoms after chronic use. The non-opioid analgesic nefopam (30–90 mg three times daily) can help moderate pain, though side-effects (nausea, anxiety, dry mouth) often limit its use. Patients with severe or intractable pain may require strong opioid analgesics, such as oxycodone or morphine.

### Non-steroidal anti-inflammatory drugs (NSAIDs)

These are among the most widely prescribed drugs, but their use has declined over recent years because long-term prescription is associated with an increased risk of cardiovascular disease. Oral NSAIDs are useful in the treatment of a range of rheumatic diseases with an inflammatory component. They inhibit the cyclo-oxygenase (COX) and prostaglandin H synthase enzymes, which convert arachidonic acid, derived from membrane phospholipids, to prostaglandins and leukotrienes by the COX and 5-lipoxygenase pathways, respectively (Fig. 26.14). There are two COX isoforms; COX-1 is constitutively expressed in gastric mucosa, platelets and kidneys, and production of prostaglandins at these sites protects against mucosal damage and regulates platelet aggregation and renal blood flow. The COX-2 enzyme is induced at sites of inflammation, producing prostaglandins that cause local pain and swelling. Inflammation also up-regulates COX-2 in the spinal cord, where it modulates pain perception. Ibuprofen, diclofenac and naproxen are non-selective drugs that inhibit both COX enzymes, whereas celecoxib and etoricoxib are

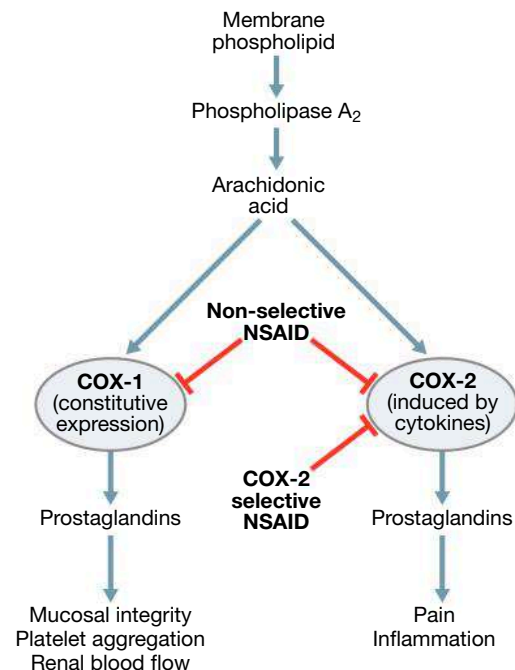

Fig. 26.14 Mechanism of action of non-steroidal anti-inflammatory drugs (NSAIDs). (COX = cyclo-oxygenase)

26.29 Commonly used NSAIDs and their risk of gastrointestinal bleeding and perforation			
Drug	Daily adult dose	Doses/day	Idiosyncratic side-effects, comments
<b>Low risk</b>			
Celecoxib	100–200 mg	1–2	Selective COX-2 inhibitor
Etoricoxib	60–120 mg	1	Selective COX-2 inhibitor
<b>Medium risk</b>			
Ibuprofen	1600–2400 mg	3–4	Gastrointestinal adverse effects more likely than with COX-2 inhibitors, even with PPI therapy
Naproxen	500–1000 mg	1–2	
Diclofenac	75–150 mg	2–3	
<b>High risk</b>			
Indometacin	50–200 mg	3–4	High incidence of dyspepsia and CNS side-effects

(CNS = central nervous system; COX = cyclo-oxygenase; PPI = proton pump inhibitor)

26.30 Risk factors for NSAID-induced peptic ulcers	
<ul style="list-style-type: none"> <li>• Age &gt; 60 years*</li> <li>• Past history of peptic ulcer*</li> <li>• Past history of adverse event with NSAID</li> <li>• Concomitant glucocorticoid use</li> <li>• High-dose or multiple NSAIDs</li> <li>• High-risk NSAIDs (see Box 26.29)</li> </ul>	
*The most important risk factors.	

selective inhibitors of COX-2. While NSAIDs have anti-inflammatory activity, they are not thought to have a disease-modifying effect in either OA or inflammatory rheumatic diseases.

Non-selective NSAIDs can damage the gastric and duodenal mucosal barrier and are associated with an increased risk of upper gastrointestinal ulceration, bleeding and perforation. The adjusted increased risk (odds ratio) of bleeding or perforation from non-selective NSAIDs is 4–5, though differences exist between NSAIDs (Box 26.29). Dyspepsia is a poor guide to the presence of NSAID-associated ulceration and bleeding, and the principal risk factors are shown in Box 26.30. Co-prescription of a proton pump inhibitor (PPI) or misoprostol (200 µg twice or 3 times daily) reduces the risk of NSAID-induced ulceration and bleeding, but H<sub>2</sub>-antagonists in standard doses are ineffective. The COX-2 selective NSAIDs are much less likely to cause gastrointestinal toxicity, but benefit is attenuated in patients on low-dose aspirin. The UK National Institute for Health and Care Excellence (NICE) guidelines advise that a PPI should be co-prescribed with all NSAIDs, including COX-2-selective NSAIDs, even though the risk of gastrointestinal events with these is low. Since chronic PPI therapy is associated with an increased risk of hip fracture, the merits of giving PPI therapy with a COX-2-selective drug need to be carefully considered.

Other side-effects of NSAIDs include fluid retention and renal impairment due to inhibition of renal prostaglandin production, non-ulcer-associated dyspepsia, abdominal pain, altered bowel habit and rashes. Interstitial nephritis, asthma and anaphylaxis can also occur but are rare.

26.31 Recommendations for the use of NSAIDs	
<ul style="list-style-type: none"> <li>• Use the lowest dose for the shortest time possible to control symptoms</li> <li>• Avoid NSAIDs in patients on warfarin</li> <li>• Allow 2–3 weeks to assess efficacy. If response is inadequate, consider a trial of another NSAID</li> <li>• Never prescribe more than one NSAID at a time</li> <li>• Co-prescribe a proton pump inhibitor for patients with risk factors for gastrointestinal adverse effects (see Box 26.30)</li> <li>• Avoid in patients with cardiovascular disease</li> </ul>	

26.32 Use of oral NSAIDs in old age	
<ul style="list-style-type: none"> <li>• <b>Gastrointestinal complications:</b> age is a strong risk factor for enteral bleeding and perforation, and for peptic ulceration. Older adults are more likely to die if they suffer NSAID-associated enteral bleeding or perforation.</li> <li>• <b>Cardiovascular disease:</b> use NSAIDs with caution in patients with cardiovascular disease. Therapy with NSAIDs may exacerbate hypertension and heart failure.</li> <li>• <b>Renal disease:</b> use of NSAIDs may cause or worsen renal impairment.</li> </ul>	

Recommendations for NSAID prescribing are summarised in Box 26.31. Because of the risk of adverse effects, NSAIDs should be used with great care in older patients (Box 26.32).

## Topical agents

Topical NSAID creams and gels and capsaicin cream can help in the treatment of OA and superficial periarticular lesions affecting hands, elbows and knees. They may be used as monotherapy or as an adjunct to oral analgesics. Topical NSAIDs can penetrate superficial tissues and even reach the joint capsule, though intrasynovial levels mainly reflect blood-borne drug delivery. Capsaicin selectively binds to the protein transient receptor potential vanilloid type 1 (TRPV1), which is a heat-activated calcium channel on the surface of peripheral type C nociceptor fibres. Initial application causes a burning sensation, but continued use depletes presynaptic substance P, with subsequent pain reduction that is optimal after a period of 1–2 weeks. Lidocaine 5% medicated patches are licensed for the treatment of post-herpetic neuropathic pain, but are also used off label for a variety of painful conditions including painful vertebral fractures, sometimes with good effects.

## Disease-modifying anti-rheumatic drugs

Disease-modifying anti-rheumatic drugs (DMARDs) comprise small-molecule inhibitors of the immune response, glucocorticoids and biologic DMARDs. DMARDs not only improve symptoms but also favourably modify disease progression in a variety of inflammatory rheumatic diseases. Small-molecule inhibitors are either classical DMARDs (cDMARDs), which have relatively non-specific inhibitory effects on the immune response (Box 26.33), or targeted synthetic DMARDs (tsDMARDs), which are designed to inhibit the effects of a specific target molecule (Box 26.34). Biologic DMARDs ('biologics') are monoclonal antibodies, fusion proteins or decoy receptors targeted towards specific cytokines, receptors and other cell-surface molecules regulating the immune response (Fig. 26.15). Most cDMARDs have the potential to cause bone marrow suppression or liver dysfunction and require regular blood monitoring, as summarised in Box 26.33. If toxicity occurs, treatment may need to be stopped temporarily and resumed at a lower dose or withdrawn completely if toxicity is severe.

### Classical DMARDs (cDMARDs)

*Methotrexate* (MTX) is the core cDMARD in RA, JIA and PsA. It inhibits folic acid reductase, preventing formation of tetrahydrofolate, which is necessary for DNA synthesis in leucocytes and other cells. It is given

### 26.33 Classical disease-modifying anti-rheumatic drugs (DMARDs)

Drug	Maintenance dose	Monitoring*			Indications
		FBC	LFTs	Other	
<b>Methotrexate (MTX)</b>	15–25 mg weekly orally or s/c	✓	✓		RA, PsA, JIA, axSpA, CPP disease
<b>Sulfasalazine (SSZ)</b>	2–4 g daily orally	✓	✓		RA, PsA, axSpA,
<b>Hydroxychloroquine (HCQ)</b>	200–400 mg daily orally	–	–	Visual function	RA, SLE, CPP disease
<b>Leflunomide (LEF)</b>	10–20 mg daily orally	✓	✓	BP	RA, PsA
<b>Azathioprine (AZA)</b>	1–2.5 mg/kg daily orally	✓	✓		SLE, SV
<b>Cyclophosphamide</b>	2 mg/kg daily orally or 15 mg/kg IV	✓	✓	eGFR	SLE, SV
<b>Mycophenolate mofetil (MMF)</b>	2–4 g daily orally	✓	✓	–	SLE, SV
<b>Ciclosporin A</b>	3–5 mg/kg daily orally	–	–	BP, eGFR	RA, PsA

\*Monitoring tests are usually done every 2 weeks on initiation of treatment for 6 weeks, then monthly for 3 months, then 3-monthly.  
(axSpA = axial spondyloarthritis; BP = blood pressure; CPP = calcium pyrophosphate; eGFR = estimated glomerular filtration rate; FBC = full blood count; IM = intramuscular; IV = intravenous; JIA = juvenile idiopathic arthritis; LFTs = liver function tests; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SV = systemic vasculitis)

### 26.34 Targeted synthetic disease-modifying anti-rheumatic drugs

Drug	Maintenance dose	Regular monitoring			Indications
		FBC	LFT	Other	
<b>Apremilast</b>	30 mg twice daily orally	–	–	–	PsA
<b>Tofacitinib</b>	5 mg twice daily orally	✓	✓	Infection	RA, PsA
<b>Baricitinib</b>	2–4 mg daily orally	–	–	Infection	RA
<b>Upadacitinib</b>	15–30 mg daily orally	–	–	Infection	RA, PsA, axSpA
<b>Filgotinib</b>	200 mg daily orally	–	–	Infection	RA

orally or subcutaneously using a variety of dose increment schedules, to a maximum of 25 mg weekly (in adults) and 15 mg/m<sup>2</sup>/week in JIA, until benefit or toxicity occurs. Folic acid (5 mg/week) should be co-prescribed to be taken the day after MTX since it reduces adverse effects without impairing efficacy. Benefit is usually observed after 4–8 weeks, but treatment should continue for 3 months before reaching the conclusion that MTX has been ineffective. The most common adverse effects are nausea, vomiting and malaise, which usually occur one 1–2 days after the weekly dose. Patients should be warned of drug interaction with sulphonamides and the importance of avoiding excess alcohol, which enhances MTX hepatotoxicity. Acute pulmonary toxicity (pneumonitis) is rare, but can occur at any time during treatment and patients should be warned to stop therapy and seek advice if they develop any new respiratory symptoms. If pneumonitis occurs, treatment should be withdrawn and high-dose glucocorticoids given. MTX must be co-prescribed with robust contraception in women of child-bearing potential and treatment must be stopped for 3 months in advance of planning a pregnancy.

*Sulfasalazine* (SSZ) can be used alone or in combination with other drugs in the treatment of RA and PsA. Its mechanism of action is incompletely understood. Nausea and gastrointestinal intolerance are the main adverse effects but leucopenia, abnormal liver function tests (LFTs) and rashes may occur. The usual starting dose is 500 mg daily, escalating in 500 mg increments every 2 weeks to a maintenance dose of 2–4 g daily until benefit or toxicity occurs. Benefit may be observed after 4–8 weeks, but treatment should be continued for 3 months before concluding that it has been ineffective. Orange staining of urine and contact lenses may occur. SSZ is generally considered to be safe during pregnancy.

*Hydroxychloroquine* (HCQ) can be used alone or in combination with other drugs in the treatment of RA and SLE in a dose of 200–400 mg daily. It acts by modulating lysosomal activity and autophagy causing inhibition of inflammatory responses. While a wide range of side-effects can theoretically occur, it is generally well tolerated in practice. With long-term use

(> 5 years) there is a risk of ocular toxicity due to accumulation in the retina, although this is uncommon. It is usual to check visual function before starting treatment and to repeat this periodically while treatment is continued. HCQ is generally considered to be safe during pregnancy.

*Leflunomide* (LEF) can be used alone or in combination with other drugs for the treatment of RA and PsA in a dose of 10–20 mg/day. It works by inhibiting dihydro-orotate dehydrogenase, an enzyme used by activated lymphocytes to synthesise pyrimidines necessary for DNA synthesis. It has low marrow toxicity, but may cause liver dysfunction, hypertension and hirsutism. It must be co-prescribed with robust contraception in women of child-bearing potential. Treatment must be stopped for a period of 2 years in advance of planning a pregnancy or undergo a washout procedure with cholestyramine to remove the drug from the system.

*Azathioprine* (AZA) is most commonly used in vasculitis and SLE, often in combination with other drugs. It is metabolised to 6-mercaptopurine (6-MP), which blocks lymphocyte proliferation by inhibiting DNA synthesis. The typical starting dose is 1 mg/kg body weight per day, increasing to 2.5 mg/kg until a response is observed or toxicity occurs. Bone marrow suppression is the most important side-effect, but nausea may also occur. Genetic polymorphisms in the enzyme thiopurine S-methyltransferase (TPMT) influence catabolism of 6-MP and sometimes genetic testing for TPMT variants is done to guide dosages. Allopurinol inhibits catabolism of azathioprine, necessitating a 75% reduction in azathioprine dose.

*Cyclophosphamide* is a cytotoxic alkylating agent that cross-links DNA and halts cell division, causing immunosuppression. It is mainly used to induce remission in life-threatening systemic vasculitis and SLE. It can be given orally in a dose of 2 mg/kg/day for 3–6 months or intravenously in a dose of 15 mg/kg every 3–4 weeks on 6–8 occasions. Adverse effects include nausea, anorexia, vomiting, bone marrow suppression, cardiac toxicity, alopecia and haemorrhagic cystitis. The risk of cystitis can be mitigated by co-administration of mesna (2-mercaptoethane sulfonate, which binds its urotoxic metabolites) and a high fluid intake.

**Fig. 26.15 Targets for biologic therapies in inflammatory rheumatic diseases.** Biologic treatments for inflammatory rheumatic diseases work by targeting key cytokines and other molecules involved in regulating the immune response. (BAFF = B-cell-activating factor of the TNF family; AMP = adenosine monophosphate; cAMP = cyclic AMP; CD = cluster of differentiation; IL = interleukin; JAK = Janus activated kinase; P = phosphate; PDE = phosphodiesterase; PKA = protein kinase A; STAT = signal transducers and activators of transcription; TNF- $\alpha$  = tumour necrosis factor alpha; TNFi = inhibitor of tumour necrosis factor)

*Mycophenolate mofetil (MMF)* works by inhibiting inosine monophosphate dehydrogenase, a rate-limiting enzyme in the synthesis of guanosine nucleotides in lymphocytes. MMF is used in SLE and vasculitis in doses of 2–4 g daily orally. Haematological toxicity is the main adverse effect.

*Ciclosporin A* is a calcineurin inhibitor that inhibits lymphocyte activation. It is occasionally used in the treatment of RA and PsA at a dose of 2.5–4 mg/kg/day orally.

*Glucocorticoids* have powerful anti-inflammatory and immunosuppressive effects and have been shown to have disease-modifying effects in various inflammatory rheumatic diseases. They promote apoptosis of many immune cells and activation of a wide range of pro-inflammatory signalling pathways. They are used orally, intravenously, intramuscularly and by intra-articular injection in the treatment of a wide range of inflammatory rheumatic diseases, as well as by local injection in patients with soft tissue rheumatism.

*Systemic glucocorticoids* are widely used in moderate to high doses to induce remission in early RA, systemic and polyarticular JIA, giant cell arteritis, polymyalgia rheumatica, vasculitis and SLE. Many patients with SLE require low dose maintenance therapy with glucocorticoids and this is sometimes also required in RA when other options are unsuitable. They are widely used in the short-term treatment of flares in many inflammatory rheumatic diseases. Glucocorticoids should be used with caution in PsA because of a rebound increase in activity of psoriasis when the effects wear off.

*Intra-articular glucocorticoids* are employed in the treatment of a wide range of inflammatory arthritides and are primarily indicated when there are one or two problem joints with persistent synovitis despite good general control of the disease. Methylprednisolone is one of the most widely used, typically in doses of 40–80 mg.

*Intramuscular methylprednisolone* (80–120 mg) is a useful way of controlling inflammatory arthritis while waiting for the effects of newly

introduced drugs to take effect. It can also be helpful in patients with stable disease who have a disease flare where a major change in DMARD strategy is not thought to be necessary.

### Targeted synthetic DMARDs (tsDMARDs)

These are small molecules targeted at specific intracellular targets involved in regulating the immune response. Treatment costs are high and these drugs are generally used as second-line agents in patients who have responded inadequately to cDMARDs.

*Janus-activated kinase (JAK) inhibitors* work by inhibiting JAK enzymes, which are a family of intracellular signalling molecules that play a key role in transducing the effects of several pro-inflammatory cytokines. The main adverse effects of JAK inhibitors are an increased risk of infections, and because of this, it is customary to screen patients for evidence of occult infection with HIV, hepatitis C, hepatitis B and previous TB before commencing therapy. Currently there are four drugs in this class. Tofacitinib (5 mg twice daily or 10 mg daily) is indicated for adults with RA and PsA. It is usually prescribed in combination with MTX, but can be used as monotherapy in patients where MTX is poorly tolerated or contraindicated. Baricitinib (2–4 mg once daily) and filgotinib (200 mg daily) are both indicated for RA. Upadacitinib (15 mg daily) is also indicated as monotherapy or in combination with MTX, for RA, PsA and AxSpA. Tofacitinib requires long-term blood monitoring for marrow and liver toxicity, but this is not required with the other JAK inhibitors once the first 3 months of therapy have been completed.

*Apremilast* is used in the treatment of PsA. It is a small molecule inhibitor of phosphodiesterase 4, an enzyme that breaks down cyclic adenosine monophosphate (cAMP). This suppresses production of pro-inflammatory cytokines, thereby reducing inflammation. Apremilast is given orally in a dose of 30 mg twice daily. The main adverse effects are gastrointestinal upset, weight loss and an increased risk of depression.

### 26.35 Biologic therapies for inflammatory rheumatic disease

Drug	Maintenance dose	Mechanism of action	Indications
Etanercept	50 mg weekly SC	Decoy receptor for TNF- $\alpha$	RA, PsA, AxSpA, JIA
Infliximab	3–5 mg/kg 8-weekly IV	Antibody to TNF- $\alpha$	RA, PsA, AxSpA, JIA
Adalimumab	40 mg 2-weekly SC		
Certolizumab	200 mg 2-weekly SC		
Golimumab	50 mg 4-weekly SC		
Rituximab	2 $\times$ 1 g 2 weeks apart IV	Antibody to CD20; destroys B cells	RA, vasculitis
Belimumab	200 mg weekly SC or 10 mg/kg 4-weekly IV	Antibody to BAFF; inhibits B-cell activation	SLE
Abatacept	125 mg weekly SC or 10 mg/kg 4-weekly IV	Inhibits T-cell activation	RA, PsA, JIA
Tocilizumab	162 mg weekly SC or 8 mg/kg 8-weekly IV	Antibody to IL-6 receptor	RA, JIA, GCA
Sarilumab	200 mg 2-weekly SC	Antibody to IL-6 receptor	RA
Ustekinumab	45 mg 12-weekly SC	Antibody to IL-12 and IL-23	PsA
Secukinumab	150 mg 4-weekly SC	Antibody to IL-17A	PsA, axSpA
Ixekizumab	80 mg 4-weekly SC	Antibody to IL-17A/F	PsA and AxSpA
Anakinra	100 mg daily SC	Decoy receptor for IL-1	RA, CAPS, AOSD, gout
Canakinumab	150 mg or 2 mg/kg 8-weekly SC	Antibody to IL-1 $\beta$	CAPS, sJIA, AOSD, gout
Guselkumab	100 mg 8-weekly SC	Antibody to IL-23	PsA

(AOSD = adult-onset Still's disease; axSpA = axial spondyloarthritis; BAFF = B cell-activating factor of the TNF family; CAPS = cryopyrin-associated periodic syndromes; CD = cluster of differentiation; GCA = giant cell arteritis; IL = interleukin; IV = intravenous; JIA = juvenile idiopathic arthritis; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SC = subcutaneous; sJIA = systemic juvenile idiopathic arthritis; SLE = systemic lupus erythematosus; TNF- $\alpha$  = tumour necrosis factor alpha)

### Biologic DMARDs

'Biologics' (monoclonal antibodies, fusion proteins or decoy receptors) are given either as self-administered subcutaneous injections every 1–4 weeks or as infusions every few weeks. The main adverse effect of biologics as a class is an increased risk of infections, and screening for occult infections is generally performed before commencing therapy as described for JAK inhibitors. Biologics are not carcinogenic, but patients who develop cancer while on treatment may exhibit accelerated progression of the tumour due to suppression of the immune response. Treatment costs are higher than with cDMARDs and tsDMARDs and many countries have set guidelines and funding restrictions that limit their use. Their mechanisms of action, dosages and indications are summarised in [Box 26.35](#).

**TNF- $\alpha$  inhibitors.** Most drugs in this class are monoclonal antibodies that bind to and neutralise TNF- $\alpha$ , but etanercept is a decoy receptor that prevents TNF- $\alpha$  binding to its receptor. Anti-TNF- $\alpha$  therapy is frequently used as the first-line biologic in RA, JIA and PsA when cDMARD therapy has been incompletely effective and as first line biologic in axSpA/AS in patients who have failed to respond adequately to NSAID therapy. Anti-TNF- $\alpha$  is contraindicated in patients with active infections and those with indwelling catheters, due to the high risk of infection. Other contraindications are heart failure (New York Heart Association grade 3 or 4) and multiple sclerosis, both of which may be worsened by treatment. Anti-TNF- $\alpha$  therapies can be used during pregnancy, but should be stopped in the third trimester since most cross the placenta and can cause immunosuppression in the neonate. An exception is certolizumab, which does not cross the placenta and can be used safely throughout pregnancy.

**Rituximab** is an antibody directed against the CD20 receptor, which is expressed on B lymphocytes and immature plasma cells. Rituximab causes profound B cell lymphopenia for several months due to complement-mediated lysis of cells that express CD20. Rituximab is indicated in RA patients where response to cDMARDs has been inadequate and to induce remission in adults and children with ANCA-associated vasculitis. In RA, treatment can be repeated when signs of improvement are wearing off (6 months to 1 year or longer). In ANCA-positive vasculitis, a single cycle of treatment may last for up to 18 months. Adverse effects include hypogammaglobulinaemia, infusion reactions, an increased risk of infections and, rarely, progressive multifocal leucoencephalopathy

(PML), a serious and potentially fatal infection of the central nervous system caused by reactivation of JC virus.

**Belimumab** is a monoclonal antibody that blocks the effects of the cytokine B cell-activating factor of the TNF family (BAFF), which is required for B cell survival and function. It is indicated in juvenile and adult patients with SLE who have had an inadequate response to cDMARDs. The main adverse effects are an increased risk of infection, leucopenia and hypersensitivity reactions following infusion.

**Abatacept** is a fusion protein in which the Fc domain of IgG has been combined with the extracellular domain of CTLA4, which blocks T-cell activation by acting as a decoy for CD28, a co-stimulatory molecule necessary for T-cell activation. It is indicated for RA and PsA and polyarticular onset JIA where the response to cDMARDs is inadequate. The main adverse effect is an increased risk of infections.

**IL-6 inhibitors.** There are two drugs in this class. Tocilizumab is a monoclonal antibody that competes with IL-6 for binding to the IL-6 receptor, thereby inhibiting IL-6 signalling. It is indicated in RA with or without MTX after inadequate response to cDMARDs and in patients 12 years of age and older with systemic JIA, who have responded inadequately to therapy with NSAIDs and systemic glucocorticoids. It is also indicated as a steroid-sparing agent in GCA. Sarilumab is a monoclonal antibody (IgG1) that works in a similar way to tocilizumab, which is licensed for treating adult RA (with concomitant MTX), where there has been an inadequate response to cDMARDs. Adverse effects of both agents include leucopenia, abnormal LFTs, hypercholesterolaemia and hypersensitivity reactions. Both drugs should be avoided during pregnancy if possible.

**Ustekinumab** is an antibody to p40, which is a subunit shared by the cytokines IL-23 and IL-12. It acts as an inhibitor of both IL-12 and IL-23 signalling and is indicated in adults with PsA who have not responded adequately to cDMARDs. It can be used as monotherapy or in combination with MTX. Adverse effects include an increased risk of infections, hypersensitivity reactions and an exfoliative dermatitis. Guselkumab is an antibody directed against the p19 protein of IL-23, which acts as a specific inhibitor of IL-23 signalling. It is effective in the treatment of PsA and can be used alone or in combination with MTX.

**IL-17 inhibitors.** There are two drugs in this class; secukinumab is a monoclonal antibody to IL-17A and ixekizumab, which binds both

IL-17A and IL-17A/F. These drugs are indicated in adults with PsA and axSpA who have not responded adequately to cDMARDs and/or anti-TNF- $\alpha$ . Adverse effects include an increased risk of triggering bouts of IBD, infections, nasopharyngitis and headache. Adverse effects include infections and exacerbation of IBD. Clinical experience indicates that these drugs are probably safe during pregnancy, but information is limited.

**Interleukin-1 inhibitors.** There are two drugs in this class. Anakinra is a human IL-1 receptor antagonist, which neutralises the effects of interleukin-1 $\alpha$  (IL-1 $\alpha$ ) and interleukin-1 $\beta$  (IL-1 $\beta$ ) by inhibiting binding to interleukin-1 type I receptor (IL-1RI). Its most frequent use is for the treatment of adult-onset Still's disease and for periodic fever syndromes (p. 76). It has some efficacy in RA, but is seldom used since other drugs are more effective. Other indications include acute gout, although it is not licensed for this condition, and chronic non-infectious osteomyelitis (see p. 1062). Adverse effects include an increased risk of infections, hypersensitivity reactions and neutropenia. Canakinumab is a monoclonal antibody directed against IL-1 $\beta$ , which is indicated for the treatment of systemic JIA (Still's disease), adult-onset Still's disease and acute flares of gout resistant to other treatments. The usual maintenance dose in adults is 150–300 mg every 8 weeks. Adverse effects include an increased risk of infections, hypersensitivity reactions and neutropenia.

## Osteoarthritis

Osteoarthritis (OA) is by far the most common form of arthritis and is a major cause of pain and disability in older people. It is characterised by focal loss of articular cartilage, subchondral osteosclerosis, osteophyte formation at the joint margin and remodelling of joint contour with enlargement of affected joints.

### Epidemiology

The prevalence rises progressively with age and it has been estimated that 45% of all people develop knee OA and 25% hip OA at some point during life. Although some are asymptomatic, the lifetime risk of having a total hip or knee replacement for OA in someone aged 50 is about 11% for women and 8% for men in the UK. There are major ethnic differences in susceptibility: the prevalence of hip OA is lower in Africa, China, Japan and South Asia than in European countries, while that of knee OA is higher.

### Pathophysiology

OA is a complex disorder, with both genetic and environmental components (Box 26.36). Family-based studies have estimated that the heritability of OA ranges from about 43% at the knee to between 60% and 65% at the hip and hand, respectively. In most cases, the inheritance is polygenic and mediated by several genetic variants of small effect. OA can be a component of multiple epiphyseal dysplasias, which are caused by single gene mutations affecting components of cartilage matrix. Structural abnormalities, such as slipped femoral epiphysis and developmental dysplasia of the hip, are also associated with a high risk of OA, presumably due to abnormal load distribution across the joint. Similar mechanisms probably explain the increased risk of OA in patients with limb deformity secondary to Paget's disease of bone. Biomechanical factors play an important role in OA related to certain occupations, such as farmers (hip OA), miners (knee OA) and elite or professional athletes (knee and ankle OA). It has been speculated that the higher prevalence of knee OA in South and East Asia might be accounted for by squatting. There is also a high risk of knee OA in people who have had destabilising injuries, such as cruciate ligament rupture, and those who have had meniscectomy. For most individuals, however, participation in recreational sport does not appear to increase the risk significantly. There is a strong association between obesity and OA, particularly of the hip knee. This is thought to be due partly to biomechanical factors, but it has also been speculated that cytokines released from adipose tissue may play a role. Oestrogen appears important; lower rates of OA have been

**Fig. 26.16 Pathological changes in osteoarthritis.** **A** Abnormal nests of proliferating chondrocytes (arrows) interspersed with matrix devoid of normal chondrocytes. **B** Fibrillation of cartilage in osteoarthritis (OA). **C** X-ray of knee joint affected by OA, showing osteophytes at joint margin (white arrows), subchondral sclerosis (black arrows) and a subchondral cyst (open arrow).

observed in women who use hormone replacement therapy (HRT), while women who receive aromatase inhibitor therapy for breast cancer often experience a flare in symptoms of OA.

Degeneration of articular cartilage is the defining feature of OA. Under normal circumstances, chondrocytes are terminally differentiated cells, but in OA they start dividing to produce nests of metabolically active cells (Fig. 26.16A). Initially, matrix components are produced by these cells at an increased rate, but at the same time there is accelerated degradation of the major structural components of cartilage matrix, including aggrecan and type II collagen (see Fig. 26.5). Eventually, the concentration of aggrecan in cartilage matrix falls and makes the cartilage vulnerable to load-bearing injury. Fissuring of the cartilage surface ('fibrillation') then occurs, leading to the development of deep vertical clefts (Fig. 26.16B), localised chondrocyte death and decreased cartilage thickness. This is initially focal, mainly targeting the maximum load-bearing part of the joint, but eventually large parts of the cartilage surface are damaged. CPP and basic calcium phosphate crystals often become deposited in the abnormal cartilage.

OA is also accompanied by abnormalities in subchondral bone, which becomes sclerotic and the site of subchondral cysts (Fig. 26.16C). Fibrocartilage is produced at the joint margin, which undergoes endochondral ossification to form osteophytes. Bone remodelling and cartilage thinning slowly alter the shape of the OA joint, increasing its surface area. It is almost as though there is a homeostatic mechanism operative in

OA that causes enlargement of the failing joint to spread the mechanical load over a greater surface area.

Patients with OA also have higher BMD values at sites distant from the joint and this is particularly associated with osteophyte formation. This is in keeping with observations made in epidemiological studies that show that patients with OA are partially protected from developing osteoporosis and vice versa. This is likely to be due to the fact that the genetic factors that predispose to osteoporosis might be protective for OA.

The synovium in OA is often hyperplastic and may be the site of inflammatory change, but to a much lesser extent than in RA and other inflammatory arthropathies. Osteochondral bodies commonly occur within the synovium, reflecting chondroid metaplasia or secondary uptake and growth of damaged cartilage fragments. The outer capsule also thickens and contracts, usually retaining the stability of the remodelling joint. The muscles surrounding affected joints commonly show evidence of wasting and non-specific type II fibre atrophy.

### Clinical features

Osteoarthritis has a characteristic distribution, mainly targeting the hips, knees, PIP and DIP joints of the hands, neck and lumbar spine (see Fig. 26.10). The main presenting symptoms are pain and functional restriction. The causes of pain in OA are not completely understood, but may relate to increased pressure in subchondral bone (mainly causing night pain), trabecular microfractures, capsular distension and low-grade synovitis. Pain may also result from bursitis and enthesopathy secondary to altered joint mechanics. Typical OA pain has the characteristics listed in Box 26.37. For many people, functional restriction of the hands, knees or hips is an equal, if not greater, problem than pain. The clinical findings vary according to severity, but are principally those of joint damage.

The correlation between the presence of structural change, as assessed by imaging, and symptoms such as pain and disability varies markedly according to site. It is stronger at the hip than at the knee and weak at most small joints. This suggests that the risk factors for pain and disability may differ from those for structural change. At the knee, for example, reduced quadriceps muscle strength and adverse psychosocial factors (anxiety, depression) correlate more strongly with pain and disability than the degree of radiographic change.

Radiological evidence of OA is very common in middle-aged and older people, and the disease may coexist with other conditions, so it is important to remember that pain in a patient with OA may be due to another cause.

### Generalised nodal OA

Characteristics of this common form of OA are shown in Box 26.38. Some patients are asymptomatic whereas others develop pain, stiffness and swelling of one or more PIP and DIP joints of the hands from the age of about 40 years onwards. Gradually, these develop posterolateral swellings on each side of the extensor tendon, which slowly enlarge and harden to become Heberden's (DIP) and Bouchard's (PIP) nodes (Fig. 26.17). Typically, each joint goes through a phase of episodic symptoms (1–5 years) while the node evolves and OA develops. Once OA is fully established, symptoms may subside and hand function often remains good. Affected joints are enlarged as a result of osteophyte formation and often show characteristic lateral deviation, reflecting the asymmetric focal cartilage loss of OA (Fig. 26.18). Involvement of the first carpometacarpal (CMC) joint is also common, leading to pain on trying to open bottles and jars, and functional impairment. Clinically, it may be detected by the presence of crepitus on joint movement and squaring of the thumb base.

Generalised nodal OA has a very strong genetic component: the daughter of an affected mother has a 1 in 3 chance of developing nodal OA herself. People with nodal OA are also at increased risk of OA at other sites, especially the knee.

### Knee OA

At the knee, OA principally targets the patello-femoral and medial tibio-femoral compartments, but eventually spreads to affect the whole of the

### 26.37 Symptoms and signs of osteoarthritis

#### Pain

- Insidious onset over months or years
- Variable or intermittent nature over time ('good days, bad days')
- Mainly related to movement and weight-bearing, relieved by rest
- Mild morning stiffness (< 15 mins) and inactivity gelling (< 5 mins) after rest
- Usually only one or a few joints painful

#### Clinical signs

- Restricted movement due to capsular thickening or blocking by osteophyte
- Palpable, sometimes audible, coarse crepitus due to rough articular surfaces
- Bony swelling around joint margins
- Deformity, usually without instability
- Joint-line or periarticular tenderness
- Muscle weakness and wasting
- Mild or absent synovitis

### 26.38 Characteristics of generalised nodal osteoarthritis

- Polyarticular finger interphalangeal joint osteoarthritis
- Heberden's ( $\pm$  Bouchard's) nodes
- Marked female preponderance
- Peak onset in middle age
- Good functional outcome for hands
- Predisposition to osteoarthritis at other joints, especially knees
- Strong genetic predisposition

**Fig. 26.17 Nodal osteoarthritis.** Heberden's nodes and lateral (radial to ulnar) deviation of distal interphalangeal joints, with mild Bouchard's nodes at the proximal interphalangeal joints.

joint (Fig. 26.19). It may be isolated or occur as part of generalised nodal OA. Most patients have bilateral and symmetrical involvement. In men, trauma is often a more important risk factor and may result in unilateral OA.

The pain is usually localised to the anterior or medial aspect of the knee and upper tibia. Patello-femoral pain is usually worse going up and down stairs or inclines. Posterior knee pain suggests the presence of a complicating popliteal cyst (Baker's cyst). Prolonged walking, rising from a chair, getting in or out of a car, or bending to put on shoes and socks may be difficult. Local examination findings may include:

- a jerky, asymmetric (antalgic) gait with less time weight-bearing on the painful side
- a varus (Fig. 26.20) or, less commonly, valgus and/or a fixed flexion deformity
- joint-line and/or periarticular tenderness (secondary anserine bursitis and medial ligament enthesopathy (see Box 26.25), causing tenderness of the upper medial tibia)

**Fig. 26.18** X-ray appearances in hand osteoarthritis. There is joint space narrowing affecting the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints in both hands. There are typical articular subchondral and 'gull wing' appearances to some osteoarthritis-affected joints, as well as osteophyte formation that is most marked at the second DIP joints bilaterally and the first PIP joint on the right hand (arrows).

**Fig. 26.19** X-ray appearances in knee osteoarthritis. **A** Advanced osteoarthritis showing almost complete loss of joint space affecting both compartments and sclerosis of subchondral bone. **B** Skyline view of the patello-femoral joint in a patient with severe patello-femoral osteoarthritis. There is almost complete loss of joint space and lateral displacement of the patella.

- weakness and wasting of the quadriceps muscle
- restricted flexion and extension with crepitus
- bony swelling around the joint line.

CPP crystal deposition in association with OA is common at the knee. This may result in a more overt inflammatory component (stiffness, effusions) and super-added acute attacks of synovitis (acute CPP crystal arthritis), which may be associated with more rapid radiographic and clinical progression.

**Fig. 26.20** Typical varus knee deformity resulting from marked medial tibio-femoral osteoarthritis.

**Fig. 26.21** X-ray of hip showing changes of osteoarthritis. Note the superior joint space narrowing (N), subchondral sclerosis (S), marginal osteophytes (O) and cysts (C).

#### Hip OA

Hip OA most commonly targets the superior aspect of the joint (Fig. 26.21). It is often unilateral at presentation, frequently progresses with superolateral migration of the femoral head and has a poor prognosis. The less common central (medial) OA shows more central cartilage loss and is largely confined to women. It is often bilateral at presentation and can be associated with generalised nodal OA. It has a better prognosis than superior hip OA and progression to axial migration of the femoral head is uncommon.

The hip shows the best correlation between symptoms and radiographic change. Hip pain is usually maximal deep in the anterior groin, with variable radiation to the buttock, anterolateral thigh, knee or shin. Lateral hip pain, worse on lying on that side with tenderness over the greater trochanter, suggests secondary trochanteric bursitis. Common functional difficulties are the same as for knee OA; in addition, restricted hip abduction in women may cause pain during sexual intercourse. Examination may reveal:

- an antalgic gait
- weakness and wasting of quadriceps and gluteal muscles

**Fig. 26.22** X-ray of spine showing typical changes of osteoarthritis. Cervical spondylosis showing disc space narrowing between C6 and C7, osteophytes at the anterior vertebral body margins (thin arrows) and osteosclerosis at the apophyseal joints (thick arrow).

### 26.39 Causes of early-onset osteoarthritis

#### Monoarticular

- Previous trauma, localised instability

#### Pauciarticular or polyarticular

- Juvenile idiopathic arthritis
- Metabolic or endocrine disease:
  - Haemochromatosis
  - Ochronosis
  - Acromegaly
  - Alkaptonuria
- Spondylo-epiphyseal dysplasia
- Late osteonecrosis
- Neuropathic joint
- Kashin–Beck disease

- pain and restriction of internal rotation with the hip flexed – the earliest and most sensitive sign of hip OA; other movements may subsequently be restricted and painful
- anterior groin tenderness just lateral to the femoral pulse
- fixed flexion, external rotation deformity of the hip
- ipsilateral leg shortening with severe joint attrition and superior femoral migration.

Obesity is associated with more rapid progression of hip OA.

#### Spine OA

The cervical and lumbar spine are the sites most often targeted by OA, where it is referred to as cervical spondylosis and lumbar spondylosis, respectively (Fig. 26.22). Spine OA may occur in isolation or as part of generalised OA. The typical presentation is with pain localised to the low back region or the neck, although radiation of pain to the arms, buttocks and legs may also occur due to nerve root compression. The pain is typically relieved by rest and worse on movement. On physical examination, the range of movement may be limited and loss of lumbar lordosis is typical. The straight leg-raising test or femoral stretch test may be positive and neurological signs may be seen in the legs where there is complicating spinal stenosis or nerve root compression.

#### Early-onset OA

Rarely, OA may present before the age of 45. In most cases, a single joint is affected and there is a clear history of previous trauma. However, specific causes of OA need to be considered in people with early-onset disease affecting several joints, especially those not normally targeted by OA, in which case rare causes need to be considered (Box 26.39).

### 26.40 Osteoarthritis in old age

- **Pain and disability:** osteoarthritis is the principal cause in old age.
- **Calcium phosphate deposition disease:** may cause acute attacks of synovitis (pseudogout) on a background of chronic osteoarthritis.
- **Falls:** reduced muscle strength and pain associated with lower limb osteoarthritis increase the risk.
- **Muscle-strengthening exercises:** safely reduce the pain and disability of knee osteoarthritis with accompanying improvements in balance and reduced tendency to fall.
- **Oral paracetamol and topical non-steroidal anti-inflammatory drugs:** safe in older people, with no important drug interactions or contraindications.
- **Intra-articular injection of glucocorticoid:** a very safe and often effective treatment, particularly useful for tiding a patient over a special event.
- **Total joint replacement:** an excellent cost-effective treatment for severe disabling knee or hip osteoarthritis in older people. There is no age limit for joint replacement surgery.

Kashin–Beck disease is a rare form of OA that occurs in children, typically between the ages of 7 and 13, in some regions of China. The cause is unknown, but suggested predisposing factors are selenium deficiency and contamination of cereals with mycotoxin-producing fungi.

#### Erosive OA

This term is used to describe an unusual group of patients with hand OA who have a more prolonged symptom phase, more overt inflammation, more disability and worse outcome than those with nodal OA. Distinguishing features include preferential targeting of PIP joints, subchondral erosions on X-rays, occasional ankylosis of affected joints and lack of association with OA elsewhere. It is unclear whether erosive OA is part of the spectrum of hand OA or a discrete subset.

#### Investigations

A plain X-ray of the affected joints should be performed and often will show one or more of the typical features of OA (see Fig. 26.16 and Figs. 26.18–26.22). In addition to providing diagnostic information, X-rays are of value in assessing the severity of structural change, which is helpful if joint replacement surgery is being considered. Non-weight-bearing postero-anterior views of the pelvis are adequate for assessing hip OA. Patients with suspected knee OA should have standing anteroposterior X-rays taken to assess tibio-femoral cartilage loss and a flexed skyline view to assess patello-femoral involvement. Spine OA can often be diagnosed on a plain X-ray, which typically shows evidence of disc space narrowing and osteophytes. If nerve root compression or spinal stenosis is suspected, MRI should be performed.

Routine biochemistry, haematology and autoantibody tests are usually normal, though inflammatory OA can be associated with a mild acute phase response. Synovial fluid aspirated from an affected joint is viscous, with a low cell count.

Unexplained early-onset OA requires additional investigation, guided by the suspected underlying condition. X-rays may show typical features of dysplasia or osteonecrosis, widening of joint spaces in acromegaly, multiple cysts, chondrocalcinosis and MCP joint involvement in haemochromatosis or disorganised architecture in neuropathic joints.

#### Management

Treatment follows the general principles outlined earlier in this chapter. Measures that are pertinent in older people are summarised in Box 26.40.

#### Education

It is important to explain the nature of the condition fully, outlining the role of relevant risk factors such as obesity, heredity and trauma. The patient should be informed that established structural changes are permanent and that, although a cure is not possible, pain and function can often be improved. The prognosis should also be discussed, mentioning that it is generally good for nodal hand OA and better for knee than hip OA.

### Lifestyle advice

Weight loss has a substantial beneficial effect on symptoms if the patient is obese and is probably one of the most effective treatments available for OA of the lower limbs. Strengthening and aerobic exercises also have beneficial effects in OA and should be advised, preferably with reinforcement by a physiotherapist. Quadriceps strengthening exercises are particularly beneficial in knee OA. Shock-absorbing footwear, pacing of activities, use of a walking stick for painful knee or hip OA, and provision of built-up shoes to equalise leg lengths can all improve symptoms.

### Non-pharmacological therapy

Acupuncture and transcutaneous electrical nerve stimulation (TENS) can be effective in knee OA. Local physical therapies, such as heat or cold, can sometimes give temporary relief.

### Pharmacological therapy

If symptoms do not respond to non-pharmacological measures, paracetamol should be tried. Addition of a topical NSAID and then capsaicin for knee and hand OA can also be helpful. Oral NSAIDs should be considered in patients who remain symptomatic. These drugs are significantly more effective than paracetamol and can be successfully combined with paracetamol or compound analgesics if the pain is severe. Strong opiates may occasionally be required. Antineuropathic drugs, such as amitriptyline, gabapentin and pregabalin, are sometimes used in patients with symptoms that are difficult to control, but the evidence base for their use is poor. Neutralising antibodies to nerve growth factor have been developed and are an effective treatment for pain in OA, but they are not yet licensed for routine clinical use.

### Intra-articular injections

Intra-articular glucocorticoid injections are effective in the treatment of knee OA and are also used for symptomatic relief in the treatment of OA at the first CMC joint. The duration of effect is usually short, but trials of serial glucocorticoid injections every 3 months in knee OA have shown efficacy for up to 1 year. Intra-articular injections of hyaluronic acid can help to an extent in knee OA, but the treatment is expensive and the effect short-lived. In the UK they have not been considered to be cost-effective by NICE.

### Neutraceuticals

Chondroitin sulphate and glucosamine sulphate have been used alone and in combination for the treatment of knee OA. There is evidence from randomised controlled trials that these agents can improve knee pain to a small extent (3%–5%) compared with placebo.

### Surgery

Surgery should be considered for patients with OA whose symptoms and functional impairment impact significantly on their quality of life despite optimal medical therapy and lifestyle advice. Total joint replacement surgery is by far the most common surgical procedure for patients with OA. It can transform the quality of life for people with severe knee or hip OA and is indicated when there is significant structural damage on X-ray. Although surgery should not be undertaken at an early stage during the development of OA, it is important to consider it before functional limitation has become advanced since this may compromise outcome. Patient-specific factors, such as age, gender, smoking and presence of obesity, should not be barriers to referral for joint replacement.

Only a small proportion of patients with OA progress to the extent that total joint replacement is required, but OA is by far the most frequent indication for this. Over 95% of joint replacements continue to function well into the second decade after surgery and most provide life-long, pain-free function. Up to 20% of patients are not satisfied with the outcome, however, and a few experience little or no improvement in pain. Other surgical procedures are performed much less frequently. Resurfacing of the femoral head can be considered for younger patients with hip OA

(age <60) as an alternative to total joint replacement. Tibial osteotomy represents an alternative to total joint replacement in younger patients with knee OA and can be effective at improving pain by altering alignment of the lower leg. Cartilage repair is sometimes performed to treat focal cartilage defects resulting from joint injury.

## Crystal-induced arthritis

A variety of crystals can deposit in and around joints and structures in the spine and cause an acute inflammatory or even chronic inflammatory arthritis or disease (Box 26.41). Several factors influence crystal formation (Fig. 26.23). There must be sufficient concentration of the chemical components (ionic product), but whether a crystal then forms depends on the balance of tissue factors that promote and inhibit crystal nucleation and growth. The inflammatory potential of crystals resides in their physical irregularity and high negative surface charge, which can induce inflammation and damage cell membranes. Crystals may also cause mechanical damage to tissues and act as wear particles at the joint surface. They can reside in cartilage or tendon for years without causing inflammation or symptoms and it is only when they are released that they trigger inflammation. This may occur spontaneously but can also result from local trauma, rapid changes in the concentration of the components that form crystals, or in association with an acute phase response triggered by intercurrent illness or surgery. In the longer term, a reduction in concentrations of the solutes that form crystals causes dissolution of crystals and remission of the arthritis.

### Gout

Gout is the most common inflammatory arthritis in men and in older women though robust epidemiological data on the prevalence of CPPD are lacking. Gout is caused by deposition of monosodium urate monohydrate crystals in and around synovial joints.

### Epidemiology

The prevalence of gout is approximately 1%–2%, with a greater than 5:1 male preponderance. Gout has become progressively more common over recent years in affluent societies due to the increased prevalence of obesity and metabolic syndrome, of which hyperuricaemia is

#### **i** 26.41 Crystal-associated arthritis and deposition in connective tissue

Crystal	Disease
<b>Common</b>	
Monosodium urate monohydrate	Acute gout Chronic tophaceous gout
Calcium pyrophosphate (CPP)	Acute CPP crystal arthritis Chronic CPP crystal arthritis Chondrocalcinosis Axial disease (e.g. crowned dens syndrome)
Basic calcium phosphate (BCP)	Calcific periarthritis Calcinosis
<b>Uncommon</b>	
Cholesterol	Chronic effusions in rheumatoid arthritis
Calcium oxalate	Acute arthritis in dialysis patients
Extrinsic crystals/semi-crystalline particles:	
Synthetic crystals	Acute synovitis
Plant thorns/sea urchin spines	Chronic monoarthritis, tenosynovitis

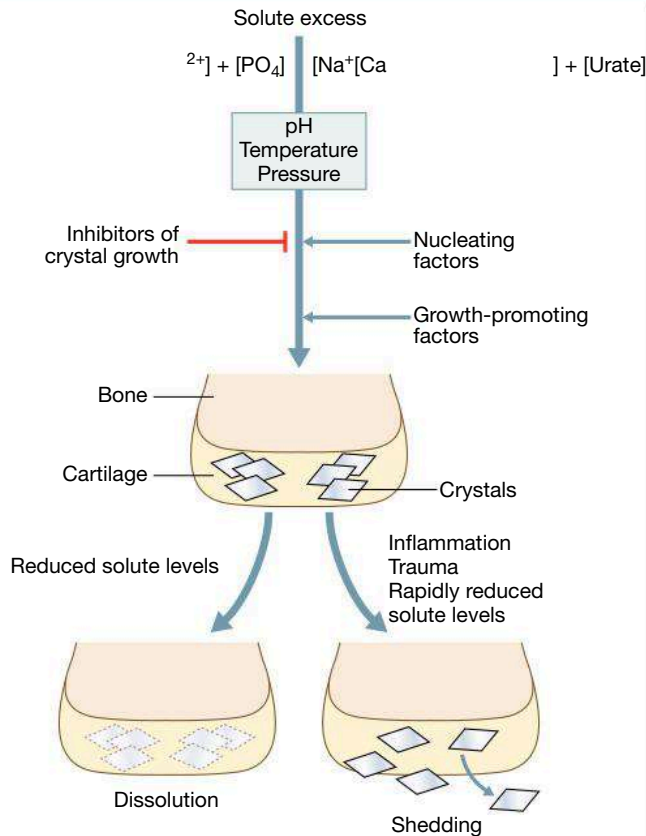

Fig. 26.23 Mechanisms of crystal formation.

an integral component. The risk of developing gout increases with age and with serum uric acid (SUA) levels. These are normally distributed in the general population and hyperuricaemia is defined as an SUA of more than 2 standard deviations above the mean for the population. SUA levels are higher in men, increase with age and are positively associated with body weight. Levels are higher in some ethnic groups (such as Maoris and Pacific islanders). Although hyperuricaemia is a strong risk factor for gout, only a minority of hyperuricaemic individuals actually develop gout.

### Pathophysiology

About one-third of the body uric acid pool is derived from dietary sources and two-thirds from endogenous purine metabolism (Fig. 26.24). The concentration of uric acid in body fluids depends on the balance between endogenous synthesis and elimination by the kidneys (two-thirds) and gut (one-third). Purine nucleotide synthesis and degradation are regulated by a network of enzyme pathways, but xanthine oxidase plays a pivotal role in catalysing the conversion of hypoxanthine to xanthine and xanthine to uric acid.

The causes of hyperuricaemia are shown in Box 26.42. In over 90% of patients, the main abnormality is reduced uric acid excretion by the kidney, which is genetically determined. Impaired renal excretion of urate also accounts for the occurrence of hyperuricaemia in chronic renal failure and for hyperuricaemia associated with thiazide diuretic therapy.

Other risk factors for gout include metabolic syndrome, high alcohol intake (predominantly beer, which contains guanosine), generalised OA and a diet relatively high in game, offal, seafood, red meat and fructose, or low in vitamin C. Lead poisoning may cause gout (saturnine gout). The association between OA and gout is thought to be due to a reduction in levels of proteoglycan and other inhibitors of crystal formation in osteoarthritic cartilage, predisposing to crystal formation.

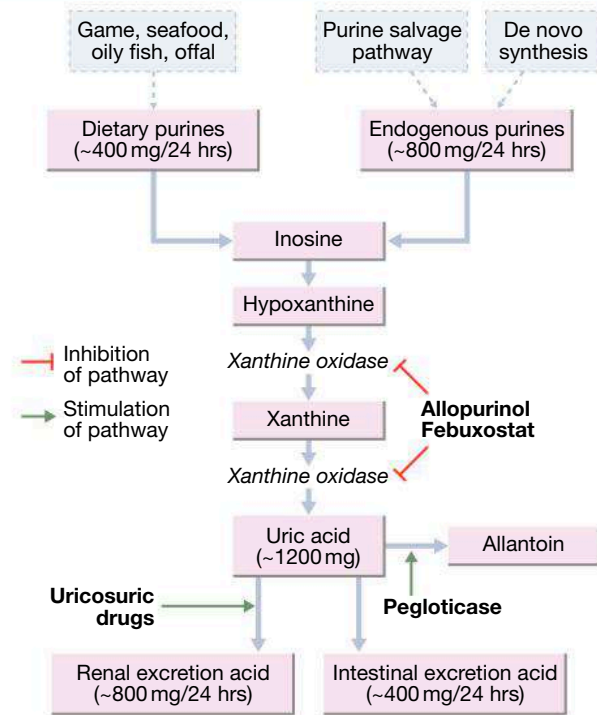

Fig. 26.24 Uric acid metabolism. The main pathways for uric acid production and elimination are shown, along with the site of action for urate-lowering therapies.

<p>*Usually genetically determined (see text). (ACE = angiotensin-converting enzyme; HPRT = hypoxanthine guanine phosphoribosyl transferase)</p>	

Some patients develop gout because they over-produce uric acid. The mechanisms are poorly understood, except in the case of a few single gene disorders where there are mutations in genes that regulate purine metabolism (see Box 26.42). Lesch-Nyhan syndrome is an X-linked recessive form of gout that is also associated with mental retardation, self-mutilation and choreoathetosis. An inherited cause should be suspected if other clinical features are present or there is an early age at onset with a positive family history. Severe hyperuricaemia can also occur in patients with haematological and other cancers who are undergoing chemotherapy due to increased purine turnover (tumour lysis

**Fig. 26.25 Podagra.** Acute gout causing swelling, erythema, and extreme pain and tenderness of the first metatarsophalangeal joint. From Goldman L, Shafer AL. *Goldman-Cecil medicine, 26th edn. Philadelphia: Elsevier; 2020.*

syndrome). This acute rise in urate seldom, if ever, causes gout but can cause acute kidney injury.

### Clinical features

The classical presentation is with an acute monoarthritis, which affects the first MTP joint in over 50% of cases (Fig. 26.25). Other common sites are the ankle, midfoot, knee, small joints of hands, wrist and elbow. The axial skeleton and large proximal joints are rarely involved. Typical features include:

- rapid onset, reaching maximum severity in 2–6 hours, worse in the early morning
- severe pain, often described as the ‘worst pain ever’
- extreme tenderness, so the patient is unable to wear a sock or to let bedding rest on the joint
- marked swelling with overlying red, shiny skin
- self-limiting over 5–14 days, with complete resolution.

During the attack, the joint shows signs of marked synovitis, swelling and erythema. There may be accompanying fever, malaise and even delirium, especially if a large joint such as the knee is involved. As the attack subsides, pruritus and desquamation of overlying skin are common. The main differential diagnosis is septic arthritis, cellulitis and reactive arthritis. Acute attacks may also manifest as bursitis, or tenosynovitis. Sometimes an acute attack will be followed by further attacks in other joints a few days later (cluster attacks), the first possibly acting as a trigger. Simultaneous polyarticular attacks are unusual.

Some people never have a second episode and in others several years may elapse before a second attack occurs. Patients with repeated attacks may progress to chronic gout, with chronic pain, joint damage, deformity and functional impairment. Patients with uncontrolled hyperuricaemia who suffer multiple attacks of acute gout may also progress to chronic gout.

The presentation of gout in old age may be atypical, with chronic symptoms rather than acute attacks (Box 26.43).

Crystals may be deposited in the joints and soft tissues to produce irregular firm nodules called tophi. These have a predilection for the extensor surfaces of fingers, hands, forearm, elbows, Achilles tendons and sometimes the helix of the ear. Tophi have a white colour (Fig. 26.26), differentiating them from rheumatoid nodules. Tophi can ulcerate, discharging white gritty material, become infected or induce a local inflammatory response, with erythema and pus in the absence of secondary infection. They are

### 26.43 Gout in old age

- **Aetiology:** a higher proportion of older patients have gout secondary to diuretic use and chronic kidney disease. Gout is often associated with osteoarthritis.
- **Presentation:** may be atypical, with painful tophi and chronic symptoms, rather than acute attacks. Joints of the upper limbs are more frequently affected.
- **Management:** acute attacks are best treated by aspiration and intra-articular injection of glucocorticoids, followed by early mobilisation. Non-steroidal anti-inflammatory drugs and colchicine should be used with caution because of increased risk of toxicity. Low doses of allopurinol (50 mg/day) should be given and increased gradually to avoid toxicity.

**Fig. 26.26 Tophi over the proximal interphalangeal joints of the hands.** From Goldman L, Shafer AL. *Goldman-Cecil medicine, 25th edn. Elsevier; 2016.*

usually a feature of long-standing gout, but can sometimes develop within 12 months in patients with chronic renal failure. Occasionally, tophi may develop in the absence of previous acute attacks, especially in patients on thiazide therapy who have coexisting OA.

In addition to causing musculoskeletal disease, chronic hyperuricaemia may be complicated by renal stone formation and, if severe, renal impairment due to the development of interstitial nephritis as a result of urate deposition in the kidney. This is particularly common in patients with chronic tophaceous gout who are on diuretic therapy.

### Investigations

The diagnosis of gout can be confirmed by the identification of urate crystals in the aspirate from a joint, bursa or tophus (see Fig. 26.6A). In acute gout, the synovial fluid may be turbid due to an elevated neutrophil count. In chronic gout, the appearance is more variable, but occasionally the fluid appears white due to the presence of urate crystals. Between attacks, aspiration of an asymptomatic first MTP joint or knee may still reveal crystals.

A biochemical screen, including renal function, uric acid, glucose and lipid profile, should be performed because of the association with metabolic syndrome. Hyperuricaemia is usually present in gout, but levels may be normal during an attack because serum urate falls during inflammation. Acute gout is characterised by an elevated ESR and CRP and with a neutrophilia, all of which return to normal as the attack subsides. Tophaceous gout may be accompanied by a modest but chronic elevation in ESR and CRP.

X-rays are usually normal in acute gout, but well-demarcated erosions may be seen in patients with chronic or tophaceous gout (Fig. 26.27). Tophi may also be visible on X-rays as soft tissue swellings. In late disease, destructive changes may occur that are similar to those in other forms of advanced inflammatory arthritis.

### Management

Management should focus on first dealing with the acute attack and then giving prophylaxis to lower SUA and prevent further attacks.

**Fig. 26.27** Erosive arthritis in chronic gout. Punched-out ('Lulworth Cove') erosions (arrows) in association with a destructive arthritis affecting the first metatarsophalangeal joint.

#### 26.44 Indications for urate-lowering drugs

- Recurrent attacks of acute gout
- Evidence of bone or joint damage
- Tophi
- Renal impairment
- Nephrolithiasis
- Chemotherapy-related hyperuricemia

#### Acute gout

Oral colchicine given in doses of 0.5 mg 2–4 times daily is the treatment of first choice in acute gout. It works by inhibiting the inflammatory (see Fig. 4.2), which reduces IL-1 $\beta$  production by macrophages. The most common adverse effects are nausea, vomiting and diarrhoea. Oral NSAIDs are also effective, but are used less commonly since many patients affected by acute gout have coexisting cardiovascular, cerebrovascular or chronic kidney disease. Oral prednisolone (15–20 mg daily for 2–3 days) or intramuscular methylprednisolone (80–120 mg daily) are highly effective and are a good choice in older patients where there is an increased risk of toxicity with colchicine and NSAID (see Box 26.43). IL-1 inhibition with anakinra or canakinumab (see Box 26.35) is effective but both treatments are expensive and so are seldom given. Local ice packs can also be used for symptomatic relief. Patients with recurrent episodes can keep a supply of an NSAID, colchicine or prednisolone and take it as soon as the first symptoms occur, continuing until the attack resolves. Joint aspiration can give pain relief, particularly if a large joint is affected, and may be combined with an intra-articular glucocorticoid injection if the diagnosis is clear and infection can be excluded.

#### Prophylaxis

Patients who have had a single attack of gout do not necessarily need to be given urate-lowering therapy, but it should be offered to individuals who have more than one acute attack within 12 months and those with complications such as tophi or erosions (Box 26.44). The long-term therapeutic aim is to prevent attacks occurring by bringing SUA below the level at which monosodium urate monohydrate crystals form. A therapeutic target of <300  $\mu\text{mol/L}$  (5 mg/dL) is recommended in the British Society of Rheumatology guidelines, whereas the European League Against Rheumatism guidelines recommend a threshold of <360  $\mu\text{mol/L}$  (6 mg/dL) or <300  $\mu\text{mol/L}$  (5 mg/dL) in those with severe gout.

Allopurinol is the drug of first choice. It inhibits xanthine oxidase, which reduces the conversion of hypoxanthine and xanthine to uric acid. The recommended starting dose is 100 mg daily, or 50 mg in older patients and in renal impairment. The dose of allopurinol should be increased by 100 mg every 4 weeks (50 mg in older patients and

those with renal impairment) until the target uric acid level is achieved, side-effects occur or the maximum recommended dose is reached (900 mg/day). Acute flares of gout often follow initiation of urate-lowering therapy. The patient should be warned about this and told to continue therapy, even if an attack occurs. The risk of flares can be reduced by prophylaxis with oral colchicine (0.5–1 mg daily) or an NSAID for the first few months. Alternatively, patients can be given a supply of colchicine, an NSAID or prednisolone to be taken at the first sign of an acute attack. In the longer term, annual monitoring of uric acid levels is recommended. In most patients, urate-lowering therapy needs to be continued indefinitely.

Febuxostat also inhibits xanthine oxidase. It is typically used in patients with an inadequate response to allopurinol and when allopurinol is contraindicated or causes adverse effects. Febuxostat undergoes hepatic metabolism and no dose adjustment is required for renal impairment. It is more effective than allopurinol, but commonly provokes acute attacks when therapy is initiated. The usual starting dose is 40–80 mg daily, increasing to 120 mg daily in patients with an inadequate response. Prophylaxis against acute attacks should be given on initiating therapy, as described for allopurinol.

Uricosuric drugs, such as probenecid, sulfinpyrazone and benzbromarone, lower urate levels but are seldom used in routine clinical practice. They are contraindicated in urate over-producers and those with renal impairment or urolithiasis and require patients to maintain a high fluid intake to avoid uric acid crystallisation in the renal tubules.

Pegloticase is a biologic treatment comprised of the enzyme uricase conjugated to monomethoxypolyethylene glycol. It breaks down uric acid and is indicated for the treatment of tophaceous gout resistant to standard therapy and is administered as an intravenous infusion every 2 weeks for up to 6 months. It is highly effective at controlling hyperuricaemia and can cause regression of tophi. The main adverse effects are infusion reactions (which can be treated with antihistamines or glucocorticoids) and flares of gout during the first 3 months of therapy. A limiting factor for longer-term treatment is the development of antibodies to pegloticase, which occur in a high proportion of cases and are associated with an impaired therapeutic response.

Lifestyle measures are as important as drug therapy in treatment of gout. Patients should be advised to lose weight if appropriate and reduce excessive alcohol intake, especially beer. Several antihypertensive drugs, including thiazides,  $\beta$ -adrenoceptor antagonists ( $\beta$ -blockers) and angiotensin converting enzyme (ACE) inhibitors, increase uric acid levels, whereas losartan has a uricosuric effect and should be substituted for other drugs if possible. Patients should avoid large amounts of seafood and offal, which have a high purine content, but a highly restrictive diet is not necessary.

### Calcium pyrophosphate deposition (CPPD) disease

Calcium pyrophosphate deposition (CPPD) disease encompasses a range of clinical presentations. Crystals can deposit in articular cartilage, synovium, entheses, tendons and ligaments – both axial and peripheral skeletal sites. The acute form of CPPD disease is acute calcium pyrophosphate (CPP) crystal arthritis ('pseudogout'). Acute CPP crystal arthritis is rare under the age of 55 years, but occurs in 10%–15% of people between 65 and 75 years and 30%–60% of those over 85 years old. It typically involves the knee, wrist, ankle, shoulder and hip. Acute CPP inflammation can also affect axial skeletal structures. Risk factors for CPPD disease are shown in Box 26.45. Frequently, patients with CPPD disease have multiple joint chondrocalcinosis and a proportion present with *chronic* CPP crystal arthritis without a history of previous *acute* CPP crystal arthritis. The picture is typically an inflammatory polyarthritis superimposed on a background of OA – typically of the wrist, shoulder or knee (Fig. 26.28). Chronic CPP crystal arthritis can be mistaken for RA by the unwary, as MCP joints can be affected (usually just 2nd and 3rd, sparing the 4th and 5th) and low titre RF is a common incidental finding in old age. The prevalence of CPPD disease affecting the axial skeletal is unknown.

### 26.45 The main risk factors for calcium pyrophosphate deposition disease

#### Common

- Older age
- Osteoarthritis\*
- Hyperparathyroidism (both primary and secondary)
- Hypovitaminosis-D (by causing secondary hyperparathyroidism)

#### Rare

- Familial factors\*
- Haemochromatosis\*
- Hypophosphatasia
- Hypomagnesaemia
- Hypoparathyroidism
- Wilson's disease

\*May be associated with structural damage to affected joints.

**Fig. 26.28 Chondrocalcinosis of the knee.** The X-ray shows calcification of the fibrocartilaginous menisci (M) and articular hyaline cartilage (H). There is also narrowing (N) of the medial tibio-femoral compartment and osteophyte (O) formation.

#### Pathophysiology

The underlying mechanisms of crystal deposition are poorly understood. Clinical studies have shown that CPP levels are raised in patients with CPPD disease, possibly due to over-production, but why this happens is unclear. In hypophosphatasia (see [Box 26.75](#)), the predisposing factor is thought to be impaired degradation of CPP due to deficiency of ALP. In OA, it is thought that a reduction in the amounts of proteoglycan and other natural inhibitors of crystal formation in the abnormal cartilage also predispose to crystal deposition (see [Fig. 26.23](#)).

#### Clinical features

The typical acute CPP crystal arthritis presentation is with a swollen tender joint that is warm and erythematous with a large effusion. Fever is common and the patient may appear confused and ill. The knee is most commonly affected, followed by the wrist, shoulder, ankle and elbow. Trigger factors include trauma, intercurrent illness, dehydration and surgery. Septic arthritis and gout are the main differential diagnoses.

Chronic CPP crystal arthritis can mimic RA, though joint involvement patterns are generally different (in chronic CPP crystal arthritis: wrists, MCP joints 2 and 3, ankles, shoulders). Affected joints usually show features of OA, with varying degrees of synovitis. Effusion and synovial thickening are usually most apparent at knees and wrists. Wrist involvement may result in carpal tunnel syndrome. Inflammatory changes can occur

at entheses such as the gluteal tendon insertions at the greater trochanters and may involve tendons and the ligamentum flavum. Inflammation around the odontoid may occur secondary to CPP crystal deposition, leading to crowned dens syndrome; this presents clinically with neck and occipital neck pain (with neck rotation being the most severely affected movement). Severe damage and instability of knees, hips or shoulders can mimic a neuropathic joint.

#### Investigations

The pivotal investigation in diagnosing acute CPP crystal arthritis is joint aspiration, followed by examination of synovial fluid using compensated polarised microscopy to demonstrate CPP crystals (see [Fig. 26.6B](#)). The aspirated fluid is often turbid and may be uniformly blood-stained, reflecting the severity of inflammation. Since sepsis and acute CPP crystal arthritis can coexist, Gram stain and culture of the fluid should be performed to exclude sepsis, even if CPP crystals are identified in synovial fluid.

For diagnosing chronic CPP crystal arthritis and CPP axial skeletal disease, X-rays of the affected joints, carefully reviewed, may show evidence of calcification in hyaline cartilage and/or fibrocartilage or at peri-articular entheses. Reviewing CT images if available (and windowed for bone), are often helpful in revealing CPP deposition in pelvic and spine structures. Screening for secondary causes (see [Box 26.45](#)) and metabolic risk factors should be undertaken in all cases of CPPD disease and abnormalities treated.

#### Management

In acute CPP crystal arthritis, ice packs, joint elevation and joint aspiration provides symptomatic relief. Once infection is excluded, intra-articular glucocorticoid can be injected. NSAIDs and colchicine (0.5–2 mg daily) are helpful, but must be used with caution in older patients. Chronic CPP crystal arthritis can respond to low-dose oral glucocorticoids, methotrexate and hydroxychloroquine. Colchicine long-term (0.5–1 mg daily) may play a role in preventing acute CPP inflammatory flare-ups. Little is known about the optimum drug management of chronic CPPD disease in the axial skeletal.

### Basic calcium phosphate deposition disease

Basic calcium phosphate (BCP) deposition disease is caused by the deposition of hydroxyapatite or apatite crystals and other basic calcium phosphate salts (octacalcium phosphate, tricalcium phosphate) in soft tissues. The main affected sites are tendons, ligaments and hyaline cartilage in patients with degenerative disease, and skeletal muscle and subcutaneous tissues in connective tissue diseases.

#### Pathophysiology

Under normal circumstances, inhibitors of mineralisation, such as pyrophosphate and proteoglycans, prevent calcification of soft tissues. When these protective mechanisms break down, abnormal calcification occurs. There are many causes ([Box 26.46](#)). In most situations, calcification is of no consequence, but when the crystals are released an inflammatory reaction may be initiated, causing local pain and inflammation.

#### Calcific periarthritis

This occurs as the result of deposition of BCP in tendons, which provokes an acute inflammatory response. Commonly the supraspinatus tendon is affected ([Fig. 26.29](#)), but other sites may also be involved, including the tendons around the hip, feet and hands. The presentation is with acute pain, swelling and local tenderness that develops rapidly over 4–6 hours. The overlying skin may be hot and red, raising the possibility of infection. Attacks sometimes occur spontaneously, but can also be triggered by trauma. Modest systemic upset and fever are common. Tendon calcification may be seen on X-ray. If the affected joint or bursa is aspirated, inflammatory fluid containing many calcium-staining (alizerin red S) aggregates may be obtained. During an acute attack, there may be a neutrophilia with an elevation in ESR and CRP. Routine biochemistry

is normal. Treatment is with analgesics and NSAIDs. Attacks may also respond to a local injection of glucocorticoid. The condition usually resolves spontaneously over 1–3 weeks and this is often accompanied by dispersal and disappearance of calcific deposits on X-ray. Large deposits sometimes accumulate, causing limitation of joint movement, and may require surgical removal.

### Acute inflammatory arthritis

Deposition of BCP occurs commonly in OA, both alone and in combination with CPP crystals, in which case it is referred to as mixed crystal deposition disease. An acute crystal-induced arthritis can occur, identical to pure acute CPP crystal arthritis.

### Milwaukee shoulder syndrome

This is a rare syndrome, in which extensive deposition of BCP crystals in large joints is associated with progressive joint destruction. It is more common in women than in men. The onset is gradual, with joint pain, sometimes precipitated by injury or overuse. The disease progresses over a few months to cause severe pain and disability, associated with joint destruction. X-rays show joint space narrowing, osteophytes and calcification. Aspiration yields large volumes of relatively non-inflammatory fluid containing abundant BCP aggregates and often cartilage fragments. The differential diagnosis is end-stage osteonecrosis, chronic sepsis or neuropathic joint. There is no acute phase response and synovial fluid cultures are negative.

26.46 Rheumatic diseases associated with basic calcium phosphate deposition	
Disease	Site of calcification
Calcific periarthritis	Tendons and ligaments
Dermatomyositis and polymyositis	Subcutaneous tissue
Systemic sclerosis (lcSScl)	Subcutaneous tissue
Mixed connective tissue disease	Subcutaneous tissue
Paget's disease of bone	Blood vessels
Ankylosing spondylitis	Ligaments
Fibrodysplasia ossificans progressiva	Subcutaneous tissues and muscle
Milwaukee shoulder syndrome	Tendons and ligaments
Albright's hereditary osteodystrophy	Muscle

(lcSScl = localised cutaneous systemic sclerosis)

Fig. 26.29 Shoulder X-ray showing supraspinatus tendon calcification (arrow).

Treatment is with analgesics, intra-articular injection of glucocorticoids, local physical treatments and physiotherapy. The clinical outcome is poor, however, and most patients require joint replacement. The cause is incompletely understood, but it has been speculated that deposition of BCP crystals activates collagenase and other proteases in articular cells, which are responsible for the tissue damage.

### Autoimmune connective tissue disease

Deposition of BCP may occur in the subcutaneous tissues and muscle of patients with systemic sclerosis and other autoimmune connective tissue diseases. Usually, the deposits are asymptomatic, but they may be associated with pain and local ulceration. The mechanism by which this occurs is unclear and there is no specific treatment.

## Fibromyalgia

Fibromyalgia (FM) is a condition of generalised pain and consequent disability. It is frequently associated with medically unexplained symptoms in other systems. The prevalence in the UK and United States is about 2%–3%. Although FM can occur at any age, including adolescence, it increases in prevalence with age, to reach a peak of 7% in women aged over 70. There is a strong female predominance of around 10:1. Risk factors include life events that cause (unresolved) psychosocial distress relating to previous abuse, marital disharmony, alcoholism or illness in the family, poor sleep health, previous injury or assault and low income. FM arises in a variety of races and cultures. FM may co-exist with other inflammatory rheumatic diseases, including axSpA and SLE.

### Pathophysiology

The cause of FM is poorly understood, but two abnormalities that may be interrelated (Fig. 26.30), and have been consistently reported in affected patients, are disturbed, non-restorative sleep and pain sensitisation, probably caused by abnormal central pain processing.

### Clinical features

The main presenting feature is widespread pain, which is often worst in the neck and back (Box 26.47). It is characteristically diffuse and unresponsive to analgesics and NSAIDs. Physiotherapy often makes FM pain worse. Fatiguability, most prominent in the morning, is another major problem and disability is often marked. Although people can usually undertake self-care (such as eating, washing and dressing), they may be unable to perform tasks such as shopping or housework. They may

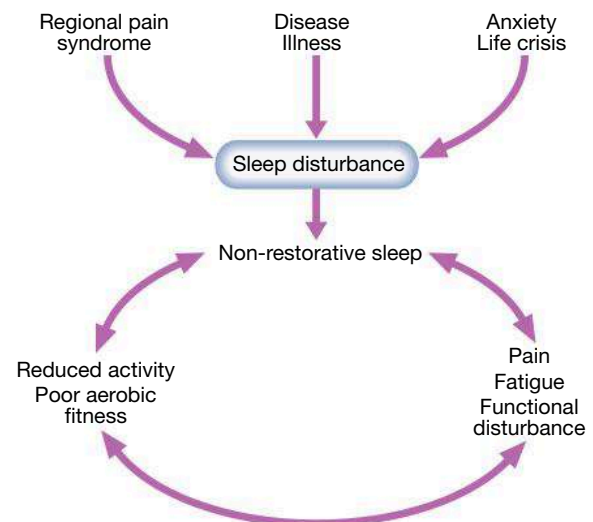

Fig. 26.30 Possible causative mechanisms in fibromyalgia.

experience major performance difficulties at work, and may even stop working, because of pain and fatigue.

Examination is unremarkable, apart from the presence of hyperalgesia on moderate digital pressure (enough just to whiten the nail of the examiner) over multiple sites (Fig. 26.31).

### Investigations and management

There are no abnormalities on routine blood tests or imaging, but it is important to screen for other conditions that could account for all or some of the patient's symptoms (Box 26.48). Imaging is not generally recommended except to exclude other causes of pain if these are suspected clinically.

The aims of management are to educate the patient about the condition, address unresolved psychological issues, achieve pain control and improve sleep. Wherever possible, education should include the

spouse, family or carer. It is conventional to acknowledge that the cause of FM is not fully understood, but the widespread pain does not reflect inflammation, tissue damage or disease. The model of a self-perpetuating cycle of poor sleep and pain (see Fig. 26.30) is a useful framework for problem-based management. Understanding the diagnosis can often help the patient come to terms with the symptoms. Repeat or drawn-out investigation may reinforce beliefs in occult serious pathology and should be avoided.

Low-dose amitriptyline (10–75 mg at night), with or without fluoxetine, may help by encouraging delta sleep and reducing spinal cord wind-up. Many people with FM, however, are intolerant of even small doses of amitriptyline. There is limited evidence for the use of tramadol, serotonin–noradrenaline (norepinephrine) re-uptake inhibitors (SNRIs) such as duloxetine, and the anticonvulsants pregabalin and gabapentin. A graded increase in aerobic exercise can improve well-being and sleep quality.

26.47 The spectrum of symptoms in fibromyalgia	
<b>Usual symptoms</b>	
<ul style="list-style-type: none"> <li>• Widespread pain</li> <li>• Fatiguability</li> <li>• Disability</li> <li>• Broken, non-restorative sleep</li> <li>• Low affect, irritability, poor concentration</li> </ul>	
<b>Variable locomotor symptoms</b>	
<ul style="list-style-type: none"> <li>• Early-morning stiffness</li> <li>• Feeling of swelling in hands</li> <li>• Distal finger tingling</li> </ul>	
<b>Additional, variable, non-locomotor symptoms</b>	
<ul style="list-style-type: none"> <li>• Non-throbbing bifrontal headache (tension headache)</li> <li>• Colicky abdominal pain, bloating, variable bowel habit (irritable bowel syndrome)</li> <li>• Bladder fullness, nocturnal frequency (irritable bladder)</li> <li>• Hyperacusis, dyspareunia, discomfort when touched (allodynia)</li> <li>• Frequent side-effects with drugs (chemical sensitivity)</li> </ul>	

26.48 Laboratory investigations recommended before finalising a diagnosis of fibromyalgia	
Test	Condition screened for
Full blood count, liver and renal function tests	General disease indicators
Erythrocyte sedimentation rate, C-reactive protein, serum amyloid A, immunoglobulins, faecal calprotectin	Inflammatory disease, Inflammatory bowel disease
Thyroid function	Hypo-/hyperthyroidism
Calcium, albumin, phosphate, alkaline phosphatase, parathyroid hormone, 25 hydroxy-vitamin D, serum angiotensin-converting enzyme	Hyperparathyroidism, osteomalacia, sarcoid
Antinuclear antibodies, extractable nuclear antigens, rheumatoid factor, anti-cyclic citrullinated peptide antibodies, complement C3 and C4, lupus anticoagulant, anti-cardiolipin antibodies	Autoinflammatory and autoimmune diseases

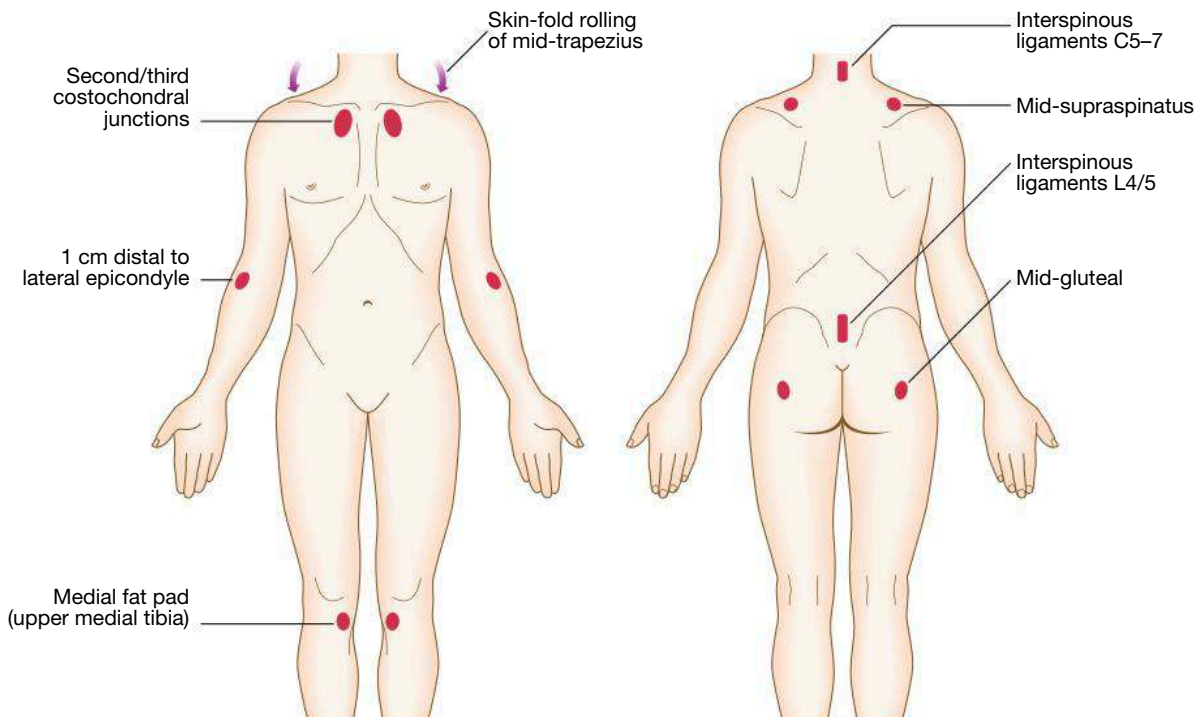

Fig. 26.31 Typical tender points in fibromyalgia.

The use of self-help strategies and a cognitive behavioural approach with relaxation techniques should be encouraged. Sublimated anxiety relating to distressing life events should be specifically explored with appropriate counselling. There are patient organisations that provide additional information and support. Although treatment may improve quality of life and ability to cope, most people remain symptomatic for many years.

## Bone and joint infections

### Septic arthritis

Septic arthritis is the most rapid and destructive joint disease. The incidence is 2–10 per 100 000 in the general population and 30–70 per 100 000 in those with pre-existing joint disease or joint replacement. Septic arthritis is associated with significant morbidity and still has a mortality of about 10% despite advances in antimicrobial therapy. The most important risk factor for mortality is increasing age.

#### Pathogenesis

Septic arthritis usually occurs as a result of haematogenous spread from infections of the skin or upper respiratory tract; infection from direct puncture wounds or secondary to joint aspiration is uncommon. Risk factors include increasing age, pre-existing joint disease (principally RA), diabetes mellitus, advanced renal disease, immunosuppression (by drugs or disease) and intravenous drug misuse. In RA, the skin is a frequent portal of entry because of maceration of skin between the toes due to joint deformity and difficulties with foot hygiene caused by hand deformity. [Box 26.49](#) describes the particular considerations in old age.

#### Clinical features

The usual presentation is with acute or subacute monoarthritis and fever. The joint is usually swollen, hot and red, with pain at rest and on movement. Although any joint can be affected, lower limb joints, such as the knee and hip, are most commonly targeted. Patients with pre-existing arthritis may present with multiple joint involvement.

The most common organism in adults is *Staphylococcus aureus*, particularly in patients with RA and diabetes, but infections with  $\beta$ -haemolytic streptococci and Gram-negative bacilli are also frequent. Tuberculosis should always be considered where local population infection prevalence is high. Gonococcal infection can present with a migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of an oligo- or monoarthritis. Painful pustular skin lesions may also be present. Gram-negative bacilli or group B, C and G streptococci are important causes among older adults and intravenous drug users. Less commonly, septic arthritis may be caused by group A streptococci, pneumococci, meningococci and *Haemophilus influenzae*. Arthritis may be a feature of Lyme disease caused by members of the *Borrelia* species of microorganisms. It is generally a late manifestation, which usually affects large joints. Brucellosis presents with an acute febrile illness, followed in some cases by the development of localised infection, which can result in arthritis, bursitis, osteomyelitis, sacroiliitis and paravertebral or psoas abscesses.

#### 26.49 Joint and bone infection in old age

- **Vertebral infection:** more common. Recognition may be delayed, as symptoms may be attributed to compression fractures caused by osteoporosis.
- **Peripheral vascular disease:** leads to more frequent involvement of the bones of the feet, and diabetic foot ulcers are also commonly complicated by osteomyelitis.
- **Prosthetic joint infections:** now more common because of the increased frequency of prosthetic joint insertion in older people.
- **Gram-negative bacilli:** more frequent pathogens than in younger people.
- **Cephalosporins:** contraindicated due to the high risk of *Clostridioides difficile*.
- **Septic arthritis:** mortality is high in older patients.

### Investigations

The pivotal investigation is joint aspiration, but blood cultures should also be taken. The synovial fluid is usually turbid or blood-stained but may appear normal. If the joint is not readily accessible, aspiration should be performed under imaging guidance or in theatre. Prosthetic joints should only be aspirated in theatre to minimise the risk of introducing infection.

Synovial fluid should be sent for Gram stain and culture; cultures are positive in around 90% of cases, but the Gram stain is positive in only 50%. In contrast, synovial fluid culture is positive in only 30% of gonococcal infections, making it important to obtain concurrent cultures from the genital tract (positive in 70%–90% of cases).

There is a leucocytosis with raised CRP in most patients, but these features may be absent in older or immunocompromised patients, or early in the disease course. Serial measurements of CRP are useful in following the response to treatment.

### Management

The principles of management are summarised in [Box 26.50](#). The patient should be admitted to hospital for pain relief and administration of parenteral antibiotics. Flucloxacillin (2 g IV 4 times daily) is the antibiotic of first choice pending the results of cultures, since it will cover most staphylococcal and streptococcal infections. If there is reason to suspect methicillin-resistant *Staphylococcus aureus* (such as a known carrier), vancomycin should be used instead while awaiting cultures. If a Gram-negative infection is suspected, initial antibiotic treatment should cover Gram-negative bacilli as well as staphylococci and streptococci. Cephalosporins are a reasonable choice in this situation, but carry a high risk of *Clostridioides difficile* infection in those aged over 65; gentamicin is a good alternative.

#### 26.50 Emergency management of suspected septic arthritis

##### Admit patient to hospital

##### Perform urgent investigations

- Aspirate joint (use imaging guidance as needed). Send synovial fluid for Gram stain and culture
- Send blood for culture, routine biochemistry and haematology, including erythrocyte sedimentation rate and C-reactive protein
- Consider sending other samples (sputum, urine, wound swab) for culture, depending on patient history, to determine primary source of infection
- Consider sending serum sample (and later a paired sample) for *Neisseria* and *Brucella* serology

##### Commence intravenous antibiotic\*

- Flucloxacillin (2 g four times daily) to cover *Staph. aureus*
- If penicillin-allergic:
  - Clindamycin (450–600 mg four times daily in younger patients)
  - Intravenous vancomycin (1 g twice daily if age > 65 years)
- If high risk of Gram-negative infection, in the immunocompromised and in IV drug users, add a 3rd generation cephalosporin
- When treating empirically before culture results are available, always seek local microbiology advice

##### Relieve pain

- Oral and/or intravenous analgesics or NSAID (caution in older patients)
- Consider local ice-packs

##### Aspirate joint

- Perform serial needle aspiration to dryness (1–3 times daily or as required)
- Consider arthroscopic drainage if needle aspiration difficult
- Consider synovial biopsy at arthroscopy for tissue for PCR analysis for TB

##### Arrange physiotherapy

- Early regular passive movement, progressing to active movements once pain controlled and effusion not re-accumulating

\*Antibiotic choice should take local epidemiology and patient risk factors into account and be supported by local guidelines where available.

26.51 Musculoskeletal manifestations of HIV	
Condition	Comment
Non-specific arthralgia and mechanical low back pain	Most common
Reactive arthritis Psoriatic arthritis Idiopathic inflammatory arthritis	Especially in men who have sex with men. Idiopathic arthritis is usually of lower limb joints and may be of SpA aetiology
Osteonecrosis Myositis or vasculitis Osteoporosis Sjögren-like disease	May be either related to HIV, to its treatment or intercurrent disease

Whatever antimicrobial regimen is chosen; changes may be required depending on the organism that is isolated. Microbiology advice should always be sought in complicated situations, such as when treating intravenous drug users, patients in intensive care and those who might be colonised by resistant organisms. It is traditional to continue intravenous antibiotics for 2 weeks and to follow this with oral treatment for another 4 weeks, but there is no evidence to support the optimal duration of treatment. Joint aspiration should be performed using a large-bore needle once or twice daily. If this is not possible, arthroscopic or open surgical drainage may be needed. Regular passive movement should be undertaken from the outset and active movements encouraged once the condition has stabilised. Infected prosthetic joints require management by the orthopaedic team, but prolonged antibiotic treatment on its own is often ineffective and removal of the prosthesis may be required for eradication of the infection.

### Viral arthritis

The usual presentation is with acute polyarthritis following a febrile illness, which may be accompanied by a rash. Most cases of viral arthritis are self-limiting and settle down within 4–6 weeks. Human parvovirus arthropathy (mainly B19) is the most common in Europe; adults may not have the characteristic ‘slapped cheek’ facial rash seen in children. The diagnosis can be confirmed by a rise in specific IgM. Polyarthritis may also occur rarely with hepatitis B and C, rubella (including rubella vaccination) and HIV infection. A variety of mosquito-borne viruses may cause epidemics of acute polyarthritis, including Ross River (Australia, Pacific), Chikungunya and O’nyong-nyong (Asia, Africa) and Mayaro viruses (South America). A wide variety of articular symptoms have been associated with HIV, mainly in the later stages of infection (Box 26.51). Management is symptomatic, with NSAIDs and analgesics.

### Osteomyelitis

In osteomyelitis, the primary sites of infection are bone and bone marrow. Any part of a bone may be involved, but there is preferential targeting of the juxta-epiphyseal regions of long bones adjacent to joints. The risk of osteomyelitis increases with age; the incidence is about 9 cases per 100 000 person-years in those under 18, rising to 41 cases in those aged 60–69 and 88 cases in those above the age of 80.

### Pathogenesis

Haematogenous spread is the most common cause in children. In adults, contiguous spread of infection from adjacent soft tissues is more common, usually in patients with infected skin ulcers (pressure sores, neuropathic or ischaemic ulcers) or following surgery. Diabetes is a particularly important risk factor, accounting for about 30% of cases in recent series. Other risk factors include immunosuppressive therapy, HIV infection and sickle-cell disease, which particularly increases the risk of *Salmonella* infection. The organisms most frequently implicated are *Staph. aureus* and  $\beta$ -haemolytic streptococci. Tuberculosis also needs

to be considered as a cause in high prevalence areas. Osteomyelitis secondary to pyogenic organisms often results in a florid inflammatory response, with a greatly increased intraosseous pressure. If untreated, the condition may cause localised areas of osteonecrosis, leading to the development of a fragment of necrotic bone that is called a sequestrum. Eventual perforation of the cortex by pus stimulates local new bone formation (involucrum) in the periosteum, often leading to the development of sinuses that discharge through the skin.

### Clinical features

The presentation is usually with localised bone pain and tenderness, often accompanied by malaise, night sweats and pyrexia. The adjacent joint may be painful to move and may develop a sterile effusion or secondary septic arthritis. Where the osteomyelitis is due to contiguous spread, there will be an overlying skin ulcer or wound, which often has necrotic tissue, purulent discharge and an offensive smell. In diabetic foot osteomyelitis, there may be no pain due to co-existent peripheral neuropathy.

### Investigations

Patients suspected of having osteomyelitis should have an MRI, which is more sensitive than X-ray for detecting early changes. Where possible, cultures should be obtained by open or imaging-guided biopsy of the lesion. If tuberculosis is suspected, PCR-based analysis of synovial fluid or biopsy material should be considered. Evidence of osteopenia, localised osteolysis and osteonecrosis may be seen on X-ray. Blood cultures should be taken, which may also reveal the causative organism. Routine bloods typically show evidence of an acute phase response with a neutrophilia and raised ESR and CRP.

### Management

Early recognition is critical as once osteomyelitis becomes established and chronic, it may prove very hard to eradicate with antibiotics alone. Ideally, antibiotics should not be started until the microbiological cause has been established. The principles are those followed for septic arthritis. An exception is in localised osteomyelitis of the toes and fingers, which can often be treated successfully with a prolonged course of oral antibiotics. Resection of the infected bone and subsequent reconstruction may be required. Complications of chronic osteomyelitis include secondary amyloidosis and skin malignancy at the margin of a discharging sinus (Marjolin’s ulcer).

### Discitis

Discitis is an unusual condition in which there is infection of the intervertebral disc, often extending into the epidural space or paravertebral soft tissues. *Staph. aureus* is the most common pathogen. Risk factors include diabetes mellitus, immunodeficiency or immunosuppressive therapy, and intravenous drug use. The presentation is with back pain accompanied by fever, and an acute phase response with high ESR and CRP and a neutrophilia. If the diagnosis is suspected, an MRI should be performed and blood cultures taken. If blood cultures are negative, open or imaging-guided biopsy of the lesion should be performed to try to identify the organism responsible. Management is with supportive care and parenteral antibiotics followed by oral antibiotics, as described for osteomyelitis.

### Tuberculosis

Tuberculosis (TB) of the musculoskeletal system is now rare in Europe and the United States, but remains common in sub-Saharan Africa and South Asia. It has been estimated to occur in about 1%–3% of patients with TB overall. In about 50% of cases, the spine is affected (Pott’s disease). Tuberculous osteomyelitis can also occur. Osteoarticular TB is thought to occur as the result of haematogenous spread from the site of primary infection, but a reactive arthritis (Poncet’s disease) can also occur in TB in the absence of direct infection. Peripheral arthritis tends

**Fig. 26.32 Tuberculosis of the spine.** MRI scan of a patient with tuberculosis of the spine, showing destruction of vertebrae T7 and T8 (arrows) with a soft tissue mass encroaching on the spinal cord posteriorly. A plain X-ray of the thoracic spine taken at the same time (not shown) was normal.

to affect weight-bearing joints such as the hip, knee and ankle, and presents with pain, swelling and restriction of movement on examination. The initial presentation of spinal TB is with back pain, progressing to cause deformity and spinal cord compression if untreated. Systemic symptoms such as fever and weight loss may or may not be present. Radiological changes develop slowly and are relatively non-specific, consisting of periarticular osteoporosis, bone erosions and joint space narrowing. In the spine, X-rays may show evidence of bone destruction and disc narrowing but appearances may be normal in early disease. Imaging with MRI is more sensitive than X-rays at detecting the features of osteoarticular TB and is the imaging investigation of first choice, although the appearances are non-specific (Fig. 26.32). The gold standard for diagnosis is synovial or tissue biopsy, which yields positive results in about 80% of cases in showing the characteristic histological features of TB. Culture of synovial fluid is positive in between 20% and 40% of cases, but examination of synovial fluid or synovial tissue by PCR can yield the diagnosis more rapidly, with positive results in more than 95% of culture-positive cases and 50%–60% of culture-negative cases. The key to treatment is to initiate appropriate anti-tuberculous therapy. According to WHO guidelines, quadruple therapy with isoniazid, rifampicin, pyrazinamide and ethambutol should be given as first-line therapy for 2 months and followed by 4 months of isoniazid and rifampicin. Treatment may be required for extended periods of 12–18 months in some cases depending on the extent of disease and clinical response. Alternative agents may be required in patients with resistant organisms, as discussed in Chapter 17. In some cases, surgical débridement may be required for extensive peripheral joint disease and surgical decompression and stabilisation for patients with severe spinal disease.

## Rheumatoid arthritis

Rheumatoid arthritis (RA) is a common form of inflammatory arthritis, occurring throughout the world and in all ethnic groups. The prevalence of RA is approximately 0.8%–1.0% in Europe and South Asia, with a female-to-male ratio of 3:1. The prevalence is lower in South-east Asia (0.4%). The highest prevalence in the world is in Pima Indians (5%). It is a chronic disease characterised by a clinical course of exacerbations and remissions.

## Pathophysiology

RA is a complex disease with both genetic and environmental components. The importance of genetic factors is demonstrated by higher concordance of RA in monozygotic (12%–15%) compared with dizygotic twins (3%) and an increased frequency of disease in first-degree relatives of patients. Genome-wide association studies have detected nearly 100 loci that are associated with the risk of developing RA. The strongest association is with variants in the HLA region and is determined by variations in three amino acids in the HLA-DR $\beta$ 1 molecule (positions 11, 71 and 74) and single variants in HLA-B (at position 9) and HLA-DP $\beta$ 1 (at position 9). The non-HLA loci generally lie within or close to genes involved in regulating the immune response. It is believed that RA occurs when an environmental stimulus, such as infection, triggers autoimmunity in a genetically susceptible host by modifying host proteins, through processes like citrullination, so that they become immunogenic. However, no single specific pathogen has been identified as a cause. An important environmental risk factor is cigarette smoking, which is also associated with more severe disease and reduced responsiveness to treatment. Remission may occur during pregnancy and sometimes RA first presents post partum. This is likely to be due to suppression of the immune response during pregnancy, but hormonal changes may also play a role.

The disease is characterised by infiltration of synovium with lymphocytes, plasma cells, dendritic cells and macrophages. There is evidence that CD4<sup>+</sup> T and B cells play important roles in the pathogenesis of RA by interacting with other cells in the synovium, as illustrated in Figure 26.33. Lymphoid follicles form within the synovium in which T- and B-cell interactions occur, causing activation of T cells to produce cytokines and activation of B cells to produce autoantibodies, including RF and ACPA. Synovial macrophages are activated by TNF- $\alpha$  and interferon-gamma (IFN- $\gamma$ ), produced by T cells. The macrophages produce several pro-inflammatory cytokines, including TNF- $\alpha$ , IL-1 and IL-6, which act on synovial fibroblasts to produce further cytokines, setting up a positive feedback loop. The synovial fibroblasts proliferate, causing synovial hypertrophy and producing matrix metalloproteinases and the proteinase ADAMTS-5, which degrade soft tissues and cartilage. Prostaglandins and nitric oxide produced within inflamed synovium cause vasodilatation, resulting in swelling and pain. Systemic release of IL-6 triggers production of acute phase proteins by the liver. At the joint margin, the inflamed synovium (pannus) directly invades bone and cartilage to cause joint erosions. A key pathogenic factor in bone erosions and periarticular osteoporosis is osteoclast activation, stimulated by the production of M-CSF by synovial cells and RANKL by activated T cells (see Fig. 26.33). New blood-vessel formation (angiogenesis) occurs, causing the inflamed synovium to become highly vascular. Within these blood vessels, pro-inflammatory cytokines activate endothelial cells, which support recruitment of yet more leucocytes to perpetuate the inflammatory process.

Later, fibrous or bony ankylosis may occur. Muscles adjacent to inflamed joints atrophy and may be infiltrated with lymphocytes. This leads to progressive biomechanical joint dysfunction, which may further amplify joint destruction.

Rheumatoid nodules occur in patients who are RF- or ACPA-positive and primarily affect extensor tendons. They consist of a central area of fibrinoid material surrounded by a palisade of proliferating mononuclear cells. Granulomatous lesions may occur in the pleura, lung, pericardium and sclera.

## Clinical features

The typical presentation is with pain, joint swelling and stiffness affecting the small joints of the hands, feet and wrists in a symmetrical fashion. Large joint involvement, systemic symptoms and extra-articular features may also occur. Clinical criteria for the diagnosis of RA are shown in Box 26.52.

Sometimes RA has an acute onset, with severe early morning stiffness, polyarthritis and pitting oedema. This occurs more commonly in old age. Another presentation is with proximal muscle stiffness mimicking polymyalgia rheumatica. Occasionally, the onset is palindromic, with relapsing and remitting episodes of pain, stiffness and swelling that last for only a few hours or days.

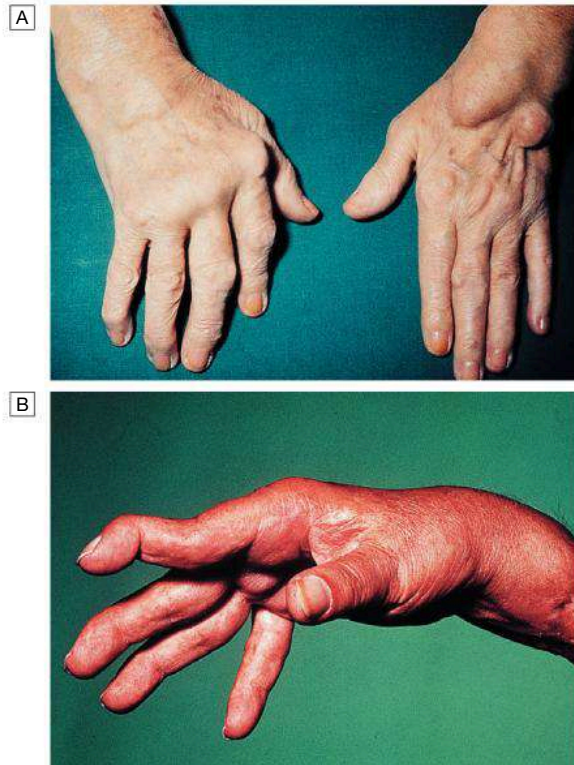

**Fig. 26.33 Pathophysiology of rheumatoid arthritis.** Some of the cytokines and cellular interactions that are important in rheumatoid arthritis are shown. (ADAMTS5 = aggrecanase; HLA = human leucocyte antigen; IFN = interferon; IL = interleukin; M-CSF = macrophage colony-stimulating factor; MMP = matrix metalloproteinase; RANKL = receptor activator of nuclear factor kappa B ligand; TNF = tumour necrosis factor)

26.52 Criteria for diagnosis of rheumatoid arthritis*	
Criterion	Score
<b>Joints affected</b>	
1 large joint	0
2–10 large joints	1
1–3 small joints	2
4–10 small joints	3
> 10 joints (at least 1 small joint)	5
<b>Serology</b>	
Negative RF and ACPA	0
Low positive RF or ACPA	2
High positive RF or ACPA	3
<b>Duration of symptoms</b>	
< 6 weeks	0
> 6 weeks	1
<b>Acute phase reactants</b>	
Normal CRP and ESR	0
Abnormal CRP or ESR	1
Patients with a score $\geq 6$ are considered to have definite RA.	
*European League Against Rheumatism/American College of Rheumatology 2010 criteria. (ACPA = anti-citrullinated peptide antibody; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; RF = rheumatoid factor)	

Examination typically reveals swelling and tenderness of the affected joints. Erythema is unusual and its presence suggests coexistent infection. Characteristic deformities may develop with long-standing uncontrolled disease, although these have become less common over recent years with more aggressive management. They include ulnar deviation of the fingers, ‘swan neck’ deformity, the boutonniere or ‘button hole’ deformity and a Z deformity of the thumb (Fig. 26.34). Dorsal subluxation of the ulna at the distal radio-ulnar joint may occur and contribute to rupture of the fourth and fifth extensor tendons. Triggering of fingers may occur because of nodules in the flexor tendon sheaths. Subluxation of the MTP joints of the feet may result in ‘cock-up’ toe deformities, causing pain on weight-bearing on the exposed MTP heads and the development of secondary adventitious bursae and callosities. In the hindfoot, a valgus deformity of the calcaneus may be observed as the result of damage to the posterior tibial tendon, then ankle and subtalar joints. This is often associated with loss of the longitudinal arch (flat foot) due to rupture of the tibialis posterior tendon. Popliteal (Baker’s) cysts may occur in patients with knee synovitis, in which synovial fluid communicates with the cyst, but is prevented from returning to the joint by a valve-like mechanism; this is not specific to RA. Rupture may be induced by knee flexion, leading to calf pain and swelling that may mimic a deep venous thrombosis (DVT).

**Systemic features**

Anorexia, weight loss and fatigue may occur throughout the disease course. Osteoporosis is a common complication and muscle-wasting may occur as the result of systemic inflammation and reduced activity. Extra-articular features are most common in patients with long-standing seropositive erosive disease, but may occasionally occur at presentation,

**Fig. 26.34** The hand in rheumatoid arthritis. **A** Ulnar deviation of the fingers with wasting of the small muscles of the hands and synovial swelling at the wrists, the extensor tendon sheaths, the metacarpophalangeal and proximal interphalangeal joints. **B** 'Swan neck' deformity of the fingers.

especially in men. Most are due to serositis, granuloma and nodule formation or vasculitis (Box 26.53).

#### Nodules

Rheumatoid nodules occur almost exclusively in RF or ACPA-positive patients, usually in extensor tendons (Fig. 26.35). They are frequently asymptomatic, but some may be complicated by ulceration and secondary infection. Nodules are more common in smokers.

#### Vasculitis

This is uncommon, but may occur in seropositive patients. The presentation is with systemic symptoms, such as fatigue and fever and nail-fold infarcts. Rarely, cutaneous ulceration, skin necrosis and mesenteric, renal or coronary artery occlusion may occur.

#### Ocular involvement

The most common symptom is dry eyes (keratoconjunctivitis sicca) due to secondary Sjögren syndrome. Scleritis and peripheral ulcerative keratitis are uncommon, but are more serious and potentially sight-threatening complications that usually present with pain and redness. Clinical features and management are discussed in more detail in Chapter 30.

#### Serositis

Serositis is usually asymptomatic, but may present with pleural or pericardial pain and breathlessness. Pericardial effusion and constrictive pericarditis may rarely occur.

#### Cardiac involvement

Heart block, cardiomyopathy, coronary artery occlusion and aortic regurgitation have all been reported, but are rare. The risk of cardiovascular disease is increased due to a combination of conventional risk factors, such as high cholesterol, smoking, hypertension, reduced

### 26.53 Extra-articular manifestations of rheumatoid disease

#### Systemic

- Fever
- Weight loss
- Fatigue
- Susceptibility to infection

#### Musculoskeletal

- Muscle-wasting
- Tenosynovitis
- Bursitis
- Osteoporosis

#### Haematological

- Anaemia
- Thrombocytosis
- Eosinophilia

#### Lymphatic

- Felty syndrome (Box 26.54)
- Splenomegaly

#### Nodules

- Sinuses
- Fistulae

#### Ocular

- Episcleritis
- Scleritis
- Scleromalacia
- Keratoconjunctivitis sicca

#### Vasculitis

- Digital arteritis
- Ulcers
- Pyoderma gangrenosum
- Mononeuritis multiplex
- Visceral arteritis

#### Cardiac

- Pericarditis
- Myocarditis
- Endocarditis
- Conduction defects
- Coronary vasculitis
- Granulomatous aortitis

#### Pulmonary

- Nodules
- Pleural effusions
- Pulmonary fibrosis
- Obliterative bronchiolitis
- Caplan syndrome
- Bronchiectasis
- Pneumothorax

#### Neurological

- Cervical cord compression
- Compression neuropathies
- Peripheral neuropathy
- Mononeuritis multiplex

#### Amyloidosis

**Fig. 26.35** Rheumatoid nodules and olecranon bursitis. Nodules were palpable within, as well as outside, the bursa.

physical activity, NSAIDs, glucocorticoids and the effects of inflammatory cytokines on vascular endothelium.

#### Pulmonary involvement

Pulmonary fibrosis may occur, but is often asymptomatic. There is some evidence that the risk of pulmonary fibrosis is increased by anti-TNF- $\alpha$  therapy, although it is uncertain whether this is causal or a marker of more severe disease in patients who require anti-TNF- $\alpha$  treatment.

**Fig. 26.36 Subluxation of cervical spine.** **A** Flexion, showing widening of the space (arrow) between the odontoid peg of the axis (behind) and the anterior arch of the atlas (in front). **B** Extension, showing reduction in this space (arrow).

### Peripheral neuropathy

Entrapment neuropathies may result from compression by hypertrophied synovium or by joint subluxation. Median nerve compression is the most common and bilateral carpal tunnel syndrome can occur as a presenting feature of RA. Other syndromes include ulnar nerve compression at the elbow or wrist, compression of the lateral popliteal nerve at the head of the fibula, and tarsal tunnel syndrome (entrapment of the posterior tibial nerve in the flexor retinaculum), which causes burning, tingling and numbness in the distal sole and toes. Diffuse symmetrical peripheral neuropathy and mononeuritis multiplex may occur in patients with rheumatoid vasculitis.

### Spinal cord compression

This rare complication is caused by compression of the spinal cord from subluxation of the cervical spine at the atlanto-axial joint or at a subaxial level (Fig. 26.36). Atlanto-axial subluxation is due to erosion of the transverse ligament posterior to the odontoid peg. It can lead to cord compression or sudden death following minor trauma or manipulation. It should be suspected in any RA patient who describes new onset of occipital headache, particularly if symptoms of paraesthesia or electric shock are present in the arms. The onset is often insidious, with subtle loss of function that may initially be attributed to active disease. Reflexes and power can be difficult to assess in patients with extensive joint disease and therefore sensory or upper motor signs are most important. Patients with evidence of spinal cord compression require urgent neurosurgical referral for stabilisation and fixation.

### Other complications

Amyloidosis is a rare complication of long-standing disease that usually presents with nephrotic syndrome. Microcytic anaemia can occur due to iron deficiency resulting from NSAID-induced gastrointestinal blood loss, whereas normochromic, normocytic anaemia with thrombocytosis occurs in patients with active disease. Felty syndrome is a rare complication of seropositive RA in which splenomegaly occurs in combination with neutropenia and thrombocytopenia (Box 26.54). Localised or generalised lymphadenopathy can occur in patients with active disease, but persistent lymphadenopathy may indicate the development of lymphoma, which is more common in patients with long-standing RA.

### Investigations

The diagnosis of RA is essentially clinical, but investigations are useful in confirming the diagnosis and assessing disease activity (Box 26.55). The ESR and CRP are usually raised, but normal results do not exclude the diagnosis, especially if only a few joints are involved. Tests for ACPA are positive in about 70% of cases and are highly specific for RA, occurring in many patients before clinical onset of the disease. Similarly, RF is also positive in about 70% of cases, most of whom also test positive for ACPA. RF is less specific than ACPA, however, and positive tests can occur in other diseases (see Box 26.7).

## 26.54 Felty syndrome

### Risk factors

- Age of onset 50–70 years
- Female > male
- European > African ancestry
- Long-standing rheumatoid arthritis
- Deforming, but inactive disease
- Seropositive for rheumatoid factor

### Common clinical features

- Splenomegaly
- Lymphadenopathy
- Weight loss
- Skin pigmentation
- Keratoconjunctivitis sicca
- Vasculitis, leg ulcers
- Recurrent infections
- Nodules

### Laboratory findings

- Normochromic, normocytic anaemia
- Neutropenia
- Abnormal liver function
- Thrombocytopenia
- Impaired T- and B-cell immunity

## 26.55 Investigations and monitoring of rheumatoid arthritis

### To establish diagnosis

- Clinical criteria
- Erythrocyte sedimentation rate and C-reactive protein
- Ultrasound or magnetic resonance imaging
- Rheumatoid factor and anti-citrullinated peptide antibodies

### To monitor disease activity and drug efficacy

- Pain (visual analogue scale)
- Early morning stiffness (minutes)
- Joint tenderness
- Joint swelling
- DAS28 (Fig. 26.37)
- Erythrocyte sedimentation rate and C-reactive protein

### To monitor disease damage

- X-rays
- Functional assessment

### To monitor drug safety

- Urinalysis
- Full blood count
- Chest X-ray
- Urea and creatinine
- Liver function tests

Ultrasound examination and MRI are not routinely required, but can be of value in patients with symptoms suggestive of RA where there is clinical uncertainty about the presence of synovitis. Plain X-rays of the hands, wrist and feet are usually normal in early RA, but periarticular osteoporosis and marginal joint erosions may be observed with more advanced disease. The main indication for an X-ray is in the assessment of patients with painful joints to determine whether significant structural damage has occurred. Patients who are suspected of having atlanto-axial disease should have lateral X-rays taken in flexion and extension, and an MRI. In those with suspected Baker's cyst, ultrasound may be required to establish the diagnosis.

The Disease Activity Score in 28 joints (DAS28) is widely used to assess disease activity, response to treatment and need for biologic therapy. It involves counting the number of swollen and tender joints in the upper limbs and knees, and combining this with the ESR and the patient's assessment of the activity of their arthritis on a visual analogue scale, where 0 indicates no symptoms and 100 the worst symptoms possible. Data are entered into a calculator to generate a numerical score. The higher the value, the more active the disease (Fig. 26.37).

### Management

The treatment goal is to suppress inflammation, control symptoms, prevent joint damage and maintain function. This involves a combination of pharmacological and non-pharmacological therapies. When RA occurs in women of child-bearing age, additional considerations need to be taken into account and these are summarised in Box 26.56.

### Pharmacological therapy

Prompt initiation of cDMARD therapy is indicated in all patients as this improves outcome. A variety of therapeutic regimens exist. A typical

**Calculation**

- Count swollen joints
- Count tender joints
- Measure erythrocyte sedimentation rate\*
- Note patient global health assessment (1–100)
- Enter data into calculator: [www.4s-dawn.com/das28](http://www.4s-dawn.com/das28)

**Interpretation**

- > 5.1 High activity
- ≥3.2–5.1 Moderate activity
- 2.6–3.2 Low disease activity
- < 2.6 Remission

**Fig. 26.37** Calculation of the Disease Activity Score 28 (DAS28).

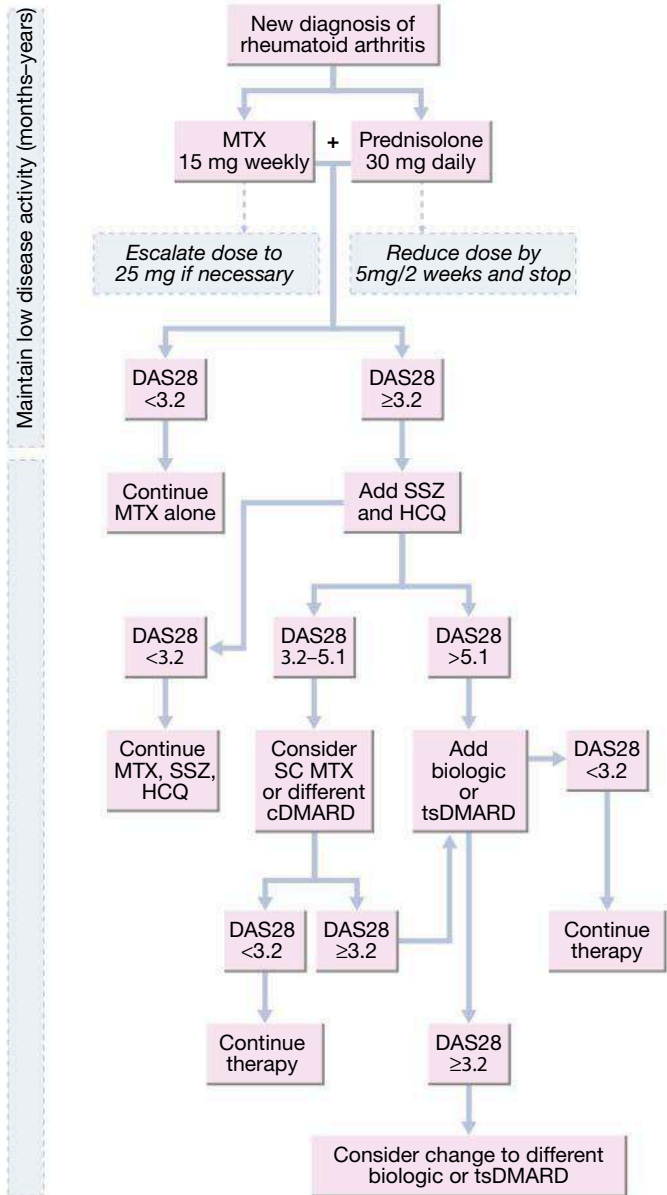

\*Erythrocyte sedimentation rate or C-reactive protein can be used for the calculation.

**26.56 Rheumatoid arthritis in pregnancy**

- **Immunological changes in pregnancy:** many patients with rheumatoid arthritis go into remission during pregnancy.
- **Conception:** methotrexate should be discontinued for ≥ 3 months and leflunomide discontinued for ≥ 24 months before trying to conceive.
- **Paracetamol:** the oral analgesic of choice during pregnancy.
- **Oral non-steroidal anti-inflammatory drugs and selective cyclo-oxygenase 2 (COX-2) inhibitors:** can be used from implantation to 20 weeks' gestation.
- **Glucocorticoids:** may be used to control disease flares; the main maternal risks are hypertension, glucose intolerance and infection.
- **DMARDs that may be used:** sulfasalazine, azathioprine and hydroxychloroquine if required to control inflammation.
- **DMARDs that must be avoided:** methotrexate, leflunomide, cyclophosphamide and mycophenolate.
- **Biologic therapy experience is limited but anti-TNF- $\alpha$  therapy appears to be safe during pregnancy.** The main risk is immunosuppression in the neonate, except for certolizumab, which does not cross the placenta in appreciable amounts.
- **Breastfeeding:** methotrexate, leflunomide and cyclophosphamide are contraindicated.

algorithm is shown in Figure 26.38. For example: on first diagnosis, prednisolone can be started in a dose of 30 mg daily gradually reducing in 5 mg increments every 2 weeks until therapy is withdrawn after about 12 weeks. At the same time, methotrexate (MTX) should be started in an initial dose of 15 mg weekly, along with folic acid 5 mg weekly, and escalated up to a maximum of 25 mg weekly, depending on the response. If the patient fails to respond adequately or dose-limiting toxicity occurs, then an additional cDMARD should be commenced in combination with MTX. A common combination is triple therapy, in which MTX, SSZ and HCQ are combined (see Fig. 26.38). Other cDMARD can be substituted or added, or subcutaneous MTX substituted for oral therapy, if the patient fails to respond fully. If disease activity remains high despite these measures, it is usual to progress to biologic or tsDMARD therapy. The most commonly used first-line biologic in RA is anti-TNF- $\alpha$  therapy, although several other options are available both in terms of tsDMARD (see Box 26.34) and other biologics (see Box 26.35). A reduction in biologic dose can be considered in patients who have been stable for 12 months or more on therapy, since it is possible to reduce the dose in up to 50% of patients without loss of therapeutic effect. Studies show that efficacy and durability of response to biologics is enhanced by co-treatment with MTX.

Disease flares can occur from time to time even in patients who are established on DMARD and biologic therapy. Transient flares can be dealt with by local joint or deep IM 'depot' steroid injections or a short course of oral prednisolone, but if a sustained flare occurs, a change in DMARD and/or biologic should be considered.

**Fig. 26.38** Algorithm for the management of rheumatoid arthritis.

(DAS28 = Disease Activity Score 28; DMARD = disease-modifying antirheumatic drug; HCQ = hydroxychloroquine; MTX = methotrexate; SSZ = sulfasalazine; ts = targeted synthetic; SC = subcutaneous)

**Non-pharmacological therapy**

Physiotherapy, occupational therapy and psychologist support are all important for RA patients. Liaison with social services may be appropriate and enhance the holistic support of patients whose lives are changed by the chronic disease. Patient-run charitable organisations can offer a wealth of education and support to RA patients and their families.

**Surgery**

Synovectomy can be helpful in joints that have failed to respond adequately to systemic therapy and intra-articular injections. Joint arthroplasty may be required where secondary OA evolves, but the need for this has diminished as the result of more aggressive medical management. Other surgical procedures that can be helpful are metatarsal osteotomies, ulna head excision with wrist synovectomy (and to prevent overlying extensor tendon rupture) and upper cervical spine fixation where there is progressive atlanto-axial subluxation. Joint fusion (wrist or triple hindfoot) can reduce pain where joint changes are severe/advanced (see Box 26.28).

### 26.57 The main clinical features of juvenile idiopathic arthritis

Subtype	Frequency	Clinical features	Immunology
Systemic juvenile idiopathic arthritis	5%	Fever, rash, arthralgia, hepatosplenomegaly	Autoantibody-negative
Oligoarthritis ( $\leq 4$ joints)	60%	Large-joint arthritis, uveitis	ANA-positive
Polyarthritis ( $\geq 5$ joints)	20%	Polyarthritis; may be extended form of oligoarthritis	ANA-positive
Enthesis-related	5%	Sacroiliitis, enthesopathy	HLA-B27-positive
RF-positive	5%	Polyarthritis, similar to RA	RF-positive, ACPA-positive
Psoriatic arthritis	5%	Same as adult disease	Autoantibody-negative

(ACPA = anti-citrullinated peptide antibody; ANA = antinuclear antibody; HLA = human leucocyte antigen; RA = rheumatoid arthritis; RF = rheumatoid factor)

## Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is the term accepted by the international community for several forms of arthritis defined by the International League of Associations for Rheumatology 2001 criteria (Box 26.57). This includes juvenile forms of psoriatic arthritis (JPsA), rheumatoid arthritis (JRA) and more undifferentiated forms of inflammatory arthritis. The majority of patients with JIA have a phenotype that is distinct from adult inflammatory arthritis and includes a strong association with uveitis. JIA affects about 1:1000 children and young people up to 16 years of age – similar to the prevalence of diabetes (1:700). The annual incidence is approximately 1 per 10000 children and young people.

Whereas joint restriction is attributed to damage in adults, in children it indicates inflammatory activity. Arthritis in children affects limb growth and has a negative effect on height and weight attainment. In young children, effective disease control can repair joint damage before puberty.

Oligoarthritis is the most common form of JIA, accounting for about 60% of cases. It is more common in females and tends to affect large joints in an asymmetrical pattern. There is an association with uveitis and many patients are ANA-positive. Polyarticular JIA is heterogeneous: some patients are RF and/or ACPA-positive, while others are negative for autoantibodies.

Systemic juvenile idiopathic arthritis (sJIA, formerly known as Still's disease) is characterised by fever, rash, arthritis, hepatosplenomegaly and serositis in association with anaemia and a raised ESR and CRP. Autoantibody tests are negative. This form of JIA is associated with haemophagocytic syndrome (p. 939).

Many cases of enthesitis-related arthritis (ERA) are likely to be self-limiting forms of SpA. ERA can progress over time into a more obviously defined SpA.

### Investigations

The ESR and CRP do not correlate well with the extent or severity of inflammation and may be normal. A very high ESR may indicate the presence of inflammatory bowel disease or (very rarely) leukaemia. Low haemoglobin is likely to be due to anaemia of chronic disease rather than iron deficiency. A positive ANA occurs in 40%–75% of cases of JIA and indicates an increased risk of eye disease. Ultrasound is the radiological investigation of choice to confirm synovitis or tenosynovitis. The false-negative rate is higher in foot and ankle disease than in other joints. Arthroscopy should be avoided unless a biopsy is required. Synovial fluid aspiration is essential if there is suspicion of infection.

### Management

The key approach is to gain early rapid control of inflammation, minimise the adverse effects of treatment and support the general physical and mental health of the patient, and family, which requires full multidisciplinary team input. Standard therapy is MTX (subcutaneous MTX is typically used in the young child). Alternative treatment includes LEF, SSZ and HCQ. AZA and ciclosporin can be used to treat JIA with uveitis. MMF and tacrolimus are considered to have a specific role in treating uveitis alone. Drug

### 26.58 Juvenile idiopathic arthritis in adolescence

- **Uveitis:** may be clinically silent and persist into adulthood. All (not just those who are ANA-positive) need ophthalmic screening for eye involvement.
- **Persistence into adulthood:** occurs in 50% of cases, especially in systemic disease. Specific supportive management through transition from adolescence to adulthood should be planned.
- **Reduced peak bone mass:** common in polyarthritis and systemic juvenile idiopathic arthritis but there are few data on fracture risk and the evidence base for treatment is poor.
- **Therapy:** methotrexate is standard treatment, used after NSAIDs alone are insufficient. Anti-TNF therapy is effective in all forms of juvenile idiopathic arthritis, but long-term safety remains unclear.

(ANA = antinuclear antibody; NSAIDs = non-steroidal anti-inflammatory drugs; TNF- $\alpha$  = tumour necrosis factor alpha)

combinations are not well studied in JIA. Where DMARDs fail, biologics (see Box 26.35), including anti-TNF- $\alpha$ , abatacept and tocilizumab, are effective in JIA, though precise indications and licensed use alone or with MTX do vary in parts of the world and according to local protocols and guidelines. Anakinra and canakinumab can be used to treat sJIA.

### Prognosis

Suboptimal outcomes are associated with delayed diagnosis and referral to the specialist multidisciplinary team, inadequate disease control, presentation with uveitis, sJIA in males and poor engagement with services. Psychological support of affected children and their families is associated with improved outcome. Oligo-JIA often resolves at puberty. Polyarticular disease and sJIA remain active into adulthood in about 50% of cases. Common issues around the transition of adolescent patients into adulthood are shown in Box 26.58.

## Spondyloarthritis

The spondyloarthritis comprise a group of related inflammatory diseases that show overlap in their clinical features and have a shared immunogenetic association with HLA-B27 (Box 26.59). The spectrum of spondyloarthritis (SpA) includes:

- axial spondyloarthritis (axSpA) comprising:
  - non-radiographic SpA (nr-axSpA)
  - radiographic axSpA (ankylosing spondylitis [AS])
- reactive SpA
- psoriatic arthritis
- arthritis with inflammatory bowel disease (enteropathic SpA).

In axSpA the axial skeleton is predominantly affected. In contrast to RA, in SpAs there are frequent and notable non-synovial musculoskeletal lesions – mainly inflammatory in nature – of ligaments, tendons,

### 26.59 Features common to all spondyloarthritis

- Asymmetrical inflammatory oligoarthritis (lower > upper limb)
- History of inflammatory back pain
- Sacroiliitis
- Osteitis (bone marrow oedema on MRI)
- Enthesitis (Achilles' tendonitis, plantar fasciitis)
- Dactylitis
- Family history common
- HLA-B27 association
- Psoriasis (of skin and/or nails)
- Uveitis
- Sterile urethritis and/or prostatitis
- Inflammatory bowel disease
- Aortic root lesions (aortic incompetence, conduction defects)

(HLA = human leucocyte antigen; MRI = magnetic resonance imaging)

periosteum and other bone lesions. A hallmark lesion of SpAs is enthesitis, which is inflammation at the site of a ligament or tendon insertion into bone. Dactylitis, inflammation of a whole finger or toe, may also occur (see Fig. 26.44).

It has been estimated that about 1% of the adult population in the United States may have a SpA (about 2.7 million). There is a striking association with HLA-B27, particularly for AS (>95%). For AS there is a male-to-female ratio of about 3:1. In Europe, more than 90% of those affected are HLA-B27-positive (HLA-B27 population prevalence in those of European origin is 9%). The overall prevalence of AS is below 0.5% in most populations. Additionally, SpAs are thought to arise as the result of an aberrant host response to infection and abnormal mucosal immunity primarily mediated through increased production of IL-23, which in turn causes activation of Th17 lymphocytes that produce IL-17, TNF- $\alpha$  and other inflammatory cytokines. In some situations, a triggering organism can be identified, as in reactive arthritis following bacterial dysentery or chlamydial urethritis, but in others the environmental trigger remains obscure. Familial clustering not only is common to the specific condition occurring in the proband, but also may extend to other diseases in the SpA group.

### Axial spondyloarthritis

Axial spondyloarthritis (axSpA) is the diagnostic term that includes patients with non-radiographic axial SpA (nr-axSpA) and ankylosing spondylitis (AS; also termed radiographic axSpA, Box 26.60). Inflammatory changes in the axial skeleton (such as sacroiliitis, see Fig. 26.40) are characteristic of axSpA and are visualised by MRI. Radiographic alterations, such as new bone formation with syndesmophytes and ankylosis, develop later in the course of the disease and, by definition, are not present in patients with nr-axSpA. A diagnosis of AS (radiographic axSpA), which requires evidence of these radiographic changes on X-ray, may only be applied many years after a patient's symptoms started. It is important to recognise that not all patients with nr-axSpA will go on to develop AS.

#### Pathophysiology

Axial SpA arises from an interaction between environmental pathogens and the host immune system in genetically susceptible individuals. Increased faecal carriage of *Klebsiella aerogenes* has been reported in patients with AS and may relate to exacerbation of both joint and eye disease. There is increasing evidence that axSpA is due to an abnormal host response to the intestinal microbiota with involvement of Th17 cells, which have a key role in mucosal immunity. This leads to production of various inflammatory cytokines, including IL-23, IL-17 and TNF- $\alpha$ , which play vital roles in the pathogenesis of enthesitis and other inflammatory lesions (Fig. 26.39).

There is a strong association between axSpA and carriage of the major histocompatibility complex (MHC) class I molecule HLA-B27. This is

### 26.60 Classification criteria for axial spondyloarthritis (ASAS)

In patients with > 3 months' back pain and age at onset < 45 years, either A or B is present:

A: Sacroiliitis on imaging\* plus  $\geq 1$  SpA feature

B: HLA-B27 plus  $\geq 2$  SpA features

SpA features are:

- Inflammatory back pain
- Arthritis
- Enthesitis (heel)
- Uveitis
- Dactylitis
- Psoriasis
- Crohn's/colitis
- Good response to NSAIDs
- SpA family history
- HLA-B27
- Elevated CRP

\*'Sacroiliitis on imaging' here is defined as either active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA, or definite radiographic sacroiliitis according to the modified New York criteria.

(ASAS = Assessment of Spondylitis International Society; CRP = C-reactive protein;

HLA = human leucocyte antigen; MRI = magnetic resonance imaging; NSAID = non-steroidal anti-inflammatory drug)

particularly striking in patients defined as having AS, more than 95% of whom are positive for HLA-B27. Other susceptibility genes also implicated in susceptibility to AS include *ERAP-1* (an endoplasmic reticulum protein with a role facilitating intracellular antigen processing and binding with its presenting MHC molecule HLA-B27), the IL-23 receptor and downstream signalling molecules involved in directing Th17 cell responses, such as *STAT3* (see Fig. 4.3). The HLA-B27 molecule itself is implicated through its antigen-presenting function or because of its propensity to form homodimers that activate leucocytes. HLA-B27 molecules may also misfold, causing increased endoplasmic reticulum stress. This could lead to inflammatory cytokine release by macrophages and dendritic cells, thus triggering inflammatory disease.

#### Clinical features

The cardinal feature of axSpA is inflammatory back pain and early morning stiffness, with low back pain radiating to the buttocks or posterior thighs if the sacroiliac joints are involved. Symptoms are exacerbated by inactivity and relieved by movement. Musculoskeletal symptoms may be prominent at entheses, may be episodic and, if persistent, can present as widespread pain and be mistaken for fibromyalgia. Fatigue is common. A history of psoriasis (current, previous or in a first-degree relative) and inflammatory bowel symptoms (current or previous) are important clues. Physical signs include a reduced range of lumbar spine movements in all directions, pain on sacroiliac stressing and a high enthesitis index. Enteses that are typically affected include Achilles' insertion, plantar fascia origin, patellar ligament entheses, gluteus medius insertion at the greater trochanter and tendon attachments at humeral epicondyles. Acute anterior uveitis is the most common extra-articular feature, which occasionally precedes joint disease. The extent of extra-articular features are shown in Box 26.61.

A number of validated clinical questionnaires, such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), Bath Ankylosing Spondylitis Functional Index (BASFI) and Ankylosing Spondylitis Disease Activity Score (ASDAS-CRP), can be used to assess disease activity and functional status.

Spinal fusion can develop as AS progresses, but it does so over many years, varies in its extent and in most cases does not cause a gross flexion deformity. However, a few patients develop marked kyphosis of the dorsal and cervical spine that may interfere with forward vision. This may prove incapacitating, especially when associated with fixed flexion contractures of hips or knees. Osteoporosis is a common complication, particularly of the spine, leading to an increased risk of vertebral fracture.

#### Investigations

The diagnosis of axSpA is aided by ultrasound or MRI of entheses, or by MRI of the sacroiliac joints and spine (Fig. 26.40). Other findings may include raised ESR and CRP (although these can be normal), anaemia

**Fig. 26.39 Pathophysiology of axial spondyloarthritis.** In genetically susceptible individuals, it is thought that bacterial components penetrate the mucosal barrier to activate macrophages and dendritic cells in the intestinal submucosa. These cells produce increased amounts of interleukin (IL)-23, which activate Th17 cells resulting in production of IL-17, tumour necrosis factor (TNF)- $\alpha$  and other inflammatory mediators. IL-17 has a pivotal role in driving inflammation, causing sacroiliitis and enthesitis. Production of IL-22 by T cells is thought to be involved in causing the new bone formation that occurs in axial spondyloarthritis. (RANKL = receptor activator of nuclear factor kappa B ligand)

## i

### 26.61 Extra-articular features of axial spondyloarthritis

- Fatigue, anaemia
- Anterior uveitis (25%)
- Prostatitis (80% of men) and sterile urethritis
- Inflammatory bowel disease (in up to 50%)
- Osteoporosis
- Osteoproliferation and osteosclerosis
- Cardiovascular disease (aortic valve disease 20%)
- Amyloidosis (rare)
- Atypical upper lobe pulmonary fibrosis (very rare)

**Fig. 26.40 Magnetic resonance imaging appearances in sacroiliitis.** Coronal MRI short T1 inversion recovery (STIR) sequence showing bilateral sacroiliitis in axial spondyloarthritis. Bone marrow oedema (circles) is present around both sacroiliac joints, which show irregularities due to erosions (arrows).

and positive HLA-B27. Faecal calprotectin is a useful screening test for associated inflammatory bowel disease.

By definition, abnormalities are not seen in X-rays in nr-axSpA. In AS, X-rays of the sacroiliac joint show irregularity and loss of cortical margins, widening of the joint space and subsequently sclerosis, joint space narrowing and fusion. Lateral thoracolumbar spine X-rays may show anterior 'squaring' of vertebrae due to erosion and sclerosis of the anterior corners and periostitis of the waist. Bridging syndesmophytes may also be seen. These are areas of calcification that follow the outermost fibres of the annulus (Fig. 26.41). In advanced disease, ossification of the anterior longitudinal ligament and facet joint fusion may also be visible. The combination of these features may result in the typical 'bamboo' spine (Fig. 26.42). Erosive changes may be seen in the symphysis pubis, ischial tuberosities and peripheral joints. Osteoporosis is common and vertebral fractures may occur. Atlanto-axial dislocation can arise as a late feature. MRI is more sensitive for detection of early sacroiliitis than X-rays (see Fig. 26.40) and can also detect inflammatory changes in the lumbar spine. DXA scanning or vertebral quantitative CT is important as part of a fragility fracture assessment.

### Management

Patient education, NSAID use (optimally, once daily or slow release taken at bedtime) and physical therapy are key interventions at the outset. For severe and/or persistent peripheral joint involvement, both SSZ and MTX are reasonable therapy choices. These medications have no impact on spinal symptoms or disease progression. In patients who fail to respond adequately or who cannot tolerate NSAIDs, progression to biologic therapy with either TNF- $\alpha$ , or IL-17A inhibitors should be considered. Anti-TNF $\alpha$  therapy is effective for both the axial and peripheral lesions of axSpA, but it is as yet unclear whether anti-TNF- $\alpha$  therapy modifies the natural history of the disease.

Local glucocorticoid injections can be useful for persistent plantar fasciitis, other enthesopathies and peripheral arthritis. Oral glucocorticoids may be required for acute uveitis, but do not help spinal disease. Severe hip, knee or shoulder arthritis with secondary OA may require

**Fig. 26.41** Radiographic changes in spondyloarthritis. **A** Fine symmetrical marginal syndesmophytes typical of ankylosing spondylitis (arrow). **B** Coarse, asymmetrical non-marginal syndesmophytes typical of psoriatic spondylitis (arrow).

**Fig. 26.42** 'Bamboo' spine of advanced ankylosing spondylitis. Note the symmetrical marginal syndesmophytes (arrows), sacroiliac joint fusion and generalised osteopenia.

arthroplasty. In AS, spinal osteotomy, to correct stoop and make eyeline/posture 'more normal', can make a significant difference to patients with severe ankylosed kyphotic spines.

### Prognosis

With such a recent definition of disease, the markers of prognosis in patients diagnosed with nr-axSpA are not fully understood. It is clear that axSpA can remain mild and/or episodic in many patients for many years but persistently high inflammatory markers and functional incapacity are markers of a poor outcome. Nonetheless, over 75% of patients with AS are able to remain in employment and enjoy a good quality of life. Even if severe ankylosis develops, functional limitation may not be marked, as long as the spine is fused in an erect posture.

## Reactive arthritis

Reactive (spondylo)arthritis (ReA) is a 'reaction' to a number of bacterial triggers with clinical features in keeping with all SpA conditions. The known triggers are *Chlamydia*, *Campylobacter*, *Salmonella*, *Shigella* and *Yersinia*. Notably, non-SpA-related reactive arthritis can occur following infection with many viruses, *Mycoplasma*, *Borrelia*, streptococci and mycobacteria, including *M. leprae*, which causes leprosy (Hansen's disease); however, the 'reaction' in these instances consists typically of myoarthralgias, is not associated with HLA-B27 and is generally not chronic. The arthritis associated with rheumatic fever is also an example of a reactive arthritis that is not associated with HLA-B27.

Sexually acquired reactive arthritis (SARA) is predominantly a disease of young men, with a male preponderance of 15:1. This may reflect a difficulty in diagnosing the condition in young women, in whom *Chlamydia* infection is often asymptomatic and hard to detect in practical terms. Between 1% and 2% of patients with non-specific urethritis seen at genitourinary medicine clinics have SARA. The syndrome of chlamydial urethritis, conjunctivitis and reactive arthritis was formerly known as Reiter's disease.

With enteric triggering infections (enteropathic ReA), HLA-B27 may predict the reactive arthritis and its severity, though the condition occurs in HLA-B27-negative people. The incidence of specific triggering infections causing ReA around the world varies, depending on the epidemiology of the infection and prevalence of HLA-B27 in the local population.

### Clinical features

The onset is typically acute, with an inflammatory enthesitis, oligoarthritis, sacroiliitis and/or spinal inflammation. Lower limb joints and entheses are predominantly affected. In all types of ReA, there may be considerable systemic disturbance, with fever and weight loss. Achilles insertional enthesitis/tendonitis or plantar fasciitis may also be present. The first attack of arthritis is usually self-limiting, but recurrent or chronic arthritis can develop and about 10% of patients will still have active disease 20 years after the initial presentation. Low back pain and stiffness due to enthesitis and osteitis are common and 15%–20% of patients develop sacroiliitis. Many extra-articular features in ReA involve the skin, especially in SARA:

- circinate balanitis, which starts as vesicles on the coronal margin of the prepuce and glans penis, later rupturing to form superficial erosions with minimal surrounding erythema, some coalescing to give a circular pattern

- keratoderma blennorrhagica, which begins as discrete waxy, yellow–brown vesico-papules with desquamating margins, occasionally coalescing to form large crusty plaques on the palms and soles of the feet
- pustular psoriasis
- nail dystrophy with subungual hyperkeratosis
- mouth ulcers
- conjunctivitis
- uveitis, which is rare with the first attack, but arises in 30% of patients with recurring or chronic arthritis.

Other complications in ReA are very rare but include aortic incompetence, conduction defects, pleuro-pericarditis, peripheral neuropathy, seizures and meningoencephalitis.

### Investigations

The diagnosis is usually made clinically, but joint aspiration may be required to exclude crystal arthritis and articular infection. ESR and CRP are raised. High vaginal swabs may reveal *Chlamydia* on culture. Except for post-*Salmonella* arthritis, stool cultures are usually negative by the time the arthritis presents, but serology may help confirm previous dysentery. RF, ACPA and ANA are negative.

In chronic or recurrent disease, X-rays show periarticular osteoporosis; proliferative erosions, notably at entheses; periostitis, especially of metatarsals, phalanges and pelvis; and large, ‘fluffy’ calcaneal spurs. In contrast to AS, radiographic sacroiliitis is often asymmetrical and sometimes unilateral, and syndesmophytes are predominantly coarse and asymmetrical, often extending beyond the contours of the annulus (‘non-marginal’) (see Fig. 26.41B). Radiographic changes in the peripheral joints and spine are identical to those seen in psoriasis.

### Management

Acute ReA should be treated with rest, NSAIDs and analgesics. Intra-articular or systemic glucocorticoids may be required in patients with severe monarticular synovitis or polyarticular disease, respectively. There is no convincing evidence for the use of antibiotics unless a triggering infection is identified. If chlamydial urethritis is diagnosed, it should be treated empirically with a short course of doxycycline or a single dose of azithromycin. Treatment with DMARDs (usually SSZ or MTX) should be considered for patients with persistent marked symptoms, recurrent arthritis or severe keratoderma blennorrhagica. Anterior uveitis is a medical emergency requiring topical, subconjunctival or systemic glucocorticoids. For DMARD-recalcitrant cases, anti-TNF- $\alpha$  therapy should be considered.

## Psoriatic arthritis

Based on data from the UK and Denmark, the estimated population prevalence of psoriatic arthritis (PsA) from registry and coding data is approximately 0.2%. It is likely the true prevalence is considerably higher, but this has not been extensively studied. The prevalence of PsA in psoriasis patients is variable, based on clinical assessment, but may be up to 40%. Early PsA may present as axSpA. The onset is usually between 25 and 40 years of age, but juvenile forms exist. Occasionally, the arthritis and psoriasis develop synchronously, but the onset of musculoskeletal and skin disease is frequently separated by many years. Classification of PsA requires key assessments of family history and screening for enthesitis (Box 26.62).

### Pathophysiology

Genetic factors have an important role in PsA and family studies have suggested that heritability may exceed 80%. Variants in the *HLA-B* and *HLA-C* genes are the strongest genetic risk factors, but more than 30 other variants also play a part. Carriage of the *HLA B27* allele in those with PsA of European descent is about 20% as compared with the background rate of 9%. Many of these variants overlap with those implicated in psoriasis, where there are more than 40 susceptibility loci. These lie

## I

### 26.62 The CASPAR criteria for psoriatic arthritis

Inflammatory articular disease (joint, spine or enthesis) with  $\geq 3$  points from the following (1 point each unless stated):

- Current psoriasis (scores 2 points)
- History of psoriasis in first- or second-degree relative
- Psoriatic nail dystrophy
- Negative IgM rheumatoid factor<sup>1</sup>
- Current dactylitis
- History of dactylitis
- Juxta-articular new bone<sup>2</sup>

<sup>1</sup>Established by any method except latex. <sup>2</sup>Ill-defined ossification near joint margins (excluding osteophytes) on X-rays of hands or feet. (CASPAR = CIASsification for Psoriatic ARthritis)

within or close to genes in the IL-12, IL-23 and nuclear factor kappa B (NF $\kappa$ B) signalling pathways. It is thought that an environmental factor, probably infectious in nature, triggers the disease in genetically susceptible individuals, leading to immune activation involving dendritic cells and T cells. CD8<sup>+</sup> T cells (which recognise antigen presented in the context of HLA class I) are more abundant than CD4<sup>+</sup> T cells within the joint, which is in keeping with the genetic association between PsA and HLA-C and B variants. There is increasing evidence that the IL-23/IL-17 pathway plays a pivotal role in PsA. It is thought that the triggering stimulus causes over-production of IL-23 by dendritic cells, which in turn promotes differentiation and activation of Th17 cells that produce the pro-inflammatory cytokine IL-17. This, along with Th1 cytokines like IFN- $\gamma$  and TNF- $\alpha$ , acts on macrophages and tissue-resident stromal cells at entheses, in bone and within the joint to produce additional pro-inflammatory cytokines and other mediators, which contribute to inflammation and tissue damage, as shown in Figure 26.43.

### Clinical features

The presentation is with pain and stiffness affecting joints, tendons, spine and entheses. Joints are typically not swollen; however, several patterns of joint involvement are recognised (see below), including an oligoarticular form. These patterns are not mutually exclusive. Marked variation in disease patterns exists, including a disease course of intermittent exacerbation and remission. Destructive arthritis and disability are uncommon, except in the case of arthritis mutilans. Though both psoriasis and PsA are associated with obesity, it is not clear if the latter plays a role in aetiopathogenesis.

#### Asymmetrical inflammatory mono-/oligoarthritis

This often presents abruptly with a combination of synovitis and adjacent periarticular inflammation. It occurs most characteristically in the hands and feet, when synovitis of a finger or toe is coupled with tenosynovitis, enthesitis and inflammation of intervening tissue to give a ‘sausage digit’ or dactylitis (Fig. 26.44A). Large joints, such as the knee and ankle, may also be involved, sometimes with very large effusions.

#### Symmetrical polyarthritis

This accounts for about 25% of cases. It predominates in women and may resemble RA, with symmetrical involvement of small and large joints in both upper and lower limbs. Nodules and other extra-articular features of RA are absent and arthritis is generally less extensive and more benign.

#### Distal interphalangeal joint arthritis

This is quite a common pattern. It can be difficult to distinguish from inflammatory generalised OA, but in PsA psoriatic nail disease is usually present (Fig. 26.44B).

#### Psoriatic spondylitis

This type presents with inflammatory back or neck pain and stiffness. Any structure in the spine can be involved, including intervertebral discs, entheses and facet joints. It may occur alone or with any of the other clinical patterns and is typically unilateral or asymmetric in severity.

**Fig. 26.43 Pathogenesis of psoriatic arthritis.** As in the case of axSpA, the IL-23/IL-17 axis is thought to play a key role in PsA. Some of the cytokines and cellular interactions important in psoriatic arthritis are also shown. (ADAMTS-5 = aggrecanase; IFN = interferon; IL = interleukin; M-CSF = macrophage colony-stimulating factor; MMP = matrix metalloproteinase; TNF = tumour necrosis factor; RANKL = receptor activator of nuclear factor kappa B ligand)

**Fig. 26.44 Psoriatic arthropathy.** **A** Dactylitis. **B** Distal interphalangeal joint pattern with accompanying nail dystrophy (pitting and onycholysis).

### Arthritis mutilans

This is a deforming erosive arthritis targeting the fingers and toes; it occurs in 5% of cases of PsA. Prominent cartilage and bone destruction results in marked digital instability. The encasing skin appears invaginated and 'telescoped' ('main en lorgnette') and the finger can be pulled back to its original length.

### Enthesitis-predominant

This form of disease presents with pain and stiffness at the insertion sites of tendons and ligaments into bone (enthesitis). Symptoms can be extensive or localised. Patients often report muscle stiffness or aches. Typically affected entheses include Achilles tendon insertions, plantar fascia origins, patellar ligament attachments, hip abductor complex insertion at lateral femoral condyle, gluteus medius insertion at greater trochanter, humeral epicondyle tendon attachments, deltoid origin at acromial edge, intercostal muscle attachments at ribs, and pelvic ligament attachments. This form of PsA can be mistaken for fibromyalgia by the unwary.

### Nail changes

Nail changes include pitting, onycholysis, subungual hyperkeratosis and horizontal ridging, which are found in 85% of patients with PsA and can occur in the absence of skin disease. The characteristic rash of psoriasis may be widespread, or confined to the scalp, natal cleft, umbilicus and genitals, or in areas where there are frictional skin effects (e.g. from clothing) where it is easily overlooked. Obtaining a history of psoriasis in a first-degree relative can be tricky but is important, given that a positive response contributes to making a diagnosis. Psoriasis and PsA may be discordant in the same individual, with onset of features sometimes years apart. The absence of psoriasis, or history of it, does not preclude a diagnosis of PsA (see [Box 26.62](#)).

## Investigations

The diagnosis is made on clinical grounds. Autoantibodies are usually negative, though low-dose RF, ACPA and ANA can be detected, and acute phase reactants, such as ESR and CRP, are raised in only a proportion of patients with active disease. X-rays may be normal or show juxta-articular osteoproliferation or erosive change with joint space narrowing. Features that favour PsA over RA include the characteristic distribution (see Fig. 26.10) of erosions with osteoproliferation, absence of periarticular osteoporosis and osteosclerosis. Imaging of the axial skeleton, in advanced disease, can show coarse, asymmetrical, non-marginal syndesmophytes, juxta-facet joint osteoproliferation and sacroiliitis. MRI and ultrasound with power Doppler are increasingly employed to detect synovial inflammation and inflammation at the entheses.

## Management

Patient education to understand the breadth, episodic nature and variability of disease is important. Weight loss may play a therapeutic role to limit clinical impact. Therapy with NSAIDs and analgesics may be sufficient to manage symptoms in mild disease. Intra-articular glucocorticoid injections can control isolated synovitis or enthesitis. Splints and prolonged rest should be avoided because of the tendency to fibrous and bony ankylosis. Patients with spondylitis should be prescribed the same exercise and posture regime as in axSpA. Therapy with cDMARDs should be considered for polyarthralgia or synovitis unresponsive to conservative treatment. MTX is the drug of first choice and is also effective for skin disease. Other cDMARDs may also be helpful, including SSZ, ciclosporin and LEF. Particular attention should be paid to monitoring liver function in patients treated with cDMARDs, since abnormalities are common in PsA. HCQ is not generally used in PsA, but can be tried if other options are unsuitable. Anti-TNF- $\alpha$  should be considered for individuals with active synovitis who respond inadequately to cDMARDs, and treatment is effective for both PsA and psoriasis. Ustekinumab, a monoclonal antibody that binds to and neutralises the p40 subunit of IL-12 and IL-23, improves joint, dactylitis and enthesitis lesions in PsA, as does guselkumab which is a specific inhibitor of IL-23. Secukinumab and ixekizumab, monoclonal antibodies that target IL-17, have similar or even greater efficacy than TNF- $\alpha$  inhibitors in PsA. Apremilast is effective in PsA when cDMARD therapy fails, but is less efficacious than biologic treatments.

## Enteropathic (spondylo)arthritis

The overall prevalence of inflammatory musculoskeletal disease in inflammatory bowel diseases (IBDs: Crohn's disease and ulcerative colitis) is not well known, as studies have not adequately assessed enthesitis and osteitis lesions, but the musculoskeletal manifestations are in keeping with a SpA phenotype. Involvement of the peripheral joints is seen in about 20% of IBD patients. Oligoarticular disease predominantly affects the large lower limb joints (knees, ankles and hips). Evidence of sacroiliitis can also be detected by imaging in a proportion of patients with IBD. Imaging evidence of sacroiliitis is present in about 15%–20% of IBD patients. Osteitis pubis is also a typical lesion. In Crohn's disease, more than in colitis, the arthritis usually coincides with exacerbations of the underlying bowel disease and the arthritis improves with effective treatment of the bowel disease. There is some suggestion that the severity and onset of inflammatory musculoskeletal symptoms can vary in association with changes in the integrity of the ileocaecal valve, raising the possibility that changes in gut flora may act as triggers for the associated SpA.

NSAIDs are best avoided, since they can exacerbate IBD. Instead, judicious use of glucocorticoids, SSZ and MTX may be considered. Liaison is necessary between gastroenterologist and rheumatologist with regard to choice of therapy. Anti-TNF- $\alpha$  therapy is effective in enteropathic arthritis, but etanercept should be avoided as it has no efficacy in IBD. Anti-IL-17A therapy should be avoided as it can trigger flares of IBD. Tofacitinib, while not specifically licensed for enteropathic arthritis,

is efficacious in ulcerative colitis and might be a further treatment option. When musculoskeletal symptoms worsen despite anti-TNF- $\alpha$  therapy, it is wise to exclude small intestinal bacterial overgrowth as a triggering cause.

## Autoimmune connective tissue diseases

Autoimmune connective tissue diseases (AICTDs) share many clinical features and are characterised by dysregulation of immune responses, with autoantibody production that is often directed at components of the cell nucleus, and tissue damage.

### Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a rare disease with a prevalence that ranges from about 0.03% in people of European descent to 0.2% in people of African Caribbean origin. Some 90% of affected patients are female and the peak age at onset is between 20 and 30 years. SLE is associated with considerable morbidity and a fivefold increase in mortality compared to age- and gender-matched controls, mainly because of an increased risk of premature cardiovascular disease.

### Pathophysiology

The cause of SLE is incompletely understood. Genetic factors play a role and the strongest region of association lies with alleles in the HLA-DR and DQ regions. However, approximately 100 other susceptibility loci, which lie within or close to genes involved in the immune response, have also been identified by genome-wide association studies. The overall heritability of SLE has been estimated to be about 40%–60%, illustrating the importance of environmental influences, although the nature of these are unclear. In a few instances, SLE is associated with inherited mutations in complement components C1q, C2 and C4, in the immunoglobulin receptor Fc $\gamma$ RIIIb and in the DNA exonuclease *TREX*. From an immunological standpoint, the characteristic feature of SLE is autoantibody production. These autoantibodies have specificity for a wide range of targets, but many are directed against antigens present within the cell or within the nucleus. This has led to the hypothesis that SLE may occur because of defects in apoptosis or in the clearance of apoptotic cells, which causes inappropriate exposure of intracellular antigens on the cell surface, leading to polyclonal B- and T-cell activation, and autoantibody production. In support of this, environmental factors that cause flares of SLE, such as ultraviolet light and infections, increase oxidative stress and cause cell damage. Whatever the underlying cause, autoantibody production and immune complex formation are thought to be important mechanisms of tissue damage in active SLE, leading to vasculitis and organ damage.

### Clinical features

Symptoms such as fever, weight loss and mild lymphadenopathy may occur during flares of disease activity, whereas others such as fatigue and low-grade joint pains can be constant and not particularly associated with active inflammatory disease.

### Arthritis

Arthralgia is a common symptom, occurring in 90% of patients, and is often associated with early morning stiffness. Tenosynovitis may also occur, but clinically apparent synovitis with joint swelling is unusual. Joint deformities may arise (Jaccoud's arthropathy) as the result of tendon damage, but joint erosions are not a feature.

### Raynaud's phenomenon

Raynaud's phenomenon (RP) is characterised by vasoconstriction of the small vessels of the hand and feet in response to cold, leading to pallor followed by cyanosis of the affected digits followed by vasodilatation causing the affected digits to turn red. This is a common feature of SLE and may antedate other symptoms by months or years. Raynaud's

**Fig. 26.45** Severe secondary Raynaud's phenomenon leading to ischaemic digital ulceration.

**Fig. 26.46** Malar rash of systemic lupus erythematosus, sparing the nasolabial folds. The rash, when mild, can be notably similar to rosacea, which may itself be associated with inflammatory joint diseases that are associated with enteral diseases.

phenomenon associated with SLE and other AICTDs (secondary RP) needs to be differentiated from primary RP, which is a benign disorder that is common in the general population (up to 5%). Features of secondary RP include age at onset of over 25 years, other features of AICTD, absence of a family history of RP, severity of symptoms, presence of digital ulceration (Fig. 26.45) and male gender. Examination of capillary nail-fold loops using an ophthalmoscope (with oil placed on the skin) can show loss of the normal loop pattern, with capillary 'fallout' and dilatation and branching of loops; these features support a diagnosis of secondary RP, but can be observed in severe primary RP.

### Skin

The skin is commonly involved in SLE and many eruptions are precipitated by exposure to ultraviolet light. The main types of skin involvement are:

- The classic malar facial rash (up to 20% of patients). This is erythematous, raised and painful or itchy, and occurs over the cheeks with sparing of the nasolabial folds (Fig. 26.46). Rosacea may mimic this rash.
- A discoid rash characterised by hyperkeratosis and follicular plugging, with scarring alopecia if it occurs on the scalp.
- Diffuse, usually non-scarring alopecia, which may also occur with active disease.
- Urticarial eruptions.

**Fig. 26.47** Livedo reticularis (as typically occurs in systemic lupus erythematosus and antiphospholipid syndrome).

- Livedo reticularis (Fig. 26.47), which is also a feature of antiphospholipid syndrome and can become frankly vasculitic, if severe.

### Kidney

Renal involvement is one of the main determinants of prognosis and regular monitoring of urinalysis and blood pressure is essential. The typical renal lesion is a proliferative glomerulonephritis, characterised by heavy haematuria, proteinuria and casts on urine microscopy.

### Cardiovascular

The most common manifestation is pericarditis. Myocarditis and Libman–Sacks endocarditis can also occur. The endocarditis is due to accumulation on the heart valves of sterile fibrin-containing vegetations, which is thought to be a manifestation of hypercoagulability associated with antiphospholipid antibodies. The risk of atherosclerosis is greatly increased, as is the risk of stroke and myocardial infarction. This is thought to be multifactorial due to the adverse effects of inflammation on the endothelium, chronic glucocorticoid therapy and the procoagulant effects of antiphospholipid antibodies.

### Lung

Lung involvement is common and most frequently manifests as pleuritic pain (serositis) or pleural effusion. Other features include pneumonitis, atelectasis, reduced lung volume and pulmonary fibrosis. The risk of thromboembolism is increased, especially in patients with antiphospholipid antibodies.

### Neurological

Fatigue, headache and poor concentration are common and often occur in the absence of laboratory evidence of active disease. More specific features of cerebral SLE include visual hallucinations, chorea, organic psychosis, transverse myelitis and lymphocytic meningitis.

### Haematological

Neutropenia, lymphopenia, thrombocytopenia and haemolytic anaemia may occur, due to antibody-mediated destruction of peripheral blood cells. The degree of lymphopenia can be a guide to disease activity.

### Gastrointestinal

Mouth ulcers may occur and can be painful. Peritoneal serositis can cause acute pain. Mesenteric vasculitis is a serious complication, which can present with abdominal pain, bowel infarction or perforation. Hepatitis is a recognised, though rare, feature.

### Paediatric disease

Renal disease and cutaneous manifestations are more frequent in juvenile-onset SLE compared to disease in adults. Similarly, there is

26.63 Criteria for the classification of systemic lupus erythematosus	
Features	Characteristics
Malar rash	Fixed erythema, flat or raised, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scarring and follicular plugging
Photosensitivity	Rash due to unusual reaction to sunlight
Oral ulcers	Oral or nasopharyngeal ulceration, which may be painless
Arthritis	Non-erosive, involving two or more peripheral joints
Serositis	Pleuritis (history of pleuritic pain or rub, or pleural effusion) or pericarditis (rub, electrocardiogram evidence or effusion)
Renal disorder	Persistent proteinuria > 0.5 g/24 hrs or cellular casts (red cell, granular or tubular)
Neurological disorder	Seizures or psychosis, in the absence of provoking drugs or metabolic derangement
Haematological disorder	Haemolytic anaemia or leucopenia* (< 4 × 10 <sup>9</sup> /L) or lymphopenia* (< 1 × 10 <sup>9</sup> /L) or thrombocytopenia* (< 100 × 10 <sup>9</sup> /L) in the absence of offending drugs
Immunological	Anti-DNA antibodies in abnormal titre or presence of antibody to Sm antigen or positive antiphospholipid antibodies
Antinuclear antibody (ANA)	Abnormal titre of ANA by immunofluorescence
An adult has SLE if any 4 of 11 features are present serially or simultaneously	
*On two separate occasions.	

subsequently a higher incidence of renal disease, malar rash, Raynaud's phenomenon, cutaneous vasculitis and neuropsychiatric manifestations than in adults.

### Investigations

The diagnosis is based on a combination of clinical features and laboratory abnormalities. To fulfil the classification criteria for SLE, at least 4 of the 11 factors shown in [Box 26.63](#) must be present or have occurred in the past. Checking of ANAs, antibodies to ENAs and complement, routine haematology, biochemistry and urinalysis are mandatory. Patients with active SLE are almost always positive for ANA. ANA-negative SLE can occur, but this is rare and in such cases antibodies to the ENA Ro or antiphospholipid antibodies are present. Anti-dsDNA antibodies are positive in most patients and are quite specific for SLE. Serum levels of C3 may be low in active SLE due to complement consumption, but in some people low C3 and C4 can also be caused by inherited deficiencies in C1, C2 or C4, all of which predispose to SLE. Studies of other family members can help to differentiate inherited deficiencies from complement consumption. A raised ESR, leucopenia and lymphopenia are typical of active SLE, and this may be accompanied by anaemia, haemolytic anaemia and thrombocytopenia. CRP is often normal in active SLE and presence of an elevated CRP in SLE raises the possibility of either serositis, or co-existing infection.

### Management

The therapeutic goals are to educate the patient about the nature of the illness, to control symptoms and to prevent organ damage and maintain normal function. Patients should be advised to avoid sun and ultraviolet light exposure and to employ sun blocks (sun protection factor 25–50).

### Mild to moderate disease

Patients with mild disease restricted to skin and joints can sometimes be managed with analgesics, NSAIDs and HCQ. Frequently, however, glucocorticoids are also necessary (prednisolone 5–20 mg/day), often in combination with immunosuppressants such as MTX, azathioprine or mycophenolate mofetil (MMF). Increased doses of glucocorticoids may be required for flares in activity or complications such as pleurisy or pericarditis. The monoclonal antibody belimumab has been shown to be effective in patients with active SLE who have responded inadequately to standard therapy. Fatigue may be problematic, but there is some evidence that low intensity regular aerobic exercise can be helpful. Poor sleep hygiene should be addressed to try to combat this symptom.

### Severe and life-threatening disease

High-dose glucocorticoids and immunosuppressants are required for the treatment of renal, CNS and cardiac involvement. A commonly used regimen is pulsed methylprednisolone (10 mg/kg IV) plus cyclophosphamide (15 mg/kg IV), repeated at 2–3-weekly intervals for six cycles. Cyclophosphamide may cause haemorrhagic cystitis, but the risk can be minimised by good hydration and co-prescription of mesna (2-mercaptoethane sulfonate), which binds its urotoxic metabolites. Because of the risk of azoospermia and premature menopause, sperm or oocyte collection and storage need to be considered prior to treatment with cyclophosphamide.

MMF has been used successfully with high-dose glucocorticoids for renal involvement with results similar to those of pulsed cyclophosphamide, but fewer adverse effects. Belimumab in combination with standard therapy significantly decreases disease activity in SLE patients and is safe and well tolerated. Its role in patients with renal and neurological disease is still under investigation.

Rituximab has been reported as being effective in case reports and case series, but randomised placebo-controlled trials have not shown benefit.

### Maintenance therapy

Following control of acute disease, oral prednisolone can be commenced in a dose of 40–60 mg daily, gradually reducing to 10–15 mg/day or less by 3 months. Azathioprine (2–2.5 mg/kg/day), MTX (10–25 mg/week) or MMF (2–3 g/day) may also be prescribed as steroid-sparing agents. The long-term aim is to try to maintain remission with the lowest dose of glucocorticoid and immunosuppressant possible. Cardiovascular risk factors, such as obesity, hypertension and hyperlipidaemia, should be controlled and patients should be advised to stop smoking and reduce excess alcohol intake.

Patients with SLE and the antiphospholipid antibody syndrome, who have had previous thrombosis, require life-long warfarin therapy. Patients with SLE are at risk of osteoporosis and hypovitaminosis D, and accordingly should be screened with biochemistry and DXA scanning.

## Systemic sclerosis

Systemic sclerosis (SSc) is an autoimmune disorder of connective tissue, which results in fibrosis affecting the skin, internal organs and vasculature. It is characterised by severe Raynaud's phenomenon, digital ischaemia ([Fig. 26.48](#)), sclerodactyly, cardiac, lung, gut and renal disease. The peak age of onset is in the fourth and fifth decades. It is a rare condition with a prevalence of 10–20 per 100 000, with a 4:1 female-to-male ratio. It is subdivided into limited cutaneous systemic sclerosis (lcSSc: 70% of cases) and diffuse cutaneous systemic sclerosis (dcSSc: 30% of cases) depending on the extent of skin involvement and presence of major organ involvement. Some patients with lcSSc have calcinosis and telangiectasia and when combined with Raynaud's phenomenon, oesophageal involvement and sclerodactyly this is referred to as the CREST syndrome (Calcinosis, Raynaud's, oesophageal involvement, Sclerodactyly and Telangiectasia), which has a good prognosis. The prognosis in dcSSc is poor (5-year survival about 70%). Features that associate with a poor prognosis include older age, diffuse skin disease, proteinuria, high ESR, a low gas transfer factor for carbon monoxide (TLCO) and pulmonary hypertension.

**Fig. 26.48 Systemic sclerosis.** Hands showing tight, shiny skin, sclerodactyly and flexion contractures of the fingers. From Callen J, Jorizzo J, Zone J, Piette W, Rosenbach M, Vleugels RA. *Dermatological signs of systemic disease, 5th edn. Elsevier; 2017.*

**Fig. 26.49 Typical facial appearance showing telangiectasias in localised cutaneous systemic sclerosis.**

### Pathophysiology

The cause of SSc is not completely understood. There is evidence for a genetic component and associations with alleles at the HLA locus have been found. The disease occurs in all ethnic groups and race may influence severity. Isolated cases have been reported in which an SSc-like disease has been triggered by exposure to silica dust, vinyl chloride, epoxy resins and trichloroethylene. There is clear evidence of immunological dysfunction: T lymphocytes, especially those of the Th17 subtype, infiltrate the skin and there is abnormal fibroblast activation, leading to increased production of extracellular matrix in the dermis, primarily type I collagen. This results in symmetrical thickening, tightening and induration of the skin (scleroderma). Arterial and arteriolar narrowing occurs due to intimal proliferation and vessel wall inflammation. Endothelial injury causes release of vasoconstrictors and platelet activation, resulting in further ischaemia, which is thought to exacerbate the fibrotic process.

### Clinical features

#### Skin

Initially, there is non-pitting oedema of fingers and flexor tendon sheaths. Subsequently, the skin becomes shiny and taut, and distal skin creases disappear. There can be capillary loss. The face and neck are often involved, with thinning of the lips and radial furrowing. In some patients, skin thickening stops at this stage. Skin involvement restricted to sites distal to the elbow or knee (apart from the face) is thus classified as lcSSc (Fig. 26.49). Involvement proximal to the knee and elbow and on the trunk is classified as 'diffuse disease' (dcSSc).

### Raynaud's phenomenon

This is a universal feature and can precede other features by many years. Involvement of small blood vessels in the extremities may cause critical tissue ischaemia, leading to localised distal skin infarction and necrosis.

### Musculoskeletal features

Arthralgia and flexor tenosynovitis are common. Restricted hand function is due to skin involvement rather than joint disease and erosive arthropathy is uncommon. Muscle weakness and wasting can result from myositis.

### Gastrointestinal involvement

Smooth muscle atrophy and fibrosis in the lower two-thirds of the oesophagus lead to reflux with erosive oesophagitis. Dysphagia and odynophagia may also occur. Involvement of the stomach causes early satiety and occasionally outlet obstruction. Recurrent occult upper gastrointestinal bleeding may indicate a 'watermelon' stomach (antral vascular ectasia; up to 20% of patients). Small intestine involvement may lead to malabsorption due to bacterial overgrowth and intermittent bloating, pain or constipation. Dilatation of bowel due to autonomic neuropathy may cause pseudo-obstruction with nausea, vomiting, abdominal discomfort and distension, often worse after food (symptoms can mimic those of an acute abdomen and can lead to erroneous laparotomy).

### Pulmonary involvement

Pulmonary hypertension complicates long-standing disease and is six times more prevalent in lcSSc than in dcSSc. It usually presents with insidiously evolving exertional dyspnoea and signs of right heart failure. Interstitial lung disease is common in patients with dcSSc who have topoisomerase 1 antibodies (Scl70). Dyspnoea can evolve slowly over time or rapidly in occasional cases.

### Renal involvement

One of the main causes of death is hypertensive renal crisis, characterised by rapidly developing accelerated phase hypertension and renal failure. Hypertensive renal crisis is much more likely to occur in dcSSc than in lcSSc, and in patients with topoisomerase 1 and RNP antibodies.

### Investigations

As SSc can affect multiple organs, routine haematology, renal, liver and bone function tests and urinalysis are essential. ANA is positive in about 95%. About 30% of patients with dcSSc have antibodies to topoisomerase 1 (Scl70). About 60% of patients have anticentromere antibodies and this is a biomarker for lcSSc and CREST syndrome. Chest X-ray, trans-thoracic echocardiography and lung function tests are recommended to assess for interstitial lung disease and pulmonary hypertension (low corrected transfer factor may indicate early pulmonary hypertension). High-resolution lung CT is recommended if interstitial lung disease is suspected. If pulmonary hypertension is suspected, right heart catheter measurements should be arranged at a specialist cardiac centre. A barium swallow can assess oesophageal involvement. A hydrogen breath test can indicate small intestinal bacterial overgrowth.

### Management

For most patients, the focus of management is to ameliorate symptoms and combat the effects of the disease on target organs. In patients with severe dcSSc, encouraging results have been obtained with autologous stem cell transplantation following myeloablative therapy with cyclophosphamide.

- *Raynaud's phenomenon and digital ulcers.* Avoidance of cold exposure, use of thermal insulating gloves/socks and maintenance of a high core temperature all help. If symptoms are persistent, calcium channel blockers, losartan, fluoxetine, sildenafil and tadalafil can be effective. Courses of intravenous prostacyclin are used for severe disease and critical ischemia. The endothelin-1 antagonist bosentan is

licensed for treating ischaemic digital ulcers and digital tip tissue health can be maintained with regular use of fucidin–hydrocortisone cream.

- **Gastrointestinal complications.** Oesophageal reflux should be treated with proton pump inhibitors and anti-reflux agents. Rotating courses of antibiotics may be required for small intestinal bacterial overgrowth (p. 848), while metoclopramide or domperidone may help patients with symptoms of dysmotility/pseudo-obstruction.
- **Hypertension.** Aggressive treatment with ACE inhibitors is needed, even if renal impairment is present.
- **Joint involvement.** This may be treated with analgesics and/or NSAIDs. If synovitis is present then therapy with MTX or other cDMARD can be of value.
- **Progressive pulmonary hypertension.** Early treatment with bosentan is required. In severe or progressive disease, heart–lung transplant may be considered.
- **Interstitial lung disease.** Cyclophosphamide is effective in slowing progression of interstitial lung disease and similar results have been observed with MMF. More recently the tyrosine kinase inhibitor nintedanib (150 mg twice daily) has shown efficacy in slowing decline of lung function in dcSScI.

### Mixed connective tissue disease

Mixed connective tissue disease (MCTD) is a condition in which some clinical features of SScI, myositis and SLE all occur in the same patient. It commonly presents with indolent puffiness of the fingers (the appearance is between that of SpA-type dactylitis and sclerodactyly) with Raynaud's phenomenon and myalgias. Most patients have anti-RNP antibodies. Management focuses on treating the individual components of the disease (see other sections).

### Sjögren syndrome

Sjögren syndrome (SS) is characterised by grittiness of the eyes and dryness of the mouth due to lymphocytic infiltration of salivary and lacrimal glands, leading to glandular fibrosis and exocrine failure. The typical age of onset is between 40 and 50 years, with a 9:1 female-to-male ratio. It is subdivided into primary Sjögren syndrome (PSS), which occurs in the absence of other autoimmune disease, and secondary Sjögren syndrome, where it occurs in association with other conditions like RA and SLE.

#### Clinical features

The eye symptoms, termed keratoconjunctivitis sicca, are due to a lack of lubricating tears, which reflects inflammatory infiltration of the lacrimal glands. Conjunctivitis and blepharitis are frequent and may lead to filamentary keratitis due to binding of tenacious mucous filaments to the cornea and conjunctiva. Oral involvement manifests as a dry mouth (xerostomia). There is a high incidence of dental caries, gingivitis, periodontitis and other dental problems. Lymphadenopathy is present in about two-thirds of patients and other sites of extraglandular involvement are listed in [Box 26.64](#). Often the most disabling symptom is fatigue. There may be an association with inflammatory small-joint OA, although formal studies have not been done to determine if this is a chance association. Sialadenitis, osteoarthritis and xerostomia (SOX) syndrome has been described; this may occur independently of PSS or, more likely, constitutes a mild form. Both interstitial lung disease (presenting with dry cough, dyspnoea and coarse crackles on lung auscultation) and interstitial nephritis (presenting with polyuria and sometimes complicated by renal tubular acidosis) may occur and both require proactive screening. PSS is associated with a 40-fold increased lifetime risk of lymphoma, though the complication is still very rare. This should be suspected if there is progressive worsening of lymphadenopathy.

#### Investigations

Support for the diagnosis can be obtained by the Schirmer tear test, which measures tear flow over 5 minutes using absorbent paper strips placed

### 26.64 Features of primary Sjögren syndrome

#### Risk factors

- Age of onset 40–60
- Female > male
- HLA-B8/DR3

#### Common clinical features

- Keratoconjunctivitis sicca
- Xerostomia
- Salivary gland enlargement
- Rashes/skin irritation
- Non-erosive arthralgia
- Generalised osteoarthritis
- Raynaud's phenomenon
- Fatigue

#### Less common features

- Low-grade fever
- Interstitial lung disease
- Anaemia, leucopenia
- Thrombocytopenia
- Cryoglobulinaemia
- Vasculitis
- Peripheral neuropathy
- Lymphadenopathy
- Lymphoreticular lymphoma
- Glomerulonephritis
- Interstitial nephritis
- Renal tubular acidosis

#### Autoantibodies frequently detected

- Rheumatoid factor
- Antinuclear antibody
- SS-A (anti-Ro)
- SS-B (anti-La)
- Gastric parietal cell
- Thyroid

#### Associated autoimmune disorders

- Systemic lupus erythematosus
- Systemic sclerosis
- Coeliac disease
- Primary biliary cholangitis
- Chronic active hepatitis
- Myasthenia gravis

(HLA = human leucocyte antigen)

on the lower eyelid; a normal result is more than 5 mm of wetting. Corneal staining with rose bengal may show punctate epithelial abnormalities over the area not covered by the open eyelid. If the diagnosis remains in doubt, it can be confirmed by demonstrating focal lymphocytic infiltrate in a minor salivary gland biopsy. Most patients have an elevated ESR and hypergammaglobulinaemia, and one or more autoantibodies, including ANA and RF are usually present. ANA-negative disease does exist, but in this case anti-Ro and anti-La antibodies are usually detectable (see [Box 26.9](#)). A chest X-ray, high resolution CT and lung function tests should be performed if symptoms suggestive of lung disease are present. Routine biochemistry and tests of urinary concentrating ability may be required if interstitial nephritis is suspected. Lymph node biopsy should be performed to exclude lymphoma in patients with progressive lymphadenopathy.

#### Management

No treatments can significantly modify the course of SS and so management is essentially symptomatic. Lacrimal substitutes, such as hypromellose, should be used during the day in combination with more viscous lubricating application at night. Soft contact lenses can be useful for corneal protection in patients with filamentary keratitis and occlusion of the lacrimal ducts is occasionally needed. Artificial saliva sprays, saliva-stimulating tablets, pastilles and oral gels can be tried for xerostomia, but often chewing gum is most effective. Adequate post-prandial oral hygiene and prompt treatment of oral candidiasis are essential. Vaginal dryness is treated with lubricants. A trial of systemic pilocarpine (5–30 mg daily in divided doses) is worthwhile in early disease to increase salivary and lacrimal secretions. HCQ (200 mg twice daily) is sometimes used in the treatment of SS, but clinical trials have not shown convincing evidence of benefit. Immunosuppression does not improve sicca symptoms, but is often used in the treatment of interstitial lung disease and interstitial nephritis although the evidence base for benefit is limited.

### Polymyositis and dermatomyositis

Polymyositis (PM) and dermatomyositis (DM) are characterised by an inflammatory infiltrate of both skeletal and smooth muscle. In DM,

**Fig. 26.50** Heliotrope rash and eyelid oedema in dermatomyositis. From Callen JP, Jorizzo JL, Bologna JL, Piette WW, Zone JZ. *Dermatological signs of internal disease*, 4th edn. Elsevier; 2009.

characteristic skin changes also occur. Both diseases are rare, with an incidence of 2–10 cases per million/year. They can occur in isolation or in association with other autoimmune diseases and both may be the presenting features of a previously undiagnosed malignancy.

### Clinical features

The typical presentation of PM and DM is with symmetrical proximal muscle weakness over a few weeks, usually affecting the lower limbs more than the upper, in adults between 40 and 60 years of age. Patients report difficulty rising from a chair, climbing stairs and lifting. Muscle pain is not a prominent feature but may be present in up to one-third of patients. Systemic features of fever, weight loss and fatigue are common. Subcutaneous calcification associated with skin ulceration may occur in both DM and PM. Respiratory or pharyngeal muscle involvement can lead to ventilatory failure or aspiration that requires urgent treatment. Interstitial lung disease occurs in up to 30% of patients and is associated with the presence of antisynthetase (Jo-1) antibodies.

The skin lesions in DM include Gottron's papules, which are scaly, erythematous or violaceous, psoriasiform plaques occurring over the extensor surfaces of PIP and DIP joints, and a heliotrope rash that is a violaceous discoloration of the eyelid in combination with periorbital oedema (Fig. 26.50). Similar rashes occur on the upper back, chest and shoulders over a 'shawl' distribution. Periungual nail-fold capillaries are often enlarged and tortuous.

### Investigations

Muscle biopsy is the pivotal investigation and shows the typical features of fibre necrosis, regeneration and inflammatory cell infiltrate (Fig. 26.51). Since muscle involvement may be patchy, it is common to perform an MRI scan prior to biopsy, which often shows features of increased signal intensity in STIR sequence images. This not only provides support for the diagnosis, but also can help choose the optimal site for a biopsy. Serum levels of creatine kinase are typically raised and are a useful measure of disease activity, although a normal creatine kinase does not exclude the diagnosis, particularly in juvenile myositis. Electromyography is very useful for highlighting non-autoimmune/non-inflammatory myopathies. Screening for underlying malignancy should be undertaken routinely (full examination, chest X-ray, serum urine and protein electrophoresis, CT of chest/abdomen/pelvis; prostate-specific antigen in men and mammography in women).

### Management

Oral glucocorticoids (prednisolone 1 mg/kg daily) are the first-line treatment of PM and DM, but high-dose intravenous methylprednisolone (1 g/day for 3 days) may be required in patients with respiratory or

**Fig. 26.51** Muscle biopsy from a patient with polymyositis. The sample shows an intense inflammatory cell infiltrate in an area of degenerating and regenerating muscle fibres.

pharyngeal weakness. If there is a good response, glucocorticoids should be reduced by approximately 25% per month aiming for a maintenance dose of 5–7.5 mg daily. Glucocorticoid-induced myopathy should be considered in patients who initially respond but then relapse. A second muscle biopsy can be of diagnostic value to guide further treatment in this situation since in the case of glucocorticoid myopathy type II fibre atrophy is observed as compared with fibre necrosis and regeneration in active myositis. Treatment should be adjusted accordingly. Although most patients respond well to glucocorticoids, additional immunosuppressive therapy may be required as steroid-sparing agents in the form of MTX, azathioprine, MMF or ciclosporin. Rituximab is sometimes used in refractory cases, but the only randomised trial of this agent did not show benefit over placebo. Intravenous immunoglobulin (IVIg) has been shown to be effective in the treatment of DM and is often used in the treatment of refractory PM and DM. Antimalarials such as HCQ and mepacrine have been used for skin-predominant disease, but the evidence for benefit is limited and based on case reports.

### Juvenile dermatomyositis

Juvenile dermatomyositis (JDM) is by far the most common inflammatory myopathy in children and adolescents, and typically does not require a search for malignancy. The incidence is 2–4 per million (United States and UK), with a median age of onset of 7 years (25% are below 4 years at diagnosis). Many clinical features are similar to those in the adult disease. JDM can be monocyclic, lasting up to 3 years (25%–40%), or polycyclic with periods of remission and relapse (60%–75%). In some cases, polycyclic JDM can be chronic and life-long. Skin ulceration occurs in 10%–20% of cases and calcinosis in about 30%.

Intravenous methylprednisolone, then oral glucocorticoids and MTX produce a rapid response in many cases. Cyclophosphamide may be used for resistant disease with skin ulceration. IVIg is given in resistant cases.

### Undifferentiated autoimmune connective tissue disease

The term undifferentiated autoimmune connective tissue disease is used to describe the situation where patients present with individual clinical features of AICTD, either simultaneously or sequentially, but do not meet the criteria for diagnosis of a specific disease. Some of these individuals may progress to develop a specific AICTD with time; others continue to have an undifferentiated disease that remains the same for many years, and in others the symptoms will recede. These patients should be kept under review with management directed at treating individual symptoms as they arise.

## Adult-onset Still's disease

Adult-onset Still's disease is a rare systemic inflammatory disorder of unknown cause with features that are in some respects similar to sJIA and familial fever syndromes (p. 71). The presentation is with intermittent fever, rash and polyarthritis or polyarthralgia. There is evidence that increased production of the pro-inflammatory cytokine interleukin-1 may play a pathogenic role. Splenomegaly, hepatomegaly and lymphadenopathy may be present. Investigations typically provide evidence of an acute phase response with raised ESR and CRP and a markedly elevated serum ferritin. Tests for RF and ANA are negative. Treatment with NSAIDs can be effective in mild cases, but in more severe disease, glucocorticoids with or without DMARD such as azathioprine, MTX or MMF, are indicated. In resistant disease, the interleukin-1 inhibitors canakinumab or anakinra can be highly effective.

## Vasculitis

Vasculitis is characterised by inflammation and necrosis of blood vessel walls, with associated damage to skin, kidney, lung, heart, brain and gastrointestinal tract. There is a wide spectrum of involvement and severity, ranging from mild and transient disease affecting only the skin, to life-threatening fulminant disease with multiple organ failure. Principal sites of involvement for the main types of vasculitis are summarised in Figure 26.52. The clinical features result from a combination of local tissue ischaemia (due to vessel inflammation and narrowing) and the systemic effects of widespread inflammation. Systemic vasculitis should be considered in any patient with fever, weight loss, fatigue, evidence of multisystem involvement, rashes, raised inflammatory markers and abnormal urinalysis (Box 26.65).

## Antineutrophil cytoplasmic antibody-associated vasculitis

Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) is a life-threatening disorder characterised by inflammatory infiltration of small blood vessels, fibrinoid necrosis and the presence of circulating antibodies to antineutrophil cytoplasmic antibody (ANCA). The combined incidence is about 10–15/1 000 000. There are three main subtypes with differing clinical features:

### Microscopic polyangiitis

Microscopic polyangiitis (MPA) is a necrotising small-vessel vasculitis found with rapidly progressive glomerulonephritis, often in association with alveolar haemorrhage. Cutaneous and gastrointestinal involvement is common and other features include neuropathy (15%) and pleural effusions (15%). Patients are usually myeloperoxidase (MPO) antibody-positive.

### Granulomatosis with polyangiitis

Granulomatosis with polyangiitis (GPA), also known as Wegener's granulomatosis, is characterised by granuloma formation, mainly affecting the nasal passages, airways and kidney. A minority of patients present with glomerulonephritis. The most common presentation of GPA is with epistaxis, nasal crusting and sinusitis, but haemoptysis and mucosal ulceration may also occur. Deafness may be a feature due to inner ear involvement and proptosis may occur because of inflammation of the retro-orbital tissue (Fig. 26.53). This causes diplopia due to entrapment of the extra-ocular muscles, or loss of vision due to optic nerve compression. Disturbance of colour vision is an early feature of optic nerve compression. Untreated nasal disease ultimately leads to destruction of bone and cartilage. Migratory pulmonary infiltrates and nodules occur in 50% of patients (as seen on high-resolution CT of lungs). Patients with GPA are usually proteinase-3 (PR3) antibody-positive.

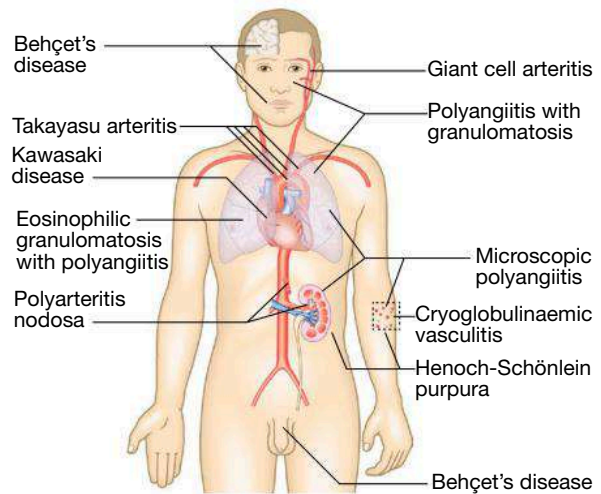

Fig. 26.52 Types of vasculitis. The anatomical targets of different forms of vasculitis are shown.

### 26.65 Clinical features of systemic vasculitis

#### Systemic

- Malaise
- Fever
- Night sweats
- Weight loss
- Myoarthralgias

#### Rashes

- Palpable purpura
- Pulp infarcts
- Ulceration
- Livedo reticularis

#### Ear, nose and throat

- Epistaxis
- Recurrent sinusitis
- Deafness

#### Respiratory

- Haemoptysis
- Cough
- Poorly controlled asthma

#### Gastrointestinal

- Abdominal pain (due to mucosal inflammation or enteric ischaemia)
- Mouth ulcers
- Diarrhoea

#### Neurological

- Sensory or motor neuropathy

### Eosinophilic granulomatosis with polyangiitis

Eosinophilic granulomatosis with polyangiitis (EGPA), also known as Churg–Strauss syndrome, is a small-vessel vasculitis with an incidence of about 1–3 per 1 000 000. Antibodies to MPO or PR3 can be detected in up to 60% of cases. It is somewhat distinct from MPA and GPA in that eosinophilia is a prominent feature. Some patients have a prodromal period for many years, characterised by allergic rhinitis, nasal polyposis and late-onset asthma that is often difficult to control. The typical acute presentation is with a triad of skin lesions (purpura or nodules), asymmetric mononeuritis multiplex and eosinophilia. Pulmonary infiltrates and pleural or pericardial effusions due to serositis may be present. Up to 50% of patients have abdominal symptoms provoked by mesenteric vasculitis.

### Investigation of AAV

Patients with active disease usually have a leucocytosis with elevated CRP and ESR. Complement levels are usually normal or slightly elevated. Eosinophilia is common in EGPA. Imaging of the upper airways, chest and nasal passages with MRI can be useful in localising abnormalities in

**Fig. 26.53** Eye involvement in antineutrophil cytoplasmic antibody-associated vasculitis.

GPA. Often, the diagnosis of AAV can be made on clinical and serological grounds in combination with the laboratory abnormalities described above, but if there is any doubt the diagnosis should be confirmed by biopsy of the kidney, skin or lesions in the sinuses and upper airways.

### Management

Management of organ-threatening AAV is with high-dose glucocorticoids and immunosuppressive therapy. A commonly used regimen is pulse intravenous methylprednisolone 0.5–1 g for 3 days coupled with intravenous cyclophosphamide 15 mg/kg every 2 weeks for 3 months. This is followed by maintenance therapy with lower-dose glucocorticoids and azathioprine, MTX or MMF. Rituximab in combination with high-dose glucocorticoids has been shown to be equally effective as oral cyclophosphamide and glucocorticoids at inducing remission in AAV. Plasmapheresis should be considered for fulminant lung disease. High dose glucocorticoids and MTX are an effective combination for treating limited AAV where there is indolent sinus, lung or skin disease. Recently mepolizumab, an inhibitor of IL-5, has been shown to reduce the risk of relapse when combined with glucocorticoids in EGPA. Patients with AAV must be followed on a regular and long-term basis since the condition has a tendency to relapse, monitoring urinalysis for blood and protein, plasma creatinine, FBC, ESR, CRP, lung function and PR3 or MPO antibody titres.

### Takayasu arteritis

Takayasu arteritis affects the aorta, its major branches and occasionally the pulmonary arteries. The typical age at onset is 25–30 years, with an 8:1 female-to-male ratio. It has a worldwide distribution, but is most common in Asia. It is characterised by granulomatous inflammation of the vessel wall, leading to its occlusion or weakening. It presents with claudication, fever, arthralgia and weight loss. Clinical examination may reveal loss of pulses, bruits, hypertension and aortic incompetence. Investigation typically shows a raised ESR and CRP and a normocytic, normochromic anaemia. The pivotal investigation is CT or MRI angiography, which reveals thickening of the vessel wall and narrowing of the lumen. Aortic coarctation, and aneurysmal dilatation may also occur. The diagnosis can also be made by <sup>18</sup>fluorodeoxyglucose PET-CT imaging, where there is increased tracer uptake in affected vessels. Treatment is with high-dose glucocorticoids and immunosuppressants, as described for ANCA-associated vasculitis. With successful treatment, the 5-year survival is 83%.

### Kawasaki disease

Kawasaki disease is a vasculitis that mostly involves the coronary vessels. It presents as an acute systemic disorder, usually affecting children under 5 years. It occurs mainly in Japan and other Asian countries,

**Fig. 26.54** Rash of systemic vasculitis (palpable purpura).

such as China and Korea, but other ethnic groups may also be affected. Presentation is with fever, generalised rash (including palms and soles), inflamed oral mucosa and conjunctival injection resembling a viral exanthem. The cause is unknown, but is thought to be an abnormal immune response to an infectious trigger. A syndrome with some similarities to Kawasaki disease has recently been reported to be a complication of COVID-19 infection in children. Cardiovascular complications include coronary arteritis, leading to myocardial infarction, transient coronary dilatation, myocarditis, pericarditis, peripheral vascular insufficiency and gangrene. Treatment is with aspirin (5 mg/kg daily for 14 days) and IVIg (400 mg/kg daily for 5 days). Ciclosporin (5 mg/kg/day) in combination with IVIg can be effective in patients with resistant disease.

### Polyarteritis nodosa

Polyarteritis nodosa has a peak incidence between the ages of 40 and 50, with a male-to-female ratio of 2:1. The annual incidence is about 2/1 000 000. Hepatitis B is an important risk factor and the incidence is 10 times higher in the Inuit of Alaska, in whom hepatitis B infection is endemic. Presentation is with fever, myalgia, arthralgia and weight loss, in combination with manifestations of multisystem disease. The most common skin lesions are palpable purpura (Fig. 26.54), ulceration, infarction and livedo reticularis (see Fig. 26.47). Pathological changes comprise necrotising inflammation and vessel occlusion, and in 70% of patients, arteritis of the vasa nervorum leads to neuropathy, which is typically symmetrical and affects both sensory and motor function. Severe hypertension and/or renal impairment may occur due to multiple renal infarctions, but glomerulonephritis is rare (in contrast to MPA). The diagnosis is confirmed by conventional or MR angiography, which shows multiple aneurysms and smooth narrowing of mesenteric, hepatic or renal systems, or by muscle or sural nerve biopsy, which reveals the histological changes described above. Treatment is with high-dose glucocorticoids and cyclophosphamide, as described for ANCA-associated vasculitis.

### Giant cell arteritis and polymyalgia rheumatica

Giant cell arteritis (GCA) is a granulomatous arteritis that affects medium- and large-sized arteries. It is commonly associated with polymyalgia rheumatica (PMR), which presents with symmetrical pain and stiffness affecting the shoulder and pelvic girdle. There is evidence that these symptoms are due to an inflammatory infiltrate of the synovium and

### 26.66 Conditions that can cause 'polymyalgic' axial and proximal limb inflammatory symptoms or mimic polymyalgia rheumatica

- Calcium pyrophosphate disease
- Spondyloarthritis
- Rheumatoid arthritis
- Hyper-/hypothyroidism
- Psoriatic arthritis (enthesopathic)
- Systemic vasculitis
- Myeloma
- Inflammatory myopathy (particularly inclusion body myositis)
- Lambert–Eaton syndrome
- Multiple separate lesions (cervical spondylosis, cervical radiculopathy, bilateral subacromial impingement, facet joint arthritis, osteoarthritis of the acromioclavicular joint)

tendon sheaths in the affected regions. Since many patients with GCA have symptoms of PMR, and some patients with PMR go on to develop GCA if untreated, many rheumatologists consider them to be different manifestations of the same underlying disorder. Both diseases are rare under the age of 60 years. The average age at onset is 70, with a female-to-male ratio of about 3:1. The prevalence of GCA in people of European descent is about 20 per 100 000 in those over the age of 50 years, while PMR affect about 60 per 100 000. Both conditions are much less common (1 in 100 000) in African and Asian populations. The cause is unknown, but there is a strong genetic component such that GCA is strongly associated with genetic variation at the HLA-DRB1 locus.

#### Clinical features

The cardinal symptom of GCA is headache, which is often localised to the temporal or occipital region and may be accompanied by scalp tenderness. Jaw pain develops in some patients, brought on by chewing or talking and is referred to as jaw claudication. Visual disturbance can occur (most specifically amaurosis) and a catastrophic presentation is with blindness in one eye due to occlusion of the posterior ciliary artery. In such cases the optic disc may appear pale and swollen with haemorrhages, but these changes may take 24–36 hours to develop and the fundi may initially appear normal. Rarely, neurological involvement may occur, with transient ischaemic attacks, brainstem infarcts and hemiparesis.

In GCA, constitutional symptoms, such as weight loss, fatigue, malaise and night sweats, are common. With PMR, there may be stiffness and painful restriction of active shoulder movements on waking. Sometimes patients can present with symptoms that are similar to RA. The affected muscles are not tender and there is no weakness or muscle-wasting. Other conditions that cause PMR-like symptoms are shown in [Box 26.66](#).

#### Investigations

The typical laboratory abnormality is an elevated ESR and CRP, often with a normochromic, normocytic anaemia. Abnormal liver function tests may also occur. Very rarely, PMR and GCA can present with a normal ESR in the early stages of disease evolution. More objective evidence for GCA should be obtained whenever possible. The two most commonly used investigations are temporal artery biopsy and ultrasound of the temporal arteries. Characteristic biopsy findings are fragmentation of the internal elastic lamina with necrosis of the media in combination with a mixed inflammatory cell infiltrate. The sensitivity is about 70% with multiple biopsies and multiple section analysis (to detect 'skip' lesions), but a negative biopsy does not exclude the diagnosis. The characteristic finding on Doppler ultrasound examination is the 'halo' sign, where the thickened vessel wall shows as a dark area surrounding a positive Doppler signal within the vessel. The overall sensitivity is about 55% and specificity about 70% in routine clinical practice. A negative result does not exclude the diagnosis.

### 26.67 Emergency management of giant cell arteritis

- Take blood for CRP, ESR and FBC
- Commence prednisolone (40–60 mg daily)
- Consider urgent ophthalmology examination in patients with visual symptoms
- Consider temporal artery biopsy or ultrasound
- Review within 1 week and adjust glucocorticoid doses according to clinical response and results of investigations

(ACPA = anti-citrullinated peptide antibody; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; CPK = creatine phosphokinase; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; FBC = full blood count)

#### Management

Prednisolone should be commenced urgently in suspected GCA because of the risk of visual loss ([Box 26.67](#)). Response is dramatic, such that symptoms largely resolve within 48–72 hours of starting therapy in virtually all patients. It is customary to use higher doses in GCA (40–60 mg prednisolone) than in PMR (15–20 mg). In both conditions, the glucocorticoid dose should be progressively reduced, guided by symptoms and ESR, with the aim of reaching a dose of 10–15 mg by about 8 weeks. The rate of reduction should then be slowed by 1 mg per month. The IL-6 inhibitor tocilizumab has been shown to reduce the risk of relapse following glucocorticoid dose reductions in GCA and is of value in patients at high risk of glucocorticoid side effects. The long-term efficacy of tocilizumab in GCA remains under investigation. If symptoms recur, the dose should be increased to that which previously controlled the symptoms and reduction attempted again in another few weeks. Immunosuppressive therapy with MTX or azathioprine may be required as steroid-sparing agents in patients where it is not possible to reduce the prednisolone dose below 10 mg daily. Most patients need glucocorticoids for an average of 12–24 months and in view of this bisphosphonate therapy is often required to protect against osteoporosis.

#### Henoch–Schönlein purpura

Henoch–Schönlein purpura is a small-vessel vasculitis caused by immune complex deposition following an infectious trigger. It is predominantly a disease of children and young adults. The usual presentation is with purpura over the buttocks and lower legs, accompanied by abdominal pain, gastrointestinal bleeding and arthralgia. Nephritis can also occur and may present up to 4 weeks after the onset of other symptoms. Biopsy of affected tissue shows a vasculitis with IgA deposits in the vessel wall. Henoch–Schönlein purpura is usually a self-limiting disorder that settles spontaneously without specific treatment. Glucocorticoids and immunosuppressive therapy may be required in patients with more severe disease, particularly in the presence of nephritis.

#### Cryoglobulinaemic vasculitis

This is a small-vessel vasculitis that occurs when immunoglobulins precipitate out in the cold. Cryoglobulins are classified into three types (see [Box 4.16](#)). Types II and III are associated with vasculitis. The typical presentation is with a vasculitic rash over the lower limbs, arthralgia, Raynaud's phenomenon and neuropathy. The ESR and CRP are elevated in active disease and C3 levels may be reduced. Some cases are secondary to hepatitis C infection and others are associated with other autoimmune diseases. Affected patients should be screened and, if positive, treated for hepatitis C. There is no consensus as to how best to treat cryoglobulinaemic vasculitis in the absence of an obvious trigger. Glucocorticoids and immunosuppressive therapy are often used empirically, but their efficacy is uncertain. In severe cases, plasmapheresis can be considered.

Fig. 26.55 Oral ulceration in Behçet's disease.

## i

### 26.68 Criteria for the diagnosis of Behçet's disease

Recurrent oral ulceration: minor aphthous, major aphthous or herpetiform ulceration at least three times in 12 months *plus* two of the following:

- Recurrent genital ulceration
- Eye lesions: anterior uveitis, posterior uveitis, cells in vitreous on slit-lamp examination, retinal vasculitis
- Skin lesions: erythema nodosum, pseudofolliculitis, papulopustular lesions, acneiform nodules
- Positive pathergy test

## Behçet's disease

This is a vasculitis of unknown aetiology that characteristically targets small arteries and venules. It is rare in Western Europe but more common in 'Silk Route' countries, around the Mediterranean and in Japan, where there is a strong genetic association with HLA-B51.

Oral ulcers are invariably present (Fig. 26.55). Unlike aphthous ulcers, they are usually deep and multiple, and last for 10–30 days. Genital ulcers are also a common problem, occurring in 60%–80% of cases. The usual skin lesions are erythema nodosum or acneiform lesions, but migratory thrombophlebitis and vasculitis also occur. Ocular involvement is common and may include anterior or posterior uveitis or retinal vasculitis. Neurological involvement occurs in 5% and mainly involves the brainstem, although the meninges, hemispheres and cord can also be affected, causing pyramidal signs, cranial nerve lesions, brainstem symptoms or hemiparesis. Recurrent thromboses also occur. Renal involvement is extremely rare.

The diagnosis is primarily made on clinical grounds (Box 26.68), but one characteristic feature that can be of diagnostic value is the pathergy test, which involves pricking the skin with a needle and looking for evidence of pustule development within 48 hours.

Oral and genital ulceration can be managed with a combination of colchicine and topical glucocorticoid preparations. Colchicine can be effective for erythema nodosum and arthralgia. Glucocorticoids and immunosuppressants such as azathioprine are indicated for uveitis, recurrent venous thrombosis and neurological disease. Anti-TNF- $\alpha$  therapy and/or thalidomide may be required in refractory patients.

## Relapsing polychondritis

Relapsing polychondritis is a rare inflammatory disease of cartilage that classically presents with acute pain and swelling of one or both ear pinnae,

sparing the lower non-cartilaginous portion. Around 30% of patients have coexisting autoimmune or connective tissue disease. Involvement of tracheobronchial cartilage may lead to a hoarseness, cough, stridor or expiratory wheeze. Other manifestations include collapse of the bridge of the nose, scleritis, hearing loss and cardiac valve dysfunction. Cartilage biopsy shows an inflammatory infiltrate in the perichondrium. Both ESR and CRP are raised in active disease. Pulmonary function tests, including flow–volume loops, should be performed to assess the degree of laryngo-tracheal disease, since this is an important cause of mortality. Mild disease usually responds to low-dose glucocorticoids or NSAIDs, whereas major tracheobronchial involvement requires high-dose glucocorticoids and immunosuppressants, as described for SLE.

## IgG4 disease

This is a rare condition (1–3/100 000) characterised by an inflammatory infiltrate of affected tissues in the early stages followed by fibrotic damage as the disease progresses. The disease may present in many ways, including with swelling of the lacrimal and salivary glands (mimicking Sjögren syndrome) and proptosis, sinusitis, hearing loss, interstitial lung disease and cranial nerve lesions (mimicking GPA). Inflammatory disease of the great vessels may occur while abdominal pain may result from infiltration of the pancreas or retroperitoneum. Thyroid involvement may manifest as Hashimoto's thyroiditis and Reidel's thyroiditis. The diagnosis may be suspected by the presence of a lymphocytic infiltrate on tissue biopsy, which is rich in IgG4-secreting plasma cells, and raised serum IgG4. Management is with glucocorticoids (prednisolone 30–40 mg/day with progressive dose reduction guided by symptoms, inflammatory markers and IgG4 levels) and an immunosuppressive such as MTX, azathioprine or MMF. Intravenous rituximab has also been used successfully using a similar regimen as in RA.

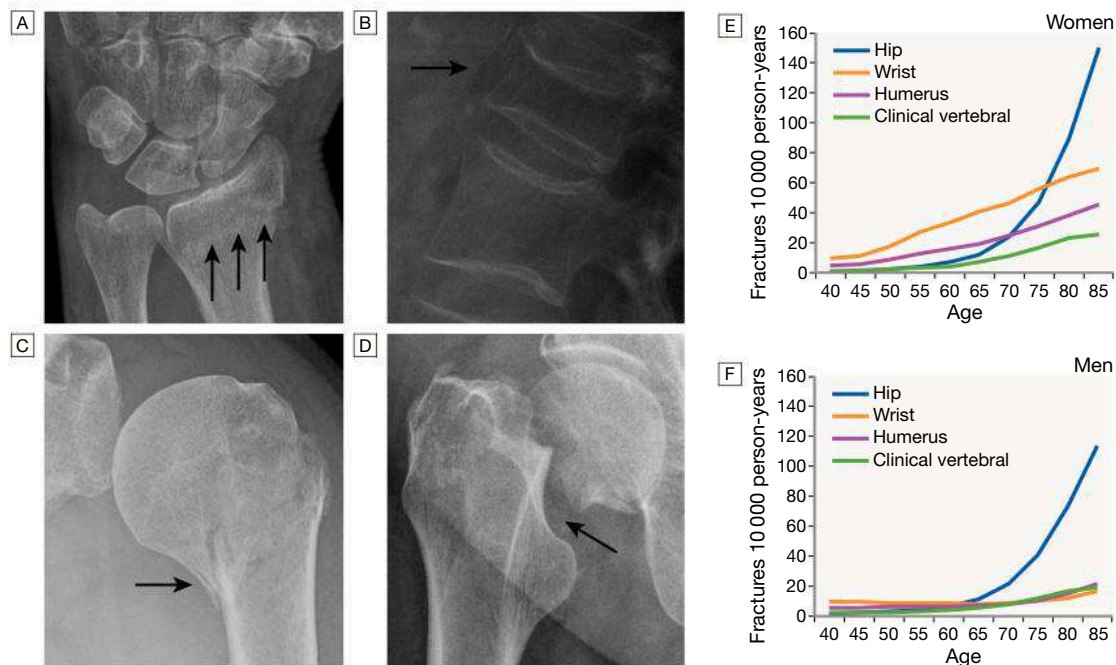

## Diseases of bone

### Osteoporosis

Osteoporosis is the most common bone disease. It has been estimated that more than 8.9 million fractures occur annually worldwide and most of these occur in patients with osteopenia or osteoporosis. About one-third of all women and one-fifth of men aged 50 and above suffer fractures at some point in life. The burden of osteoporosis-related fractures is predicted to increase by two- to threefold by 2050 on a worldwide basis, due to ageing of the population. Osteoporosis is under-diagnosed and under-treated throughout Asia, particularly in rural areas, due to low provision of technologies like DXA, which are required to make the diagnosis. Osteoporosis-related fractures can affect any bone, but common sites are the forearm (Colles' fracture), spine (vertebral fractures), humerus and hip. All of these fractures become more common with increasing age (Fig. 26.56). Since only about one-third of vertebral fractures come to medical attention (clinical vertebral fractures), the true number of patients with vertebral fracture is likely to be much greater than that shown in Figure 26.56. Hip fractures are the most serious complication of osteoporosis and have an immediate mortality of about 12% and a continued increase in mortality of about 20% when compared with age-matched controls. Treatment of hip fracture accounts for the majority of the health-care costs associated with osteoporosis.

### Pathophysiology

The defining feature of osteoporosis is reduced bone density, which causes micro-architectural deterioration of bone tissue and leads to an increased risk of fracture, in response to minor trauma. The risk of fracture increases markedly with age in both genders (see Fig. 26.56). This is mostly attributable to an increased risk of falling with age, but is also due in part to an age-related decline in bone density, especially in

**Fig. 26.56** Fractures associated with osteoporosis. **A** Wrist. **B** Vertebrae. **C** Humerus. **D** Hip. The fracture sites are indicated by black arrows. **E** and **F** The changing incidence of each of these fractures with age in women and men, respectively. From Curtis EM, van der Velde R, Moon RJ, et al. *Epidemiology of fractures in the United Kingdom, 1988–2012: variation with age, sex, geography, ethnicity and socioeconomic status. Bone* 2016; 87:19–26.

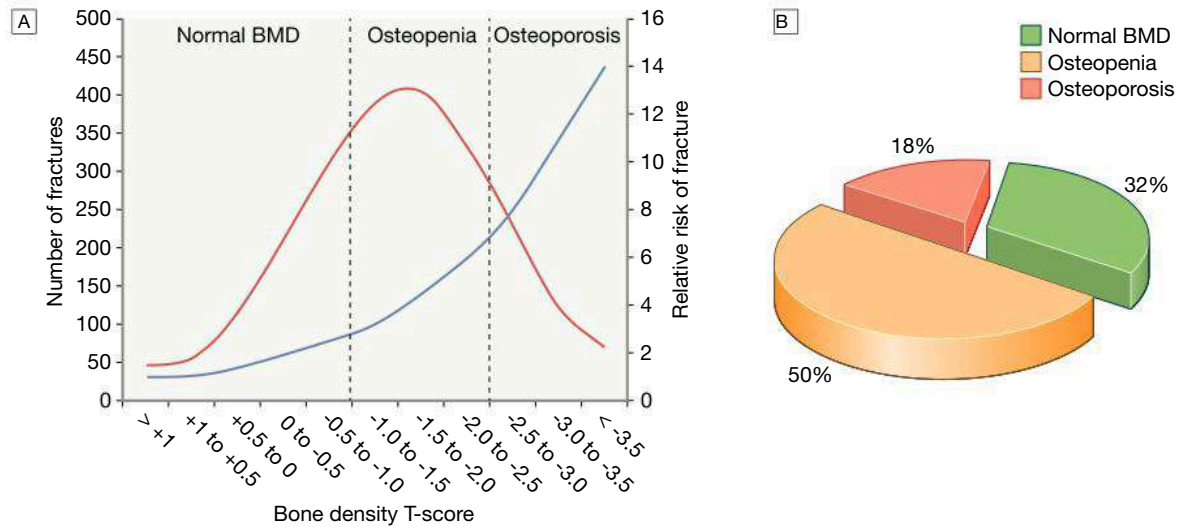

**Fig. 26.57** Changes in bone mass with age. Changes in men (blue line) and women (red line).

women (Fig. 26.57). Bone mass increases during growth to reach a peak between the ages of 20 and about 45 years, but falls thereafter in both genders with an accelerated phase of bone loss after the menopause in women due to oestrogen deficiency. The loss of bone with ageing is caused by an imbalance in the bone remodelling cycle, whereby the amount of new bone formed by osteoblasts cannot keep pace with the amount that is removed by osteoclasts (see Fig. 26.2). The reduction in bone formation is thought to be partly due to differentiation of bone marrow stem cells to adipocytes, as opposed to osteoblasts. Osteoporosis sometimes occurs because of failure to attain adequate levels of peak bone mass, but is more commonly due to age-related bone loss.

Osteoporosis is a complex disease that can occur in association with a wide variety of risk factors, as summarised in Box 26.69. Genetic factors account for up to 80% of variation in bone density and genome-wide association studies have shown that susceptibility is determined in part by a large number of common variants, some of which are involved in the RANK and Wnt signalling pathways (see Fig. 26.3). Rarely, osteoporosis may be caused by mutations in single genes. Environmental factors, such as exercise and calcium intake during growth and adolescence,

**Fig. 26.58** Relation between bone mineral density (BMD) and fractures. **A** The relative risk of fracture increases exponentially as BMD falls (blue line), and is 14-fold higher in people with a T-score of  $<-3.5$  compared with those with normal BMD. In absolute terms, however, more fractures occur in people with normal BMD or osteopenia (red line). **B** The number of fractures that occur in people with normal BMD, osteopenia and osteoporosis.

are important in maximising peak bone mass and in regulating rates of post-menopausal bone loss. Smoking has a detrimental effect on BMD and is associated with an increased fracture risk, partly because female smokers have an earlier menopause than non-smokers. Heavy alcohol intake is a recognised cause of osteoporosis and fractures, but moderate intake does not substantially alter risk.

#### Idiopathic osteoporosis

The term idiopathic osteoporosis is frequently used to describe the occurrence of osteoporosis in patients with no specific underlying cause. It is slightly misleading, since most, if not all, patients in this category have age-related osteoporosis or osteoporosis associated with inheritance of genetic variants that regulate bone density.

### Secondary osteoporosis

Osteoporosis can occur in association with a variety of diseases and drug treatments, and in many cases more than one disease or risk factor is operative. The most important causes are summarised in [Box 26.69](#). Secondary causes of osteoporosis are particularly common in men, occurring in up to 50% of patients. Hypogonadism, glucocorticoid use (see below) and alcohol excess are the most important predisposing factors.

#### Glucocorticoid-induced osteoporosis

Glucocorticoid-induced osteoporosis is a common problem in patients with systemic inflammatory and chronic pulmonary diseases. The risk of osteoporosis is related to dose and duration of glucocorticoid therapy and increases substantially in patients who have taken more than 7.5 mg of prednisolone daily for more than 3 months (or an equivalent dose of another glucocorticoid). Inhaled glucocorticoids can reduce bone density, but the risk of osteoporosis is much lower than with systemic therapy. Glucocorticoids mainly cause osteoporosis by inhibiting bone formation and causing apoptosis of osteoblasts and osteocytes. Other contributory mechanisms include inhibition of intestinal calcium absorption, increased renal excretion of calcium and secondary hyperparathyroidism, which stimulates osteoclastic bone resorption.

#### Pregnancy-associated osteoporosis

This is a rare form of osteoporosis that typically presents with back pain and multiple vertebral fractures usually during the third trimester or puerperium. It is discussed in more detail in Chapter 32.

### 26.70 Indications for dual X-ray absorptiometry (DXA)

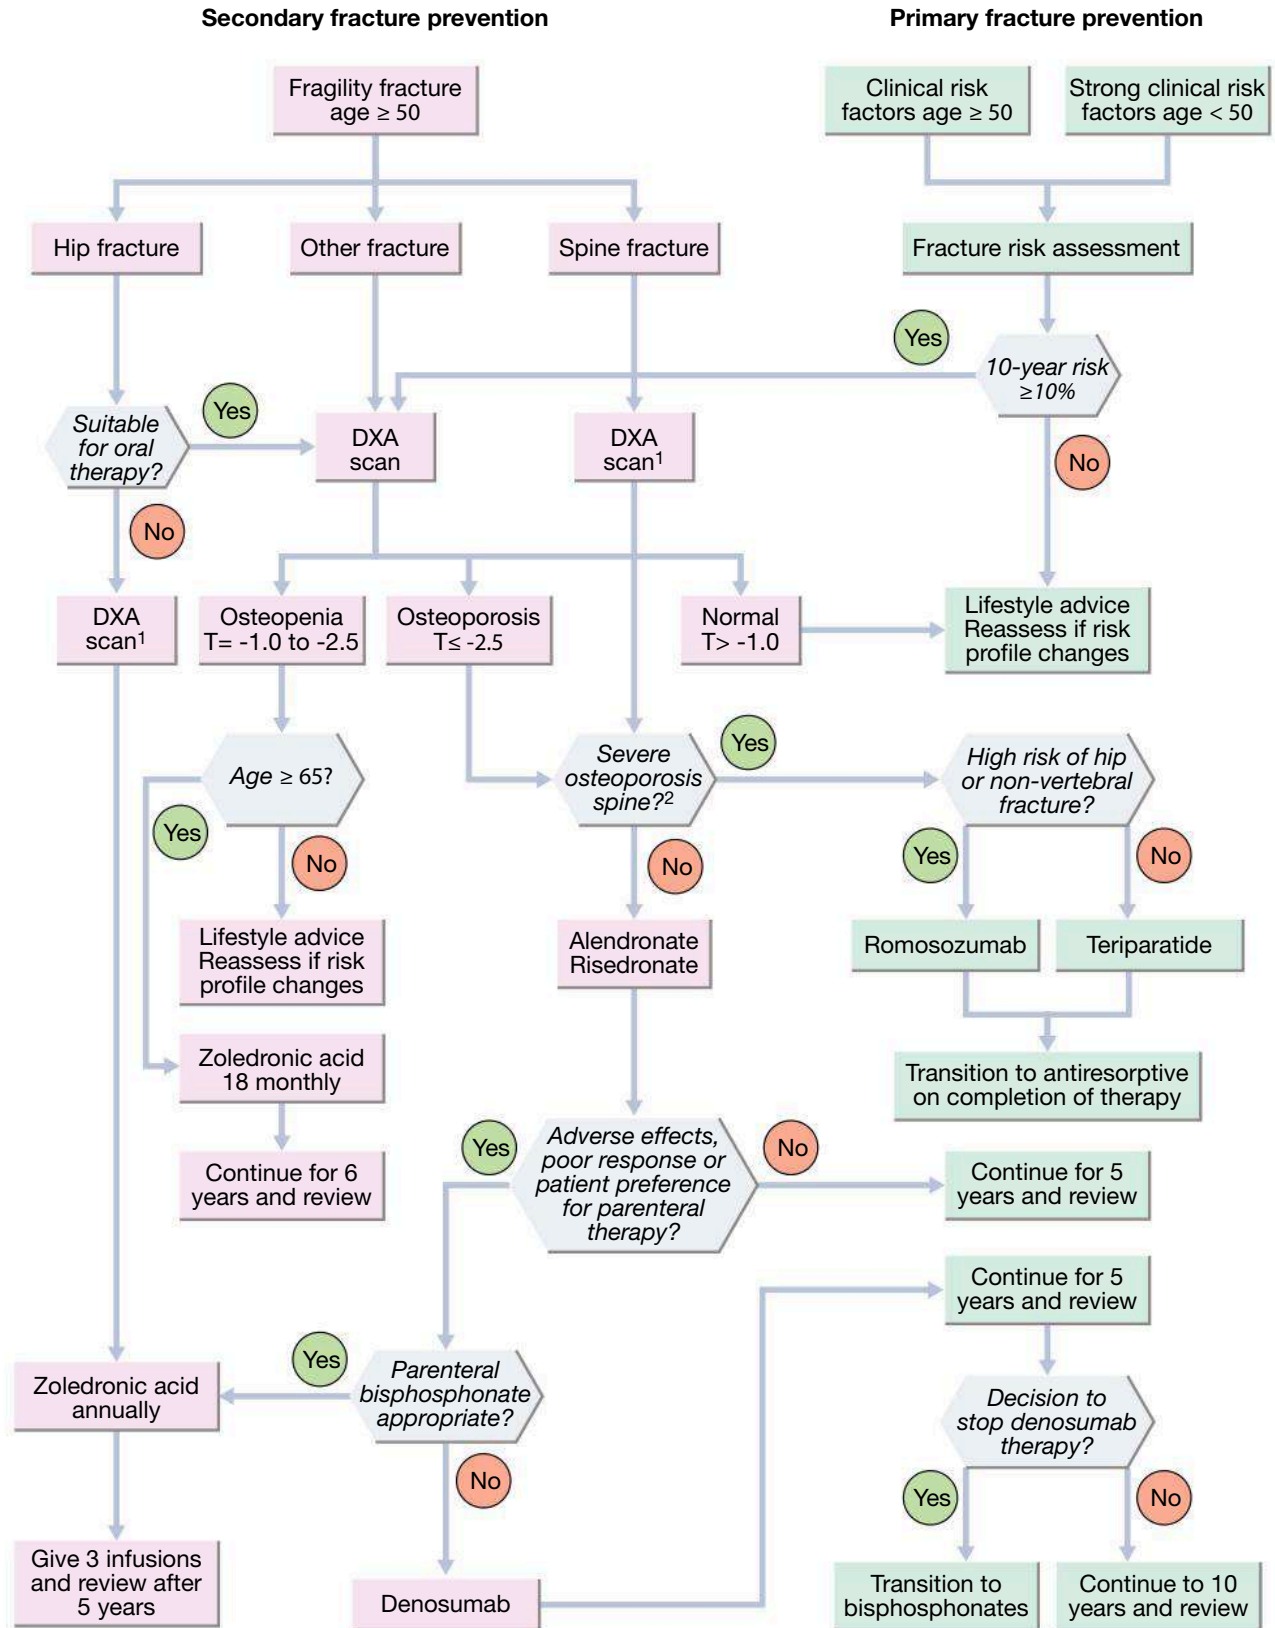

- Low-trauma fracture, age  $>50$  years
- Clinical risk factors and 10-year fracture risk  $>10\%$
- Glucocorticoid therapy ( $>7.5$  mg prednisolone daily for  $>3$  months)
- Baseline and follow-up assessment of response of osteoporosis to treatment
- Assessment of progression of osteopenia to osteoporosis
- Age  $<50$  years and strong risk factors for osteoporosis

#### Clinical features

Osteoporosis does not cause symptoms until a fracture occurs. Non-vertebral fractures are almost always caused by a traumatic event, most usually a simple fall. The term 'fragility fracture' is used to describe a fracture that occurs as the result of a fall from standing height or less. These are typical of osteoporosis. It is important to remember that the majority of people who suffer a fragility fracture do not have osteoporosis; some have normal BMD, but most have osteopenia ([Fig. 26.58](#)). The clinical signs of fracture are pain, local tenderness and deformity. In hip fracture, the patient is (with rare exceptions) unable to weight-bear and has a shortened and externally rotated limb on the affected side. The presentation of vertebral fractures is variable. Some patients present with acute severe back pain. This may radiate to the anterior chest or abdominal wall and be mistaken for a myocardial infarction, aortic dissection or intra-abdominal pathology. In others the presentation is with height loss and kyphosis in the absence of pain or with chronic back pain. Osteoporosis may be suspected by the finding of radiological osteopenia or vertebral deformities on imaging that has been performed for other reasons.

#### Investigations

The most important investigation is DXA (see [Fig. 26.9](#)). This should be considered in patients aged over 50 who have already suffered a fragility fracture, and in those with clinical risk factors ([Box 26.70](#)) when a fracture risk assessment tool has returned an elevated value. The risk at which DXA should be performed remains a subject of debate, but a 10-year risk of over 10% has been suggested, since there is evidence of benefit from treatment at this level. Other indications for DXA are in patients under 50 years who have very strong risk factors, such as premature menopause or high-dose glucocorticoids. [Figure 26.59](#) provides a suggested algorithm for the investigation of patients with suspected osteoporosis.

**Fig. 26.59** Algorithm for the diagnosis and management of osteoporosis. <sup>1</sup>DXA scan advisable to obtain baseline BMD but not necessary to initiate treatment. <sup>2</sup>One severe or two or more moderate vertebral fractures on X-ray, and T-score < -1.5 at any site or spine T score < -4.0. Adapted from SIGN 142. www.sign.ac.uk

A history should be taken to identify any predisposing causes, such as early menopause, excessive alcohol intake, smoking and glucocorticoid therapy. Signs of endocrine disease, neoplasia and inflammatory disease should be sought on clinical examination. A falls history should be taken and screening tests performed to assess the risk of falls (p. 1297). Screening for secondary causes of osteoporosis should be performed, as summarised in [Box 26.71](#).

### Management

The aim of treatment is to reduce the risk of fracture and this can be achieved by a combination of approaches.

26.71 Investigations to consider in suspected osteoporosis	
Investigation	Secondary cause of osteoporosis
Urea, creatinine and electrolytes	Chronic kidney disease
Liver function tests and albumin	Chronic liver disease
Full blood count, erythrocyte sedimentation rate	Inflammatory disease Myeloma
Tissue transglutaminase antibodies	Coeliac disease
Serum calcium and phosphate, 25(OH)D, PTH	Primary and secondary hyperparathyroidism, vitamin D deficiency. Normocalcaemic PHPT exists with reference range calcium
Thyroid function tests	Hyperthyroidism
Serum protein electrophoresis	Myeloma Monoclonal gammopathy of uncertain significance
Urine Bence Jones protein	Myeloma
Testosterone and gonadotrophins	Male hypogonadism
Oestrogen and gonadotrophins	Female hypogonadism <sup>1</sup>
Bone biopsy	Unexplained early-onset osteoporosis <sup>2</sup>

<sup>1</sup>Only required for unexplained osteoporosis in young women who are amenorrhoeic. <sup>2</sup>Seldom required.  
(25(OH)D = 25 hydroxy-vitamin D; PTH = parathyroid hormone)

### Non-pharmacological interventions

Advice on smoking cessation, moderation of alcohol intake, adequate dietary calcium intake and exercise should be given. Those with recurrent falls or unsteadiness on a 'get up and go' test (p. 1297) should be referred to a multidisciplinary falls-prevention team. Hip protectors can reduce the risk of hip fracture in selected patients, but adherence is often poor.

### Pharmacological interventions

Several drug treatments are now available to reduce the risk of fracture in osteoporosis. The dosages, mode of administration and indications are summarised in [Box 26.72](#). More detail on the individual drugs is provided below.

**Bisphosphonates** Bisphosphonates are the first-line treatment for osteoporosis. These are a class of drugs with a central core of P-C-P atoms, to which various side-chains are attached. Following administration, they target bone surfaces and are ingested by osteoclasts during the process of bone resorption. The bisphosphonate is released within the osteoclast, causing cell death and thereby bone resorption. This in turn causes an increase in bone density, but this is principally due to increased mineralisation of bone, rather than an increase in bone mass ([Fig. 26.60](#)). Bisphosphonates reduce the risk of fractures in osteoporosis, but do not completely prevent the occurrence of fractures.

Oral bisphosphonates are typically given for a period of 5 years, at which point the need for continued therapy should be evaluated, with a repeat DXA if possible. If patients have remained free of fractures after 5 years and if BMD levels have increased and no longer remain in the osteoporotic range, it is usual to instigate a 5-year spell off therapy. Treatment may be continued for up to 10 years in patients whose BMD levels remain in the osteoporotic range after 5 years and in those with pre-existing vertebral fractures. A change in treatment should be considered in patients who have lost BMD despite oral bisphosphonates (more than 4% at any site). Most commonly, this will be a switch to parenteral zoledronic acid which is often given by annual infusion of 5 mg for 3 consecutive years followed by a spell of 2 years without treatment. Infusions every 18 months over a spell of 6 years have also been found to be effective for fracture prevention.

Oral bisphosphonates are poorly absorbed from the gastrointestinal tract and should be taken on an empty stomach with plain water; no

Fig. 26.60 Mechanism of action of bisphosphonates.

26.73 Adverse effects of bisphosphonates	
<b>Common</b>	<ul style="list-style-type: none"> <li>• Upper gastrointestinal intolerance (oral)</li> <li>• Acute phase response (intravenous)</li> </ul>
<b>Less common</b>	<ul style="list-style-type: none"> <li>• Atrial fibrillation (intravenous zoledronic acid)</li> <li>• Hypocalcaemia (intravenous bisphosphonates)</li> <li>• Atypical subtrochanteric fractures</li> </ul>
<b>Rare</b>	<ul style="list-style-type: none"> <li>• Uveitis</li> <li>• Osteonecrosis of the jaw</li> <li>• Oesophageal ulceration</li> </ul>

food should be eaten for 30–45 minutes after administration. They are contraindicated in patients with oesophageal stricture or achalasia, since tablets may stick in the oesophagus, causing ulceration and perforation. Upper gastrointestinal upset occurs in about 5% of cases. Oral bisphosphonates can be used in patients with gastro-oesophageal reflux disease, but may cause worsening of symptoms. The most common adverse effect with intravenous bisphosphonates is a transient influenza-like illness with fever, malaise, anorexia and generalised aches, which occurs 24–48 hours after administration. This is self-limiting, but can be treated with paracetamol or NSAIDs if necessary. It predominantly occurs after the first exposure and tolerance develops thereafter. Other adverse effects are shown in Box 26.73. Osteonecrosis of the jaw is characterised by the presence of necrotic bone in the mandible or maxilla, typically occurring after tooth extraction when the socket fails to heal. This complication is very rare in osteoporosis, but patients receiving bisphosphonates should be advised to pay attention to good oral hygiene. There is no evidence that temporarily stopping bisphosphonates for tooth extraction alters the risk of osteonecrosis of the jaw. Atypical subtrochanteric fractures have been described in patients who have received long-term bisphosphonates and appear to be the result of over-suppression of normal bone remodelling. In the vast majority, the benefits of bisphosphonate therapy far outweigh the risks, but it is important for treatment to be targeted to patients with low BMD who are most likely to benefit.

**Denosumab** Denosumab is a monoclonal antibody that inhibits bone resorption by neutralising the effects of RANKL (see Fig. 26.2). It is administered by subcutaneous injection of 60 mg every 6 months in the

### 26.74 Osteoporosis in old age

- **Bone loss:** due to increased bone turnover, with an age-related defect switch in differentiation of bone marrow stromal cells to form adipocytes as opposed to osteoblasts.
- **Fractures due to osteoporosis:** common cause of morbidity and mortality, although fracture healing is not delayed by age.
- **Recurrent fractures:** those who suffer a fragility fracture are at increased risk of further fracture, so should be investigated for osteoporosis and treated if this is confirmed.
- **Falls:** risk factors for falls (such as visual and neuromuscular impairments) are independent risk factors for hip fracture in older people, so intervention to prevent falls is as important as treatment of osteoporosis.
- **Intravenous zoledronic acid:** reduces mortality and subsequent fracture in selected older patients with hip fractures.
- **Calcium and vitamin D:** reduce the risk of fractures in those who are housebound or living in care homes.

treatment of osteoporosis and has similar efficacy to zoledronic acid. One potential adverse effect is hypocalcaemia, but this can be mitigated by calcium and vitamin D supplements. Denosumab may rarely cause osteonecrosis of the jaw and atypical subtrochanteric fractures. When denosumab is stopped, there is a rebound increase in bone turnover that can be associated with an increased risk of vertebral fracture and even hypercalcaemia. Because of this denosumab needs to be continued on a long-term basis; if it has to be stopped for any reason, bisphosphonate therapy should be given to inhibit the rebound increase in bone turnover.

**Calcium and vitamin D** Combined calcium and vitamin D supplements have limited efficacy in the prevention of osteoporotic fractures when given alone, but are widely used as an adjunct to other treatments. A typical daily dosage is 1000 mg calcium and 800 IU vitamin D. Calcium and vitamin D supplements have efficacy in preventing fragility fractures in old age or in institutionalised patients, who are at high risk of deficiency (Box 26.74). Vitamin D supplements alone do not prevent fractures in osteoporosis, but there is evidence that the response to bisphosphonates is blunted in patients with vitamin D deficiency. If the patient's dietary calcium is sufficient, stand-alone vitamin D supplements (800 IU daily) can be prescribed as an adjunct to anti-osteoporosis therapies. Calcitriol (1,25(OH)<sub>2</sub>D<sub>3</sub>), the active metabolite of vitamin D, is licensed for treatment of osteoporosis but it is seldom used because the data on fracture prevention are less robust than for other agents.

**Teriparatide** Teriparatide (TPTD) is the 1-34 fragment of human PTH. It is an effective treatment for osteoporosis, which works by stimulating new bone formation. Although TPTD also stimulates bone resorption, the increase in bone formation is greater, resulting in increased bone density, particularly at sites rich in trabecular bone such as the spine. It is given by a self-administered subcutaneous injection in a dose of 20 µg daily for 2 years. At the end of this period, bisphosphonate therapy or another inhibitor of bone resorption should be administered to maintain the increase in BMD. Oral bisphosphonates and TPTD should not be given in combination, however, since the bisphosphonate blunts the anabolic effect. The efficacy of TPTD for prevention of non-vertebral fractures is similar to that of bisphosphonates, but it is superior to oral bisphosphonates in preventing vertebral fractures. The most common adverse effects are headache, muscle cramps and dizziness. Mild hypercalcaemia may occur, but it is usually asymptomatic and does not require discontinuation of treatment. Monitoring of serum calcium is not required during TPTD treatment.

**Abaloparatide** Abaloparatide is the 1-34 fragment of PTH-related protein which has effects similar to those of TPTD. It is given as a self-administered injection of 80 µg daily for 18 months. At the end of this period an inhibitor of bone resorption should be given to maintain the increase in bone mass. Efficacy has been demonstrated for the prevention of vertebral fractures.

26.75 Causes of osteomalacia and rickets		
Cause	Predisposing factor	Mechanism
<b>Vitamin D deficiency</b>		
Classical	Lack of sunlight exposure and poor diet	Reduced cholecalciferol synthesis in the skin/low levels of vitamin D in the diet
Gastrointestinal disease	Malabsorption	Malabsorption of dietary vitamin D and calcium
<b>Failure of 1,25 vitamin D synthesis</b>		
Chronic renal failure	Hyperphosphataemia and kidney damage	Impaired conversion of 25(OH)D <sub>3</sub> to 1,25(OH) <sub>2</sub> D <sub>3</sub>
Vitamin D-resistant rickets type I (autosomal recessive)	Loss-of-function mutations in renal 25(OH)D 1 $\alpha$ -hydroxylase enzyme	Impaired conversion of 25(OH)D <sub>3</sub> to 1,25(OH) <sub>2</sub> D <sub>3</sub>
<b>Vitamin D receptor defects</b>		
Vitamin D-resistant rickets type II (autosomal recessive)	Loss-of-function mutations in vitamin D receptor	Impaired response to 1,25(OH) <sub>2</sub> D <sub>3</sub>
<b>Defects in phosphate and pyrophosphate metabolism</b>		
Hypophosphataemic rickets (X-linked dominant)	Mutations in <i>PHEX</i>	Increased FGF23 production (mechanism unclear)
Autosomal dominant hypophosphataemic rickets	Mutation in <i>FGF23</i>	Mutant FGF23 is resistant to degradation
Autosomal recessive hypophosphataemic rickets	Mutations in <i>DMP1</i>	Increased production of FGF23. Local deficiency of DMP1 inhibits mineralisation
Tumour-induced hypophosphataemic osteomalacia	Ectopic production of FGF23 by tumour	Over-production of FGF23
Hypophosphatasia	Mutations in <i>ALPL</i> , which encodes alkaline phosphatase	Inhibition of bone mineralisation due to accumulation of pyrophosphate in bone
<b>Iatrogenic and other causes</b>		
Bisphosphonate therapy	High-dose etidronate/pamidronate	Drug-induced impairment of mineralisation
Aluminium	Use of aluminium-containing phosphate binders or aluminium in dialysis fluid	Aluminium-induced impairment of mineralisation
Fluoride	High fluoride in water	Inhibition of mineralisation by fluoride
(FGF23 = fibroblast growth factor 23)		

**Romozumab** This is a neutralising antibody to sclerostin, which is produced by osteocytes and acts to inhibit bone formation (see Fig. 26.3). Romozumab is a highly effective treatment for osteoporosis and works by inhibiting bone resorption and stimulating bone formation. It is indicated for the treatment of severe osteoporosis, where it is given by self-administered subcutaneous injection 210mg once a month for 12 months. Following completion of treatment, an inhibitor of bone resorption should be given to maintain the increase in bone density. Romozumab is significantly more effective than oral alendronic acid at preventing fractures of all types and it is one of the most effective treatments for osteoporosis currently available. Adverse effects are uncommon, although a slight excess of cardiovascular events was observed in some clinical trials and because of that it is contraindicated in patients with a previous history of myocardial infarction or stroke.

**Hormone replacement therapy** Cyclical HRT with oestrogen and progestogen prevents post-menopausal bone loss and reduces the risk of vertebral and non-vertebral fractures in post-menopausal women. It is primarily indicated for the prevention of osteoporosis in women with an early menopause and for treatment of women with osteoporosis in their early fifties who have troublesome menopausal symptoms. It is not recommended above the age of 60 because of an increased risk of breast cancer, cardiovascular disease and venous thromboembolism.

**Raloxifene** Raloxifene is a selective oestrogen receptor modulator (SERM) that acts as a partial agonist at oestrogen receptors in bone and liver, but as an antagonist in breast and endometrium. It is effective in reducing the risk of vertebral fractures, but does not influence the risk of non-vertebral fracture and is seldom used. Adverse effects include muscle cramps, worsening of hot flushes and an increased risk of venous thromboembolism. Bazedoxifene is a related SERM that has similar effects to raloxifene.

### Tibolone

Tibolone has partial agonist activity at oestrogen, progestogen and androgen receptors. It has been shown to prevent vertebral and non-vertebral fractures in post-menopausal osteoporosis. Treatment is associated with a slightly increased risk of stroke, but a reduced risk of breast cancer.

### Surgery

Orthopaedic surgery with internal fixation is frequently required to reduce and stabilise osteoporotic fractures. Patients with intracapsular fracture of the femoral neck generally need hemi-arthroplasty or total hip replacement in view of the high risk of osteonecrosis.

Vertebroplasty is sometimes used in the treatment of painful vertebral compression fractures. It involves injecting methyl methacrylate (MMA) into the affected vertebral body under sedation and local anaesthesia. Randomised trials have not shown convincing evidence of benefit as compared with a sham procedure. Kyphoplasty is used under similar circumstances, but in this case a needle is introduced into the affected vertebral body and a balloon is inflated, which is then filled with MMA. It has similar efficacy to vertebroplasty. Serious adverse effects may occur with both procedures, including spinal cord compression due to leakage of MMA and fat embolism.

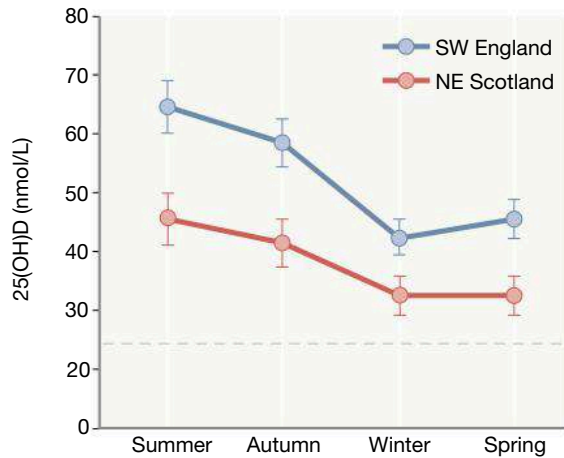

## Osteomalacia, rickets and vitamin D deficiency

Osteomalacia and rickets are characterised by defective mineralisation of bone. The most common cause is vitamin D deficiency, but both conditions can also occur as the result of inherited defects in renal phosphate excretion, inherited defects in the vitamin D receptor and in the pathways responsible for vitamin D activation. Other causes are summarised in Box 26.75 and are discussed in more detail below. The term osteomalacia refers to the syndrome when it occurs in adults; rickets is the equivalent in children.

## Vitamin D deficiency

Vitamin D deficiency is a biochemical diagnosis, which is defined to be present when serum 25(OH)D concentrations are below 25 nmol/L (10 ng/mL). People with vitamin D levels in the range 25–50 nmol/L (10–20 ng/mL) are said to have vitamin D insufficiency, whereas those with 25(OH)D levels above 50 nmol/L (20 ng/mL) are classified as having normal vitamin D status. The likelihood of developing vitamin D deficiency

**Fig. 26.61** Seasonal changes in vitamin D concentrations. (To convert nmol/L to ng/mL, multiply by 2.5.) Adapted from McDonald HM, Mavroidi A, Fraser WD, et al. Sunlight and dietary contributions to the seasonal vitamin D status of cohorts of healthy postmenopausal women living at northerly latitudes: a major cause for concern? *Osteoporosis Int* 2011; 22:2461–2472.

is strongly related to sunlight exposure. It is common in northern latitudes (or southern latitudes in the southern hemisphere) and shows seasonal variation. Vitamin D deficiency is more common in the winter and spring and less common in summer and autumn (for a UK example, see Fig. 26.61). People with dark skin and those who wear facial coverings are more prone to developing vitamin D deficiency.

## Pathogenesis

The source of vitamin D and pathways involved in regulating its metabolism are shown in Figure 26.62. In normal individuals, vitamin D (also known as cholecalciferol) comes from two sources: about 70% is made in the skin, where 7-dehydrocholesterol is converted to cholecalciferol under the influence of ultraviolet light, whereas the remaining 30% is derived from the diet. The main dietary sources are oily fish and meat, although bread and dairy products are fortified with vitamin D in some countries. On entering the circulation, vitamin D is hydroxylated in the liver to form 25(OH)-vitamin D and this is further hydroxylated in the kidney to form 1,25(OH)<sub>2</sub>D, the biologically active metabolite. The 1,25(OH)<sub>2</sub>D primarily acts on the gut to increase intestinal calcium absorption, but also acts on the skeleton to stimulate bone remodelling. Synthesis of 1,25(OH)<sub>2</sub>D is regulated by a negative feedback loop orchestrated by the parathyroid glands. When vitamin D levels fall – as the result of lower sunlight exposure or dietary lack – production of 1,25(OH)<sub>2</sub>D is reduced, causing a reduction in calcium absorption from the gut. This causes a transient fall in serum calcium, which is detected by calcium-sensing receptors on the parathyroid chief cells; this increases PTH secretion, which restores calcium levels to normal. Vitamin D deficiency is, therefore, usually characterised by a low level of 25(OH)D and a raised level of PTH. Sometimes, low 25(OH)D levels may be observed in the presence of a normal PTH concentration. This is of uncertain clinical significance and can be due to variations in levels of vitamin D-binding protein. Serum concentrations of vitamin D are under genetic control and are associated with variants close to the GC gene, which encodes vitamin D-binding

**Fig. 26.62** Vitamin D metabolism. Vitamin D is produced in the skin from 7-dehydrocholesterol (7-DHC) by ultraviolet B (UVB) light. The 7-dehydrocholesterol reductase enzyme, which is encoded by the *DHCR7* gene, opposes the effect of UVB by converting 7-DHC to cholesterol. The vitamin D then undergoes hydroxylation steps in the liver and kidney to form the active metabolite 1,25(OH)<sub>2</sub>D, which regulates calcium homeostasis by stimulating calcium absorption from the diet and bone resorption. See text for details. (PTH = parathyroid hormone)

protein; the *DHCR7* gene, which encodes 7-dehydrocholesterol reductase, responsible for catalysing conversion of 7-DHC to cholesterol; the *CYP2R1* gene, which encodes vitamin D-25-hydroxylase, responsible for hydroxylation of vitamin D in the liver; and the *CYP24A1* gene, which encodes vitamin D-24-hydroxylase, responsible for converting 25(OH)D to the inactive metabolite 24,25(OH)<sub>2</sub>D.

### Clinical features

Low circulating levels of vitamin D do not cause symptoms unless the vitamin D deficiency is severe, so the diagnosis of vitamin D deficiency is primarily made as the result of biochemical testing. A wide range of diseases, including most types of cancer, diabetes, multiple sclerosis and chronic inflammatory diseases have been associated with vitamin D deficiency. Current evidence suggests that these are not causal associations, but explained by confounding whereby people who are unwell have reduced sunlight exposure and poor diet. If vitamin D deficiency is prolonged and severe, then osteomalacia and rickets may occur, as discussed below.

### Investigations

The diagnosis can be made by measurement of serum 25(OH)D. In patients with low 25(OH)D, measurements of PTH, serum calcium, phosphate and ALP should also be considered. Low levels of 25(OH)D in the absence of other abnormalities is unlikely to be of any clinical significance and in many cases is likely to be due to low levels of vitamin D-binding protein, the levels of which are genetically determined. If low 25(OH)D levels are combined with raised levels of PTH, this is of more significance since it indicates secondary hyperparathyroidism, which if untreated and prolonged, may impair bone health and eventually lead to osteomalacia or rickets.

### Management

Vitamin D supplements should be considered in patients who have low 25(OH)D levels and raised levels of PTH. In most young adults, greater exposure to UV light and cholecalciferol in a dose of 800 IU daily should be sufficient to correct the deficiency. Short courses of high-strength vitamin D can also be used, such as 20 000 IU once weekly for 4–6 weeks. The benefit of treating low 25(OH)D values in the absence of other abnormalities of calcium biochemistry is uncertain. There is some evidence that response to bisphosphonate treatment of osteoporosis is impaired in patients with vitamin D deficiency and this is an indication for supplements. Similarly, patients who are receiving intravenous bisphosphonates and denosumab for osteoporosis should have vitamin D deficiency corrected by supplementation to reduce the risk of hypocalcaemia.

## Osteomalacia and rickets

Severe and prolonged vitamin D deficiency can result in the occurrence of osteomalacia in adults and rickets in children. Improvements in nutrition mean that these are now relatively uncommon conditions in high-income countries, but they remain prevalent in older housebound individuals, who may have a poor diet and limited sunlight exposure, in women who wear facial coverings such as the niqab or burka, and in people with malabsorption.

### Pathogenesis

Osteomalacia and rickets occur as the result of chronic secondary hyperparathyroidism, which invariably accompanies severe and long-standing vitamin D deficiency. The sustained elevation in PTH levels maintains normal levels of serum calcium by increasing bone resorption, which eventually causes progressive demineralisation of the skeleton. Phosphate released during the process of bone resorption is lost through increased renal excretion, resulting in hypophosphataemia. The raised levels of PTH stimulate osteoblast activity and cause new bone formation, but the matrix is not mineralised properly because of deficiency of calcium and phosphate. The under-mineralised bone is soft, mechanically weak and subject to fractures, particularly stress fractures. Normal levels of

serum calcium tend to be maintained until a very advanced stage, when hypocalcaemia may occur.

### Clinical features

Vitamin D deficiency in children causes delayed development, muscle hypotonia, craniotabes (small unossified areas in membranous bones of the skull that yield to finger pressure with a cracking feeling), bossing of the frontal and parietal bones and delayed anterior fontanelle closure, enlargement of epiphyses at the lower end of the radius and swelling of the rib costochondral junctions ('rickety rosary'). Osteomalacia in adults can present with fractures and low BMD, mimicking osteoporosis. Other symptoms include bone pain and general malaise. Proximal muscle weakness is prominent and the patient may walk with a waddling gait and struggle to climb stairs or stand up from a chair. There may be bone and muscle tenderness on pressure and focal bone pain can be due to fissure fractures of the ribs and pelvis.

### Investigations

The diagnosis can usually be made by measurement of serum 25(OH)D, PTH, calcium, phosphate and ALP. Typically, serum ALP levels are raised, 25(OH)D levels are undetectable and PTH is markedly elevated. Serum phosphate levels tend to be low, but serum calcium is usually normal, unless the disease is advanced. X-rays often show osteopenia or vertebral crush fractures and, with more advanced disease, focal radiolucent areas (pseudofractures or Looser zones) may be seen in ribs, pelvis and long bones (Fig. 26.63). In children, there is thickening and widening of the epiphyseal plate. A radionuclide bone scan may show multiple hot spots in the ribs and pelvis at the site of fractures and the appearance may be mistaken for metastases. Where there is doubt, the diagnosis can be confirmed by bone biopsy, which shows the pathognomonic increased thickness and extent of osteoid seams (see Fig. 26.63).

### Management

Osteomalacia and rickets respond promptly to treatment with vitamin D. A wide variety of doses can be used. Treatment with between 10 000 and 25 000 IU daily for 2–4 weeks is associated with rapid clinical improvement, an elevation in serum 25(OH)D and a reduction in PTH. Serum ALP levels sometimes rise initially as mineralisation of bone increases, but eventually fall to within the reference range as the bone disease heals. Subsequently, the dose of vitamin D can usually be reduced to a maintenance level of 800–1600 IU daily (10–20 µg), except in patients with malabsorption, who may require higher maintenance doses.

## Vitamin D-resistant rickets

This is a genetically determined condition that presents in childhood with rickets that is resistant to therapy with vitamin D in standard dosages.

**Fig. 26.63 Osteomalacia.** **A** Photomicrograph of a toluidine blue-stained bone biopsy from a patient with osteomalacia showing thickened osteoid seams, stained light blue (arrows) covering most of the bone surface (left). Calcified bone is stained purple. **B** X-ray of a patient with osteomalacia showing a stress fracture of the tibia (arrow).

### Pathogenesis

Type I vitamin D-resistant rickets (VDRR) is caused by inactivating mutations in the 25(OH)D-1 $\alpha$ -hydroxylase (*CYP27B1*) enzyme, which converts 25(OH)D to the active metabolite 1,25(OH)<sub>2</sub>D<sub>3</sub>. Type II VDRR is caused by inactivating mutations in the vitamin D receptor, which impair its ability to activate gene transcription. Both are recessive disorders and consanguinity is common.

### Clinical features

These are as described above for infantile rickets. The diagnosis is usually first suspected when the patient fails to respond to vitamin D supplementation.

### Investigations

The biochemical features of type I VDRR are similar to those of ordinary vitamin D deficiency, except that levels of 25(OH)D are normal, but 1,25(OH)<sub>2</sub>D is low. In type II VDRR, 25(OH)D is normal, but PTH and 1,25(OH)<sub>2</sub>D<sub>3</sub> values are raised. The diagnosis can be confirmed by genetic testing.

### Management

Type I VDRR responds fully to treatment with the active vitamin D metabolites 1 $\alpha$ -hydroxy-vitamin D (1–2  $\mu$ g daily, orally) or 1,25-dihydroxy-vitamin D (0.25–1.5  $\mu$ g daily, orally). Calcium supplements are not necessary unless there is dietary deficiency. Type II VDRR sometimes responds partially to very high doses of active vitamin D metabolites, which can activate the mutant receptor, although additional calcium and phosphate supplements are also necessary.

## Hereditary hypophosphataemic rickets

This group of disorders are caused by inherited defects in renal tubular phosphate reabsorption. The most common is X-linked hypophosphataemic rickets (XLH), but autosomal dominant and autosomal recessive forms also occur (see [Box 26.75](#)).

### Pathophysiology

Most forms of hereditary hypophosphataemic rickets are associated with raised circulating concentrations of the phosphate-regulating hormone fibroblast growth factor 23 (FGF23). This hormone is produced by osteocytes (see [Fig. 26.3](#)) and enters the circulation, where it is normally inactivated by proteolytic cleavage. Production of FGF23 by osteocytes is under tonic inhibition by DMP1 and PHEX. In XLH, the inhibitory effect on FGF23 production is lost due to mutations in *PHEX* and a similar situation occurs in autosomal recessive hypophosphataemic rickets (ARHR1) due to loss-of-function mutations in *DMP1*. In autosomal dominant hypophosphataemic rickets (ADHR), the FGF23 protein carries mutations that prevent FGF23 being degraded, thereby causing accumulation of intact FGF23 hormone in the circulation. In all three diseases, the elevation in FGF23 results in osteomalacia and rickets by causing phosphaturia by up-regulation of sodium-dependent phosphate transporters in the renal tubules, and also by inhibiting conversion of 25(OH)D to 1,25(OH)<sub>2</sub>D by the kidney, which in turn causes reduced calcium and phosphate absorption from the gut.

### Clinical features

The presentation is with symptoms and signs of rickets during childhood that do not respond to vitamin D supplementation. In adults, hypophosphataemic rickets may be accompanied by dental abscesses, and by bone and joint pain due to the development of an enthesopathy.

### Investigations

The diagnosis can be confirmed by the finding of low serum phosphate levels and a reduction in tubular reabsorption of phosphate. Serum levels of vitamin D are normal and PTH is normal or elevated. Serum concentrations of FGF23 are markedly elevated. The causal mutations can be identified by genetic testing.

### Management

The aim of treatment is to ameliorate symptoms, restore normal growth and maintain serum phosphate levels within the reference range. Traditionally, treatment has been with phosphate supplements (1–4 g daily) and alfacalcidol (1–2  $\mu$ g daily) or calcitriol (0.5–1.5  $\mu$ g daily), with the aim of promoting intestinal calcium and phosphate absorption. Levels of calcium and phosphate, as well as renal function, should be monitored regularly and the doses of phosphate and vitamin D metabolites carefully titrated to maintain serum phosphate within the normal range, but avoid hypercalcaemia. Burosumab is a neutralising antibody to FGF23 which can reverse the biochemical abnormalities in hereditary hypophosphataemic rickets. It is currently licensed for the treatment of XLH in children where it has been shown to be superior to standard therapy with phosphate supplements and active vitamin D metabolites at healing rickets. It is also effective at reversing hypophosphataemia in adults, and trials are currently in progress to examine the effects on clinical outcome of the disease in adults.

## Tumour-induced osteomalacia

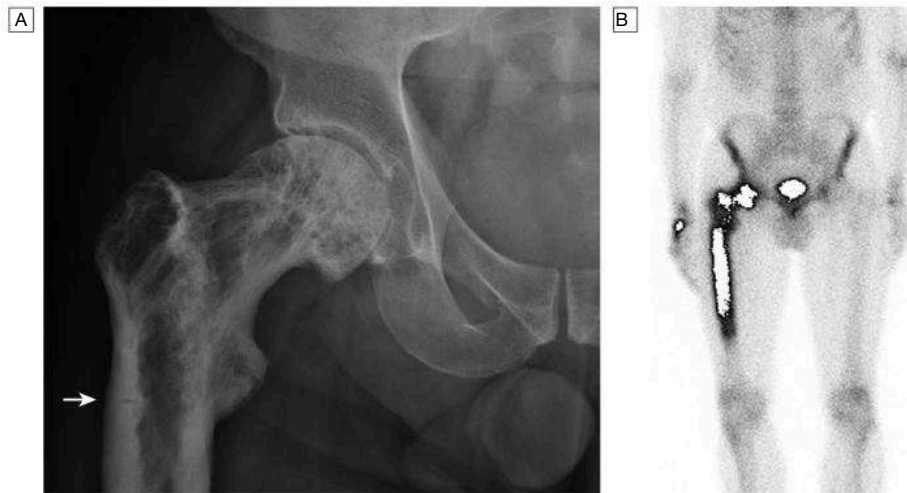

This is a rare syndrome caused by over-production of FGF23 by mesenchymal tumours. The presentation is with severe osteomalacia and hypophosphataemia in an adult patient with no obvious predisposing risk factor for vitamin D deficiency. Biochemical findings are as described for hereditary hypophosphataemic rickets. The underlying tumour can be difficult to find and multiple modality imaging with whole-body MRI, CT and somatostatin or gallium-68 DOTATATE scintigraphy is often needed. Options for medical management include phosphate supplements and active vitamin D metabolites or burosumab, but the treatment of choice is surgical resection of the primary tumour, which is curative.

## Hypophosphatasia

Hypophosphatasia is an autosomal recessive disorder caused by loss-of-function mutations in the *TNALP* gene, which results in accumulation of pyrophosphate and inhibition of bone mineralisation. The typical presentation is with severe intractable rickets during infancy, sometimes in association with seizures. Investigations show low or undetectable levels of serum ALP, but normal levels of calcium, phosphate, PTH and vitamin D metabolites. Urine excretion of pyridoxal 5' phosphate and phosphoethanolamine (substrates for ALP) is increased. In severely affected patients, remarkable therapeutic responses have been obtained with recombinant ALP therapy (asfotase alfa), which is curative. Heterozygous carriers of mutation in *TNALP* may present in adulthood with osteoporosis, fractures and low ALP values. The best mode of treatment for these patients remains to be determined.

## Other causes of osteomalacia

These are summarised in [Box 26.75](#). Osteomalacia may occur as a component of renal osteodystrophy in patients with chronic kidney disease. The mechanism is reduced conversion of 25(OH)D into the active metabolite 1,25(OH)<sub>2</sub>D by the failing kidney. Aluminium intoxication is now rare due to reduced use of aluminium-containing phosphate binders and removal of aluminium from the water supplies used in dialysis. If aluminium intoxication is suspected, the diagnosis can be confirmed by demonstration of aluminium at the calcification front in a bone biopsy. Osteomalacia due to bisphosphonates has mostly been described in patients with Paget's disease who are receiving etidronate and high-dose pamidronate. It is usually asymptomatic and healing occurs when treatment is stopped. Excessive fluoride intake causes osteomalacia due to direct inhibition of mineralisation and is common in parts of the world where there is a high fluoride content in drinking water. The condition reverses when fluoride intake is reduced.

**Fig. 26.64** Paget's disease of bone. **A** X-ray showing Paget's disease of the upper right femur illustrating osteolytic and osteosclerotic bone, a coarsened trabecular pattern and bone expansion with a stress fracture (arrow) visible on the lateral aspect of the femur. **B** Bone scintigraphy from the same patient showing intense tracer uptake in the affected bone.

## Paget's disease of bone

Paget's disease of bone (PDB) is characterised by focal areas of increased and disorganised bone remodelling involving one or more skeletal sites. The disease is common in the UK, affecting about 1% of those aged above 55, and in other countries in Europe. It is rare in Scandinavia and Asia. The prevalence doubles each decade from the age of 50 onwards and affects up to 8% of the UK population by the age of 85.

### Pathophysiology

The primary abnormality is increased osteoclastic bone resorption, accompanied by marrow fibrosis, increased vascularity of bone and increased, but disorganised, bone formation. Osteoclasts in PDB are greater in number and unusually large, containing characteristic nuclear inclusion bodies. Genetic factors are important and mutations in the *SQSTM1* gene are a common cause of classical PDB. The presence of nuclear inclusion bodies in osteoclasts has fuelled speculation that PDB might be caused by a slow virus infection, but this remains unproven. Biomechanical factors may influence which bones are affected, as PDB often starts at sites of muscle insertions into bone and, in some cases, localises to bones or limbs that have been subjected to repetitive trauma or overuse. Involvement of subchondral bone can compromise the joint and predispose to OA. The prevalence of PDB has fallen in many countries over recent decades, suggesting that environmental factors play a role, but their identity remains unclear.

### Clinical features

The axial skeleton is predominantly affected and common sites of involvement are the pelvis, femur, tibia, lumbar spine, skull and scapula. The most common presentation is with bone pain localised to an affected site, but bone deformity, deafness and pathological fractures may also be presenting features. Many patients are asymptomatic and in about 20% of cases the diagnosis is made on the basis of an X-ray or blood test performed for another reason. Clinical signs include bone deformity and expansion, and increased warmth over an affected bone. Neurological problems, such as deafness, cranial nerve defects, nerve root pain, spinal cord compression and spinal stenosis, may occur due to enlargement of affected bones and encroachment on the spinal cord and nerve foramina. Surprisingly, deafness is seldom due to compression of the auditory nerve, but instead is conductive in nature due to osteosclerosis of the temporal bone. The increased vascularity of pagetic bone can very rarely precipitate high-output cardiac failure in older patients with limited cardiac

26.76 Medical management of Paget's disease		
Drug	Route of administration	Dose
Risedronate	Oral	30 mg daily for 2 months
Pamidronate	IV	1–3 × 60 mg infusions
Zoledronic acid	IV	1 × 5 mg infusion
Calcitonin	SC	100–200 IU 3 times weekly for 2–3 months

(IV = intravenous; SC = subcutaneous)

reserve. Osteosarcoma is an unusual but serious complication that presents with increasing pain and swelling of an affected site.

### Investigations

The characteristic features are an isolated elevation in ALP and bone expansion on X-rays, with alternating areas of radiolucency and osteosclerosis (Fig. 26.64A). Levels of ALP can be normal if only a single bone is affected. The best way of identifying affected sites is a radio-nuclide bone scan, which shows increased uptake in affected bones (Fig. 26.64B). If the bone scan is positive, X-rays should be taken to confirm the diagnosis. Bone biopsy is not usually required, but may help to exclude osteosclerotic metastases in cases of diagnostic uncertainty.

### Management

The main indication for treatment with inhibitors of bone resorption is bone pain, which is thought to be due to increased metabolic activity (Box 26.76). Patients should be carefully assessed to determine the cause of the pain since it can be difficult to differentiate the pain caused by increased metabolic activity of PDB from that caused by complications such as bone deformity, nerve compression symptoms and OA. Zoledronic acid is considered the treatment of choice since it is highly effective at suppressing elevated bone turnover in PDB and is most likely to give a favourable pain response. Intravenous pamidronate and oral risedronate can also be effective. If there is doubt about whether the pain is due to PDB, it can be worthwhile giving a therapeutic trial of bisphosphonate to determine whether the symptoms improve. Although there is always the possibility of a 'placebo effect', a positive response usually indicates that the pain was due to increased metabolic activity. Repeated courses of bisphosphonates can be given if symptoms recur. There is not any firm evidence as yet to suggest

that prophylactic bisphosphonates prevent the development of complications in PDB, but this issue is under investigation.

## Other bone diseases

### Complex regional pain syndrome type 1

Complex regional pain syndrome (CRPS) type 1 is characterised by gradual onset of pain, swelling and local tenderness, usually affecting a limb extremity. It may be triggered by fracture, but can also occur in association with soft tissue injury, pregnancy and intercurrent illness or can develop spontaneously. The cause is unknown, but abnormalities of the sympathetic nervous system are thought to play a pathogenic role. The affected limb is swollen and tender, and there may be evidence of regional autonomic dysfunction with abnormal sweating and changes in skin colour and temperature. The diagnosis is primarily clinical, based on the features shown in Box 8.12. Support for the diagnosis can be obtained with MRI, which shows bone marrow oedema, or radionuclide bone scan, which shows a local increase in tracer uptake. X-rays typically show localised patchy osteoporosis. Haematology, biochemistry and immunology are normal.

The aims of treatment are to control pain and encourage mobilisation. Analgesics, NSAIDs, antineuropathic agents, calcitonin, glucocorticoids,  $\beta$ -adrenoceptor antagonists ( $\beta$ -blockers), sympathectomy and bisphosphonates have all been tried, but none is particularly effective. Although some cases resolve with time, many individuals have persistent symptoms and fail to regain normal function.

### Osteonecrosis

Osteonecrosis is the term used to describe death of bone due to impairment of its blood supply. The most commonly affected sites are the femoral head, humeral head, navicular and scaphoid. In some cases, the condition occurs as the result of direct trauma that interrupts the blood supply to the affected bone. This is the reason for osteonecrosis of the femoral head following fractures of the femoral neck and in patients with thrombophilia, antiphospholipid syndrome, Gaucher's disease and haemoglobinopathies, such as sickle cell disease. Other important predisposing factors include high-dose glucocorticoid treatment, alcohol excess, SLE, HIV and radiotherapy, but in many of these conditions the pathophysiology is poorly understood. The presentation is with pain localised to the affected site, which is exacerbated by weight-bearing. The diagnosis can be confirmed by MRI, which shows evidence of subchondral necrotic bone and bone marrow oedema. X-rays are normal in the early stages, but later may show evidence of osteosclerosis and deformity of the affected bone. There is no specific treatment. Management should focus on controlling pain and encouraging mobilisation. Symptoms often improve spontaneously with time, but joint replacement may be required in patients who have persisting pain in association with significant structural damage to the affected joint.

### Scheuermann's osteochondritis

This disorder predominantly affects adolescent boys, who develop a dorsal kyphosis in association with irregular radiographic ossification of the vertebral end plates. It has a strong genetic component and may sometimes be inherited in an autosomal dominant manner. Most patients are asymptomatic, but back pain aggravated by exercise and relieved by rest may occur. Excessive exercise and heavy manual labour before epiphyseal fusion has occurred may aggravate symptoms. Management consists of advice to avoid excessive activity and provision of protective postural exercises. Rarely, corrective surgery may be required if there is severe deformity. Scheuermann's disease can sometimes present for the first time in adulthood, when it can be confused with osteoporotic vertebral fractures. It can be differentiated from osteoporosis by the characteristic X-ray changes, which show mild wedge deformity of 3–4

adjacent vertebrae, irregularity of the vertebral end plates, and normal BMD on DXA examination.

### Fibrous dysplasia

This is an acquired systemic disorder that mainly affects the skeleton and is caused by somatic mutations in the *GNAS1* gene. The characteristic presentation is with bone pain and pathological fractures. Associated features include endocrine dysfunction, especially precocious puberty, and café-au-lait skin pigmentation (McCune–Albright syndrome). The diagnosis can usually be made by imaging, which shows focal, predominantly osteolytic lesions with bone expansion on X-rays (Fig. 26.65), and focal increased uptake on bone scan. The condition may cause a single (monostotic) or multiple (polyostotic) lesions. The condition can superficially resemble Paget's disease of bone, but the earlier age of onset and pattern of involvement are usually distinctive. Very rarely, malignant change can occur and should be suspected if there is a sudden increase in pain and swelling. Management is symptomatic. Intravenous bisphosphonates are often used in an attempt to control pain, but the evidence base for their efficacy is weak. Orthopaedic surgery may be required for treatment of fracture and deformity or to prevent a pathological fracture in a weight-bearing bone. Endocrine manifestations, such as precocious puberty, may require specific treatment.

### Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is the name given to a group of disorders characterised by severe osteoporosis and multiple fractures in infancy and childhood. Most cases are caused by mutations in the *COL1A1* and *COL1A2* genes, which encode the proteins that make type I collagen. These result in reduced collagen production (in mild OI) or in formation of abnormal collagen chains that are rapidly degraded (in severe OI). Mutations in several other genes have been described that can cause OI, some of which affect post-translational modification of collagen and

**Fig. 26.65 Fibrous dysplasia.** X-ray of the right humerus in a patient with polyostotic fibrous dysplasia showing multiple expansile osteolytic lesions and a pathological fracture in the humeral mid-shaft (arrowed).

others that affect bone formation. Many patients have no family history. Some of these have new mutations whereas others may have recessive forms of the disease. The Silience classification is commonly used to grade severity. This varies from neonatal lethal OI (type II), through very severe OI with multiple fractures in infancy and childhood (types III and IV), to mild (type I), in which affected patients typically have blue sclerae. The diagnosis of OI is usually obvious clinically, based on the presentation with multiple low-trauma fractures during infancy. The disease can be mistaken for non-accidental injury in childhood and for osteoporosis in adulthood; in such cases, genetic testing can be of diagnostic value. Treatment is multidisciplinary, involving surgical reduction and fixation of fractures and correction of limb deformities, with physiotherapy and occupational therapy for rehabilitation of patients with bone deformity. Bisphosphonates are widely used in the treatment of OI, especially intravenous pamidronate and zoledronic acid in children, but there is limited evidence for efficacy in fracture prevention.

## Osteopetrosis

Osteopetrosis is the collective name given to a rare group of inherited diseases caused by failure of osteoclast function. Presentation is highly variable, ranging from a lethal disorder that presents with bone marrow failure in infancy to a milder and sometimes asymptomatic form that presents in adulthood. Severe osteopetrosis is inherited in an autosomal recessive manner and presents with failure to thrive, delayed dentition, cranial nerve palsies (due to absent cranial foramina), blindness, anaemia and recurrent infections due to bone marrow failure. The adult-onset type (Albers-Schönberg disease) shows autosomal dominant inheritance and presents with bone pain, cranial nerve palsies, osteomyelitis, OA or fracture; it is sometimes detected as an incidental radiographic finding. The responsible mutations affect either the genes that regulate osteoclast differentiation (*RANK*, *RANKL*), causing 'osteoclast-poor' osteopetrosis, or the genes involved in bone resorption, causing 'osteoclast-rich' osteopetrosis. These include mutations in the *TCIRG1* gene, which encodes a component of the osteoclast proton pump, and mutations in the *CLCN7* gene, which encodes the osteoclast chloride pump. The most effective treatment is bone marrow transplantation that can provide a source of osteoclasts that resorb bone normally, but this is not effective in patients with *RANKL* mutations. Medical management has generally limited efficacy, but IFN $\gamma$  treatment may improve blood counts and reduce the frequency of infections.

## Sclerosing bone dysplasias

These are rare diseases characterised by osteosclerosis and increased bone formation. Van Buchem disease and sclerosteosis are recessive disorders caused by loss-of-function mutations in the *SOST* gene, which normally suppresses bone formation (see Fig. 26.3). The resulting lack of functional sclerostin causes increased bone formation and bone overgrowth, leading to enlargement of the cranium and jaw, tall stature and cranial nerve palsies. There is no effective treatment. High bone mass syndrome is a benign disorder caused by mutations in the *LRP4* or *LRP5* gene, which is characterised by unusually high bone density. The mutations render the LRP receptors resistant to the inhibitory effects of SOST. Most patients are asymptomatic, but bone overgrowth in the palate (torus palatinus) and enlargement of the mandible can occur in later life. Treatment is not usually required. Camurati-Engelmann disease is an autosomal dominant condition caused by gain of function in the *TGFB1* gene. It presents with bone pain, muscle weakness and osteosclerosis mainly affecting the diaphysis of long bones. Glucocorticoids can help the bone pain, although usually analgesics are also required.

## Bone and joint tumours

Primary tumours of bones and joints are rare, have a peak incidence in childhood and adolescence, and can be benign or malignant

### 26.77 Primary tumours of the musculoskeletal system

Cell type	Benign	Malignant
Osteoblast	Osteoid osteoma	Osteosarcoma
Chondrocyte	Chondroma Osteochondroma	Chondrosarcoma
Fibroblast	Fibroma	Fibrosarcoma
Bone marrow cell	Eosinophilic granuloma	Ewing's sarcoma
Endothelial cell	Haemangioma	Angiosarcoma
Osteoclast precursor	Giant cell tumour	Malignant giant cell tumour

(Box 26.77). Paget's disease of bone accounts for most cases of osteosarcoma occurring above the age of 40.

## Osteosarcoma

This is a rare tumour with an incidence of 0.6–0.85 per 100 000 population. It is the most common primary bone tumour. Most patients present under the age of 30, but osteosarcoma also occurs in old age in association with Paget's disease. The presentation is with local pain and swelling. X-rays show expansion of the bone with a surrounding soft tissue mass, often containing islands of calcification. If the diagnosis is being considered, MRI or CT should be performed to determine the extent of tumour. Patients suspected of having osteosarcoma should be referred to a specialist team for biopsy. Treatment depends on histological type, but generally involves surgical removal of the tumour, followed by chemotherapy and radiotherapy. The prognosis is normally good in cases that present in childhood and adolescence, but poor in older patients.

## Chondrosarcoma

This is the second most common primary bone tumour. Presentation is as described for osteosarcoma. The treatment of choice is surgical resection since chondrosarcomas are relatively resistant to chemotherapy and radiotherapy. The prognosis is good for low-grade tumours, but poor for anaplastic tumours.

## Ewing's sarcoma

This is the third most common sarcoma, which presents almost exclusively under the age of 40. Presentation is as described for osteosarcoma. Treatment is by local excision and surgical resection. The prognosis is excellent for patients who present before metastasis has occurred.

## Metastatic bone disease

Metastatic bone disease may present in a variety of ways: with localised or generalised progressive bone pain, generalised regional pain, symptoms of spinal cord compression, or acute pain due to pathological fracture. Systemic features, such as weight loss and anorexia, and symptoms referable to the primary tumour are often present. The tumours that most commonly metastasise to bone are myeloma and those of bronchus, breast, prostate, kidney and thyroid. Management is discussed in Chapter 7.

## Rheumatological involvement in other diseases

Many systemic diseases can affect the locomotor system and many drugs may cause adverse musculoskeletal effects (Box 26.78). The most

common examples are described here. Bone disease may also occur in sarcoidosis, haemophilia and sickle-cell anaemia.

## Malignant disease

Malignant disease can cause a variety of non-metastatic musculoskeletal problems (Box 26.79). One of the most striking is hypertrophic pulmonary osteoarthropathy (HPOA), characterised by clubbing and painful swelling of the limbs, periosteal new bone formation and arthralgia/arthritis. The most common causes are bronchial carcinoma and mesothelioma. Bone scans show increased periosteal uptake before new bone is apparent on X-ray. The course follows that of the underlying malignancy and HPOA resolves if this is cured.

## Endocrine disease

Hypothyroidism may present with carpal tunnel syndrome or, rarely, with painful, symmetrical proximal myopathy and muscle hypertrophy. Both resolve with levothyroxine replacement. Primary hyperparathyroidism is associated with osteoporosis and also predisposes to CPPD disease and to calcific peri-arthritis, especially in patients with renal disease.

Diabetes mellitus commonly causes diabetic cheirarthropathy, characterised by tightening of skin and periarticular structures, causing flexion deformities of the fingers that may be painful. Diabetic osteopathy presents as forefoot pain with radiographic progression from osteopenia to complete osteolysis of the phalanges and metatarsals. Diabetes also predisposes to osteoporosis, fragility fractures, adhesive capsulitis, Dupuytren's contracture, osteomyelitis, septic arthritis and Charcot's joints.

Acromegaly can be associated with mechanical back pain, with normal or excessive movement; carpal tunnel syndrome; Raynaud's syndrome and an arthropathy (50%). This arthropathy mainly affects the large joints and has clinical similarities to OA, but with a normal or increased range of movement. X-rays may show widening of joint spaces, squaring of bone ends, generalised osteopenia and tufting of terminal phalanges. It does not improve with treatment of the acromegaly and is an important cause of reduced quality of life in affected individuals.

## Haematological disease

Haemochromatosis is complicated by an arthropathy in about 50% of cases. It typically presents between the ages of 40 and 50 and may predate other features of the disease. The small joints of the hands and wrists are typically affected but the hips, shoulders and knees may also be involved. The X-ray changes resemble OA, but cysts are often multiple and prominent with little osteophyte formation. Involvement of the radiocarpal and MCP joints may occur, which is unusual in primary OA, and about 30% have CPPD. Treatment of the haemochromatosis does not influence the arthropathy and management is as described for OA. Haemophilia can be complicated by haemarthrosis, which, if recurrent, can result in the development of secondary OA. Sickle-cell disease may be associated with bone pain, osteonecrosis and osteomyelitis. Thalassaemia may be complicated by bone deformity, especially affecting the craniofacial bones, and by osteoporosis.

## Neurological disease

Neurological disease may result in rapidly destructive arthritis of joints, first described by Charcot in association with syphilis. The cause is incompletely understood, but may involve repetitive trauma as the result of sensory loss and altered blood flow secondary to impaired sympathetic nervous system control. The main predisposing diseases and sites of involvement are:

- diabetic neuropathy (hindfoot)
- syringomyelia (shoulder, elbow, wrist)
- leprosy (hands, feet)
- tabes dorsalis (knees, spine).

## 26.78 Drug-induced effects on the musculoskeletal system

Musculoskeletal problem	Principal drug
Secondary gout	Thiazides, furosemide, alcohol
Osteoporosis	Glucocorticoids, heparin, glitazones, aromatase inhibitors, GnRH agonists
Osteomalacia	Anticonvulsants, etidronate and pamidronate (high-dose)
Osteonecrosis	Glucocorticoids, alcohol
Drug-induced lupus syndrome	Procainamide, hydralazine, isoniazid, chlorpromazine, minocycline, anti-TNF- $\alpha$ biologics
Arthralgias	Glucocorticoid withdrawal, glibenclamide, methyldopa, ciclosporin, isoniazid, barbiturates, bisphosphonates, aromatase inhibitors
Myalgia	Glucocorticoid withdrawal, L-tryptophan, fibrates, statins
Myopathy/myositis	Glucocorticoids, chloroquines, penicillamine, statins, zidovudine, colchicine, fibrates, alcohol
Arthritis	Immune checkpoint inhibitors (ICIs)
Vasculitis	Penicillins, cephalosporins, sulphonamides, thiazides, phenytoin, allopurinol

(ACTH = adrenocorticotropic hormone; GnRH = gonadotrophin-releasing hormone)

## 26.79 Rheumatological manifestations of malignancy

- Polyarthritis
- Dermatomyositis and polymyositis
- Hypophosphataemic osteomalacia
- Hypertrophic osteoarthropathy
- Vasculitis, connective tissue disease
- Raynaud's syndrome
- Polymyalgia rheumatica-like syndrome

The presentation is with subacute or chronic monoarthritis. Pain can occur, especially at the onset, but once the joint is severely deranged, pain is often minimal and signs become disproportionately greater than symptoms. The joint is often grossly swollen, with effusion, crepitus, marked instability and deformity, but usually no increased warmth. X-rays show disorganisation of normal joint architecture and often multiple loose bodies (Fig. 26.66), and either no (atrophic) or gross (hypertrophic) new bone formation. Management principally involves orthoses and occasionally arthrodesis.

## Miscellaneous conditions

### Anterior tibial compartment syndrome

This is characterised by severe pain in the front of the lower leg, aggravated by exercise and relieved by rest. Symptoms result from fascial compression of the muscles in the anterior tibial compartment and may be associated with foot drop. Treatment is by surgical decompression.

### Carpal tunnel syndrome

This is a common nerve entrapment syndrome caused by compression of the median nerve at the wrist. It presents with numbness, tingling

**Fig. 26.66** Wrist X-ray showing a neuropathic (Charcot) joint in a patient with syringomyelia. Note the disorganised architecture with complete loss of the proximal carpal row, bony fragments and soft tissue swelling.

and pain in a median nerve distribution. The most common causes are hypothyroidism, diabetes mellitus, rheumatoid arthritis, obesity and pregnancy (especially in the third trimester). In some patients, no underlying cause may be identified. Carpal tunnel syndrome often responds to treatment of the underlying condition, but other options include local glucocorticoid injections and surgical decompression.

### Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a common disorder, affecting 10% of men and 8% of women over the age of 65, but its prevalence increases further with age and is associated with obesity, hypertension and type 2 diabetes mellitus. It is characterised by syndesmophytes and florid new bone formation along the anterolateral aspect of contiguous vertebral bodies (Fig. 26.67). DISH is distinguished from lumbar spondylosis by the absence of disc space narrowing and marginal vertebral body sclerosis, and from ankylosing spondylitis by the absence of sacroiliitis or apophyseal joint fusion. It is usually an asymptomatic radiographic finding, but can cause back pain or pain at peripheral sites, such as the heel, in association with enthesophyte formation.

### Dupuytren's contracture

Dupuytren's contracture is characterised by fibrosis and contracture of the superficial palmar fascia of the hands. The patient is unable to extend the fingers fully and there is puckering of the skin with palpable nodules. The ring and little fingers are usually the first and worst affected. Dupuytren's contracture is usually painless, but causes problems due to limitation of hand function and snagging of the curled fingers in pockets. It is age-related, usually bilateral and more common in men. There is a strong genetic component and sometimes may be familial, with dominant inheritance. The condition can be associated with plantar fibromatosis, Peyronie's disease, alcohol misuse and chronic vibration injury. It is very slowly progressive. Often no treatment is required, but it can be treated medically by local injections of collagenase or surgically by fasciotomy if symptoms are troublesome.

### Joint hypermobility

Joint hypermobility is caused by increased laxity of connective tissues. It is commonly observed in a number of hereditary conditions including: Marfan syndrome, which arises from mutations in the *FBN1* gene; osteogenesis imperfecta and Ehlers–Danlos syndrome types I, II and IV, caused by mutations in the *COL3A1*, *COL5A1* and *COL5A2* genes.

**Fig. 26.67** Diffuse idiopathic skeletal hyperostosis (DISH). Anteroposterior X-ray of the thoracic spine showing right-sided, flowing new bone joining contiguous thoracic vertebrae. The disc spaces are preserved.

### 26.80 Modified Beighton score for joint hypermobility

Clinical test	Score
Extend little finger > 90°	1 point each side
Bring thumb back parallel to/touching forearm	1 point each side
Extend elbow > 10°	1 point each side
Extend knee > 10°	1 point each side
Touch floor with flat of hands, legs straight	1 point
Hypermobile = a score of 6 or more points out of a possible 9 for epidemiological studies, or 4 or more points (with arthralgia in four or more joints) for a clinical diagnosis of the benign joint hypermobility syndrome	

The term hypermobile Ehlers–Danlos syndrome (hEDS), which is also known as EDS type III, is used to describe a polygenic form of joint hypermobility. Patients with this condition have hypermobile joints in combination with a range of symptoms such as chronic joint and ligamentous pain, fibromyalgia-like symptoms, recurrent dislocations, easy bruising, abdominal symptoms, insensitivity to local anaesthetic, mitral valve prolapse and postural orthostatic tachycardia syndrome (POTS), in which there is dizziness, hypotension and an increased heart rate on standing. The diagnosis of hEDS can be made if the modified Beighton score is 4 or above (Box 26.80) in the presence of one or more of the above clinical features. It is useful to distinguish hEDS from the milder hypermobility spectrum disorder (HSD), which is the name given to the syndrome where joint hypermobility is accompanied by some, but not all, features of hEDS.

### Inclusion body myositis

Inclusion body myositis (IBM) is the most frequent primary myopathy in middle age and after. It is characterised by slowly progressive muscle weakness and atrophy, with pathological changes of inflammation, degeneration and mitochondrial abnormality in affected muscle fibres. IBM typically presents with distal muscle weakness. In time, muscles atrophy. Investigation is the same as for polymyositis. There is typically a slightly elevated creatine kinase and myopathic changes on EMG.

Muscle biopsy shows abnormal fibres containing rimmed vacuoles and filamentous inclusions in the nucleus and cytoplasm. Therapeutic response to glucocorticoids and immunosuppressants is poor. There is anecdotal report of efficacy with IVIg, but trial evidence is lacking.

### Pigmented villonodular synovitis

Pigmented villonodular synovitis is an uncommon proliferative disorder of synovium, which typically affects young adults. It is caused by a somatic chromosomal translocation in synovial cells that places the *CSF1* gene downstream of the *COL6A3* gene promoter. The result is local over-production of M-CSF, which causes accumulation of macrophages in the joint. The presentation is with joint swelling, limitation of movement and local discomfort. The diagnosis can be confirmed by MRI or synovial biopsy. Treatment is by surgical or radiation synovectomy.

### Scoliosis

Scoliosis is characterised by an abnormal lateral curvature of the spine of greater than 10 degrees. Scoliosis may be secondary to known disorders or idiopathic. In about 20% of cases, scoliosis is secondary to a neuromuscular disorder, such as muscular dystrophy, cerebral palsy or neurofibromatosis. It may also occur in association with hereditary connective tissue diseases, such as Marfan syndrome. Scoliosis may also develop in later life, usually as a result of structural changes in the spine from degenerative change. The term idiopathic scoliosis is used to describe the remaining cases where there is no obvious cause. In fact, there is strong evidence from twin studies that idiopathic scoliosis is genetically mediated, in keeping with the finding that it is evident during childhood or adolescence. It is often asymptomatic, but it can persist into adulthood and may become symptomatic, associated with evolving degenerative changes.

The diagnosis of scoliosis can be made clinically by physical examination and confirmed by X-ray. External bracing and/or surgical intervention are considered in adolescents with severe deformities to correct deformity or prevent progression, but the evidence base is poor. In adulthood, treatment is symptomatic in nature with analgesics, NSAIDs or antineuropathic medications.

### Spondylolysis

Spondylolysis describes a break in the integrity of the vertebral neural arch. The principal cause is an acquired defect in the pars interarticularis due to a fracture, mainly seen in gymnasts, dancers and runners, in whom it is an important cause of back pain. Spondylolisthesis describes the condition in which a defect causes slippage of a vertebra on the one below. This may be congenital, post-traumatic or degenerative. Rarely, it can result from metastatic destruction of the posterior elements. Uncomplicated spondylolysis does not cause symptoms, but spondylolisthesis can lead to low back pain aggravated by standing and walking. Occasionally, symptoms of nerve root or spinal compression may occur. The diagnosis can be made on oblique X-rays of the lumbar spine, but MRI may be required if there is neurological involvement. Advice on posture and muscle-strengthening exercises is required in mild cases. Surgical fusion is indicated for severe and recurrent low back pain. Surgical decompression is mandatory prior to fusion in patients with significant lumbar stenosis or symptoms of cauda equina compression.

### Chronic non-infectious osteomyelitis

Chronic non-infectious osteomyelitis (CNO) is characterised by pain, swelling and osteosclerosis of affected bones. It may target a single bone or multiple bones when it is called chronic recurrent multifocal osteomyelitis (CRMO). The conditions can occur in the absence of other features or be part of the synovitis–acne–pustulosis–hyperostosis–osteitis (SAPHO) syndrome. These disorders often target the clavicles and bones of the anterior chest wall but other bones may be affected, including the

mandible and lower limb bones. SAPHO syndrome may be part of a spectrum of autoinflammatory bone disease that includes chronic recurrent (sterile) multifocal osteomyelitis in children and adolescents. Other features of SAPHO include a pustular rash affecting the palms and soles of the feet, enthesitis, spondylodiscitis, sacroiliitis and synovitis of peripheral joints. These disorders tend to present in children or young adults. Radionuclide bone scans show increased uptake in affected bones with osteosclerosis and bone expansion on X-rays and CT scans. Various treatments have been used, including glucocorticoids, DMARDs, bisphosphonates, anakinra and anti-TNF- $\alpha$ , with most success arising from biologic use. The cause is unknown, but has been suggested to be an autoinflammatory process triggered by a micro-organism.

### Trigger finger

This occurs as the result of stenosing tenosynovitis in the flexor tendon sheath, with intermittent locking of the finger in flexion. It can arise spontaneously or in association with inflammatory diseases such as RA. Symptoms usually respond to local glucocorticoid injections, but surgical decompression is occasionally required.

## Multiple Choice Questions

- 26.1. Which of the following statements about classical disease modifying antirheumatic drugs (cDMARDs) are true?
- A. Leflunomide has a short half-life and clears from the body quickly when it is stopped
  - B. Sulfasalazine stains contact lenses yellow
  - C. A patient's thiopurine S-methyltransferase (TPMT) genetic polymorphism should be checked before prescribing mycophenolate mofetil
  - D. Systemic glucocorticoids can cause a rebound psoriasis flare when stopped after a treatment course for psoriatic arthritis
  - E. Methotrexate is safe to take throughout pregnancy

Answer: B and D.

A is *False* – leflunomide has a long half and takes many months to clear from the body when stopped. Excretion of leflunomide can be expedited by a short course of cholestyramine. B is *True* – urine can be yellow-stained also. C is *False* – TPMT is checked before azathioprine is prescribed. 1 in 300 people have a homozygous TPMT allele genotype which leads to very slow drug metabolism, which increases the risk of azathioprine toxicity markedly. D is *True*. E is *False* – methotrexate needs to be stopped 3 months before conception.

- 26.2. Which of the following statements about biologic disease-modifying antirheumatic drugs (bDMARDs/'biologics') are true?
- A. Biologics are carcinogenic
  - B. Ustekinumab is an antibody to p40, which is a subunit shared by the cytokines IL-23 and IL-12. It acts as an inhibitor of both IL-12 and IL-23 signalling and is indicated in adults with psoriatic arthritis
  - C. Like all anti-TNF- $\alpha$  therapies, etanercept can be used in axial spondyloarthritis patients to also control associated Crohn's disease
  - D. All anti-TNF- $\alpha$  bDMARDs should be stopped in the third trimester since they all cross the placenta and can cause immunosuppression in the neonate
  - E. In ANCA-positive vasculitis, a single cycle of rituximab (anti-CD20) treatment may last for up to 18 months

Answer: B and E.

A is *False* – biologics are not carcinogenic, but patients who develop cancer while on treatment may exhibit accelerated progression of the tumour due to suppression of the immune response. B is *True*. C is *False* – anti-TNF- $\alpha$  therapies generally are effective in enteropathic arthritis, but etanercept should be avoided as it has no efficacy in IBD. D is *False* – most should be stopped but an exception is certolizumab, which does not cross the placenta and can be used safely throughout pregnancy. E is *True*.

- 26.3. In general, infections that affect the musculoskeletal system are not common but their effects can be severe. Which of the following statements about infections are true?
- A. Overall the risk of death from septic arthritis is 1%
  - B. Gonococcal septic arthritis is generally a polyarthritis
  - C. Diabetes is a particularly important risk factor for osteomyelitis, accounting for about 30% of cases
  - D. Where TB of a joint is suspected fluid should be drawn and analysed by microscopy, culture and PCR
  - E. Spine involvement (Poncet's disease) is rare in cases of musculoskeletal TB

Answer: C and D.

A is *False* – overall, septic arthritis still has a mortality of about 10% despite advances in antimicrobial therapy. B is *False* – gonococcal infection can present with a migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of an oligo- or monoarthritis. Painful pustular skin lesions may also be present. C is *True*. D is *True* – culture of synovial fluid is positive in between 20% and 40% of cases, but examination of synovial fluid or synovial tissue by PCR can yield the diagnosis more rapidly, with positive results in more than 95% of culture-positive cases and 50%–60% of culture-negative cases. E is *False* – Poncet's disease occurs in about 50% of cases of musculoskeletal TB.

## Clinical examination in skin disease

### 8 Detailed morphology of individual lesions

Use a magnifying lens in good lighting to assist  
Use correct terminology (see definitions throughout text)

▲ Magnifying lens image of benign naevus

▲ Palmoplantar pustulosis

### 7 Overall description of individual lesions

Discrete, grouped, confluent, reticulate (lace-like), linear

### 6 Morphology of rash

Monomorphic or polymorphic

### 5 Involvement of axillae/groins

e.g. hidradenitis suppurativa

### 4 Nail involvement

▲ Psoriatic changes in nails and peri-ungual involvement

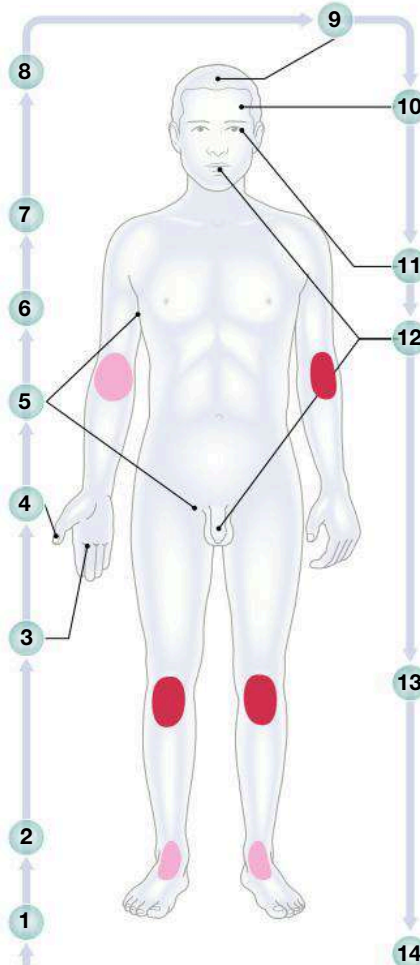

### 3 Involvement of hands, including nail folds and finger webs

### 2 If symmetrical

- Extensor, e.g. psoriasis
- Flexor, e.g. eczema

### 1 Distribution of rash

Symmetrical vs asymmetrical  
Proximal vs distal vs facial  
Localised vs widespread

#### Observation

The patient must be undressed, with make-up and dressings removed, and examined in good lighting. Consider the following:

- Age
- General health
- Distress
- Scratching

### 9 Examination of scalp

Hair loss  
Scalp changes

▲ Alopecia areata

### 10 Involvement of face

Central  
Hairline  
Cheeks and nasal bridge: 'butterfly' distribution  
Sparing of light-protected sites, e.g. behind ears, under chin

### 11 Eye involvement

e.g. Conjunctivitis/blepharitis in rosacea or eyelash loss in alopecia areata

### 12 Oral and genital involvement

▲ Reticulate (lacy) network on buccal mucosa in lichen planus. May also be genital involvement

### 13 Joint involvement

e.g. Psoriatic arthritis

▲ Arthritis, plaque psoriasis and psoriatic nail dystrophy

### 14 General medical examination

Including lymph nodes and other systems as indicated

It is tempting to examine the skin first. This is a mistake; take a history, then examine the skin and the rest of the patient.

**1. History-taking    2. Drug/allergy history    3. Examination of skin    4. Closer inspection    5. General examination**

Include:

- Onset and course
- Exacerbating/relieving factors
- Past history of skin disease, atopy or autoimmune disease
- Social history, occupation, recreation
- Psychological impact, gauged by health-related life quality indices
- Always take a detailed drug and allergy history
- Include all systemic and topical drugs, and over-the-counter preparations
- Examine skin, hair, nails and mucous membranes
- Is it a rash or a lesion?
- Distribution and morphology important for rash
- Use of a magnifying lens and/or dermatoscope may be invaluable
- Site, size and detailed morphology of a lesion are essential factors to elicit
- General examination, incl. peripheral lymph nodes, may be indicated/important
- Skin diseases may have systemic features (e.g. cardiovascular disease in psoriasis); many systemic diseases have dermatological features (e.g. diabetes)

**6. Define type of lesion using correct terminology**

Helps in differential diagnosis and allows colleagues to visualise the process. Other definitions are provided in the chapter.

<p><b>Macule/patch</b></p>  <p>Macule: circumscribed flat area of colour change <math>\leq 1</math> cm diameter; patch: <math>&gt; 1</math> cm</p>	<p><b>Papule</b></p>  <p>Discrete elevation <math>\leq 1</math> cm diameter</p>	<p><b>Nodule</b></p>  <p>Like papule but deeper (into dermis or subcutaneous layer), with flat top <math>&gt; 1</math> cm diameter</p>	<p><b>Plaque</b></p>  <p>Raised area <math>&gt; 1</math> cm diameter</p>
<p><b>Vesicle</b></p>  <p>Small (<math>\leq 1</math> cm diameter) fluid-filled blister</p>	<p><b>Blisters/bullae</b></p>  <p>Large (<math>&gt; 1</math> cm diameter) fluid-filled blister</p>	<p><b>Pustule</b></p>  <p>Visible accumulation of pus in blister</p>	<p><b>Petechiae/purpura</b></p>  <p>Petechiae: tiny macules due to extravascular blood in dermis; purpura: larger, may be palpable</p>

**7. Score activity**

Tools for objective assessment of disease severity, such as the Psoriasis Area and Severity Index (PASI), are important in assessing severity and treatment responses.

Four body parts are each scored individually

(A) Each of the four body parts is scored:

Redness (erythema)	0-4
Thickness (induration)	0-4
Scaling (desquamation)	0-4

(B) The area of each involved body part is scored:

0	0%
1	$< 10\%$
2	10-29%
3	30-49%
4	50-69%
5	70-89%
6	90-100%

(C) 10%    20%    30%    40%

To find the PASI score, add together: (A) Sum for each part  $\times$  (B) % of that part involved  $\times$  (C) % weighting of that body part  
 Minimum = 0; maximum = 72

Diseases affecting the skin are common, and important because the absence of normal skin function, as well as sometimes being life-threatening, can severely impair quality of life. This may be exacerbated by the fact that people with skin disease can suffer the effects of stigma, often brought about by the ill-informed understanding of others with respect to skin diseases, particularly as regards visually disfiguring skin changes or the belief that they are contagious.

Skin diseases affect all ages and there are more than 2000 different types and presentations. Assessment of the skin is valuable in the management of anyone presenting with a medical problem and, conversely, assessment of the other body systems is important when managing primary skin diseases. This chapter concentrates on common skin diseases and those that are important components of general medical conditions. Skin infections, including those related to the human immunodeficiency virus (HIV), tuberculosis, leprosy (Hansen's disease) and syphilis, are also discussed in [Chapters 14, 17, 13 and 15](#), respectively.

## Functional anatomy and physiology

The skin covers just under 2m<sup>2</sup> in the average adult. The outer layer is the epidermis, a stratified squamous epithelium consisting mainly of keratinocytes. The epidermis is attached to, but separated from, the underlying dermis by the basement membrane. The dermis is less cellular and supports blood vessels, nerves and epidermal-derived appendages (hair follicles and sweat glands). Below it is the subcutis, consisting of adipose tissue.

### Epidermis

In most sites, the epidermis is only 0.1–0.2mm thick, except on the palms or soles, where it can extend to several millimetres. Keratinocytes make up approximately 90% of epidermal cells ([Fig. 27.1](#)). The main proliferative compartment is the basal layer. Keratinocytes synthesise a range of structural proteins, such as keratins, loricrin and filaggrin (filament aggregating protein), which play key roles in maintaining the skin's barrier function. Keratinocytes are also responsible for synthesis of vitamin D under the influence of ultraviolet B (UVB) light. There are more than 50 types of keratin and their expression varies by body site, site within the epidermis and disease state. Mutations of certain keratin genes can result in blistering disorders and ichthyosis (characterised by scale without major inflammation). As keratinocytes migrate from the basal layer, they differentiate, producing a variety of protein and lipid products. Keratinocytes undergo apoptosis in the granular layer before losing their nuclei and becoming the flattened corneocytes of the stratum corneum (keratin layer). The epidermis is a site of lipid production, and the ability of the stratum corneum to act as a hydrophobic barrier is the result of its 'bricks and mortar' design; dead corneocytes with highly cross-linked protein membranes ('bricks') lie within a metabolically active lipid layer synthesised by keratinocytes ('mortar'). Terminal differentiation of keratinocytes relies on the keratin filaments being aggregated and this is, in part, mediated by filaggrin. Mutations of the filaggrin gene are found in ichthyosis vulgaris and in some patients with atopic eczema.

The skin is a barrier against physical stresses and infections. Cell-to-cell attachments must be able to transmit and dissipate stress, a function performed by desmosomes. Diseases that affect desmosomes, such as pemphigus, result in blistering due to keratinocyte separation.

The remaining 10% of epidermal cells are:

- *Langerhans' cells*: these are dendritic, bone marrow-derived cells that circulate between the epidermis and local lymph nodes. Their prime function is antigen presentation to lymphocytes. Other dermal antigen-presenting dendritic cells are also present.
- *Melanocytes*: these occur predominantly in the basal layer and are of neural crest origin. They synthesise the pigment melanin from

tyrosine, package it in melanosomes and transfer it to surrounding keratinocytes via their dendritic processes.

- *Merkel cells*: these occur in the basal layer and are thought to play a role in signal transduction of fine touch. Their embryological derivation is unclear.

### Basement membrane

The basement membrane (see [Fig. 27.1](#)) is an anchor for the epidermis and allows movement of cells and nutrients between dermis and epidermis. The cell membrane of the epidermal basal cell is attached to the basement membrane via hemi-desmosomes. The lamina lucida lies immediately below the basal cell membrane and is composed predominantly of laminin. Anchoring filaments extend through the lamina lucida to attach to the lamina densa. This electron-dense layer consists mostly of type IV collagen; from it extend loops of type VII collagen, forming anchoring fibrils that fasten the basement membrane to the dermis.

### Dermis

The dermis is vascular and supports the epidermis structurally and nutritionally. It varies in thickness from just over 1mm on the inner forearm to 4mm on the back. Fibroblasts are the predominant cells but others include mast cells, mononuclear phagocytes, T lymphocytes, dendritic cells, neurons and endothelial cells. The acellular part of the dermis consists mainly of collagen I and III, elastin and reticulin, synthesised by fibroblasts. Support is provided by an amorphous ground substance (mostly glycosaminoglycans, hyaluronic acid and dermatan sulphate), whose production and catabolism are altered by hormonal changes and ultraviolet radiation (UVR). Based on the pattern of collagen fibrils, the superficial dermis is termed the 'papillary dermis', and the deeper, coarser part is the 'reticular dermis'.

### Epidermal appendages

#### Hair follicles

There are 3–5 million hair follicles, epidermal invaginations that develop during the second trimester. They occur throughout the skin, with the exception of palms, soles and parts of the genitalia (glabrous skin). The highest density of hair follicles is on the scalp (500–1000/cm<sup>2</sup>). Newborns are covered with fine 'lanugo' hairs, which are usually non-pigmented and lack a central medulla; these are subsequently replaced by vellus hair, which is similar but more likely to be pigmented. By contrast, scalp hair becomes terminal hair, which is thicker with a central medulla, is usually pigmented and grows longer. At puberty, vellus hairs in hormonally sensitive regions, such as the axillary and genital areas, become terminal hairs.

Human hairs grow in a cycle with three phases: anagen (active hair growth), catagen (transitional phase) and telogen (resting phase). The duration of each phase varies by site. On the scalp, anagen lasts several years, catagen a few days and telogen around 3 months. The length of hair at different sites reflects the differing lengths of anagen.

#### Sebaceous glands

Sebaceous glands are epidermal downgrowths, usually associated with hair follicles and composed of modified keratinocytes. The cells of the sebaceous gland (sebocytes) produce a range of lipids, discharging the contents into the duct around the hair follicle. Sebum excretion is under hormonal control, with androgens increasing it (as do progesterones, to a lesser degree) and oestrogens reducing it. In animals, sebum is important for hair waterproofing but its role in humans is unclear.

#### Sweat glands

Eccrine sweat glands develop in the second trimester and are also epidermal invaginations found all over the body. Their coiled ducts open directly on to the skin surface. They play a major role in

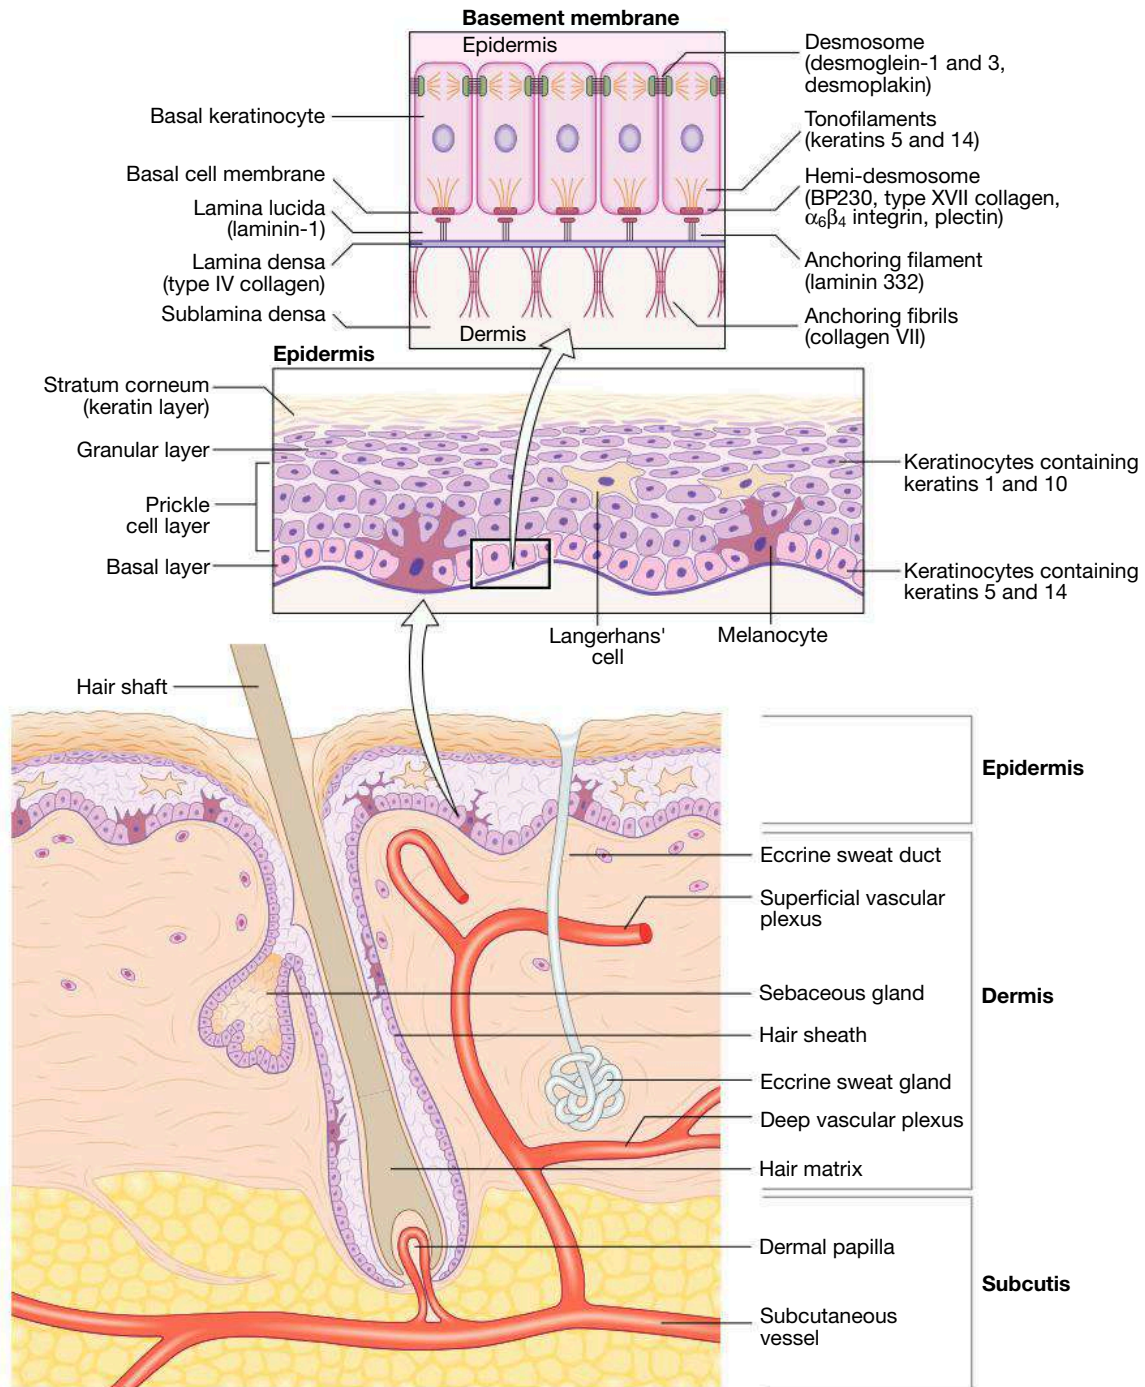

Fig. 27.1 Structure of normal skin.

thermoregulation and, unusually, are innervated by cholinergic fibres of the sympathetic nervous system. Eccrine glands of the palms and soles are innervated differently and are activated in the 'fight or flight' response. Apocrine sweat glands are restricted to the axillae and the mammary and genital areas, are connected to hair follicles and are not involved in thermoregulation.

### Nails

Fingernail growth commences at approximately 8 weeks of gestation and is complete by 32 weeks. Toenails develop slightly later. The anatomy of the nail apparatus is described later in the chapter.

### Blood vessels and nerves

Human skin has a plentiful blood supply, arranged in superficial and deep plexuses consisting of arterioles, arterial and venous capillaries, and venules. The upper plexus in the papillary dermis communicates with the lower plexus at the junction between the dermis and the subcutis. Capillary loops arise from terminal arterioles in the horizontal papillary plexus. Blood vessels are supplied by sympathetic and parasympathetic nerves, with the relative contributions of the pathways differing by site. Sympathetic signals are important in mediating autonomic-induced vasoconstriction. The blood supply of skin is far greater than

that required for normal skin physiology and reflects the importance of skin in thermoregulation.

## Functions of the skin

The skin has many functions, all of which can be affected by disease (Box 27.1). Skin changes associated with ageing are shown in Box 27.2.

## Investigation of skin disease

### Magnifying glass

A hand-held or freestanding magnifying lens used under good lighting conditions (ideally daylight) is valuable for examination of the skin.

### Wood's light

Wood's light is a long-wavelength UVA/short-wavelength visible (violet) light source that can be used in various ways. In hypopigmentation, such as in vitiligo, it can help in appreciating the extent of disease. In pigmented conditions, such as melasma, it can determine whether pigmentation is mainly epidermal (sharp cut-off under Wood's lamp) or mixed epidermal and dermal (ill-defined cut-off). Wood's lamp can also be used to help with the diagnosis of some fungal infections because of their characteristic fluorescence.

### Dermatoscopy and diascopy

Dermatoscopy (also known as dermoscopy and epiluminescence microscopy) is increasingly performed with hand-held dermatoscopes. What makes dermatoscopy unique is the fact that it allows visualisation through contact of a glass plate on the instrument with a liquid film applied to the skin, or through special optics to allow non-contact dermatoscopy, enabling deeper structures to be seen without interference from reflection and refraction of light in the epidermis.

Diascopy is simply pressing on the lesion with a glass slide. This provides some of the effect of dermatoscopy, but is mainly used to remove blood from vascular lesions to make the appearance of the lesion clearer. Granulomatous skin diseases may have a characteristic appearance under diascopy, such as in lupus vulgaris (cutaneous tuberculosis), in which 'apple jelly nodules' are typically seen on diascopy.

### Skin biopsy

Skin biopsy is a pivotal investigation in dermatology and can be used in a range of dermatological presentations. In the most common scenario, a skin biopsy is undertaken in order to obtain tissue on which to perform standard histopathology. However, tissue may also be subjected to a variety of staining and culture techniques, including immunostaining. Histopathological examination of skin biopsies is especially useful for tumour diagnosis. When a dermatologist or pathologist with dermatopathology expertise is involved, it can also assist in the diagnosis of inflammatory skin diseases. It is rare for histopathology of a previously undiagnosed inflammatory skin disease to provide a diagnosis on its own; clinico-pathological correlation is critical. Most biopsies are stained with haematoxylin and eosin but other stains may be useful in special situations, such as for fungal hyphae, iron or mucin. Direct immunofluorescence can also be undertaken on a fresh skin biopsy, allowing antigen visualisation using fluorescein-labelled antibodies; this is especially important in the diagnosis of autoimmune bullous disorders or connective tissue disease, such as cutaneous lupus.

## 27.1 Functions of the skin

Function	Structure/cell involved
<b>Protection against:</b> Chemicals, particles, desiccation Ultraviolet radiation	Stratum corneum Melanin produced by melanocytes and transferred to keratinocytes Stratum corneum hyperproliferation
Antigens, haptens	Langerhans' cells, lymphocytes, mononuclear phagocytes, mast cells, dermal dendritic cells
Microorganisms	Stratum corneum, Langerhans' cells, mononuclear phagocytes, mast cells, dermal dendritic cells
<b>Maintenance of fluid balance</b> Prevents loss of water, electrolytes and macromolecules	Stratum corneum
<b>Shock absorber</b> Strong, elastic and compliant covering	Dermis and subcutaneous fat
<b>Sensation</b>	Specialised nerve endings mediating pain and withdrawal Itch leading to scratch and removal of a parasite
<b>Metabolism</b> Detoxification of xenobiotics, retinoid metabolism, isomerisation of urocanic acid	Predominantly keratinocytes
<b>Temperature regulation</b>	Eccrine sweat glands and blood vessels
<b>Protection, and fine manipulation of small objects</b>	Nails
<b>Hormonal</b> Steroidogenesis, testosterone synthesis and conversion to other androgenic steroids	Hair follicles, sebaceous glands
Conversion of thyroxine ( $T_4$ ) to triiodothyronine ( $T_3$ )	Keratinocytes
Conversion of 7-dehydrocholesterol to vitamin D	Keratinocytes
<b>Pheromonal</b> Importance unknown in humans	Apocrine sweat glands, possibly sebaceous glands
<b>Psychosocial, grooming and sexual behaviour</b>	Appearance, tactile quality of skin, hair, nails

## 27.2 Skin changes in old age

- **Chronological ageing:** due to the intrinsic ageing process.
- **Photo-ageing:** due to cumulative ultraviolet radiation (UVR) exposure and superimposed on intrinsic ageing.
- **Typical changes:** include atrophy, laxity, yellow discoloration, wrinkling, dryness, irregular pigmentation, and thinning and greying of hair.
- **Causes:** age-related alterations in structure and function of the skin, cumulative effects of environmental insults, especially UVR and smoking, cutaneous consequences of disease in other organ systems.
- **Consequences:** reduction in immune and inflammatory responses, reduction in absorption and clearance of topical medications, reduced healing, increased susceptibility to irritants, dermatitis, adverse drug effects (including topical glucocorticoid-induced atrophy and purpura) and diseases such as skin cancer.

## Microbiology

### Bacteriology

Bacterial swabs may identify a causative infective agent. However, organisms identified from the skin surface may not be the cause of the skin disease but instead may simply reflect colonisation of skin that has already been damaged by a primary skin disease.

### Virology

A number of techniques, including immunofluorescence and polymerase chain reaction (PCR), are available to diagnose herpes simplex or herpes zoster viruses from vesicle fluid.

### Mycology

Scale, nail clippings (or scrapings of crumbly subungual hyperkeratosis) and plucked hairs can be examined by light microscopy. If potassium hydroxide and a simple light microscope are available, this can be performed in any outpatient clinic. Microbiology laboratories will also routinely undertake microscopy and culture for fungi and yeasts.

## Patch testing

Patch testing is the investigation of choice for delayed, cell-mediated, type IV hypersensitivity reactions to topical agents, which clinically manifest as dermatitis. Potential allergens (see [Box 27.23](#)) are applied as patches to the back under occlusion for 48 hours, in vehicles and at concentrations that minimise false-positive and false-negative reactions. After 48 hours the patches are removed and patch-test readings are undertaken at time points of up to 7 days after patch-test application, with the most typical time point being at 96 hours. When interpreting patch test readings, it is important to determine the clinical relevance of any allergic reactions before giving avoidance advice.

Photopatch testing is similar to patch testing but investigates delayed hypersensitivity reactions to a topically applied agent (usually a sunscreen or topical non-steroidal anti-inflammatory drug (NSAID)) after the absorption of UVR. It involves applying substances in duplicate and irradiating one set with UVR (typically UVA, 5 J/cm<sup>2</sup>), readings then being conducted in a similar manner to patch testing.

## Prick tests and specific immunoglobulin E testing

Prick tests are used to investigate cutaneous type I (immediate) hypersensitivity reactions to various antigens such as pollen, house dust mite or dander. The skin is pricked with commercially available stylets through a dilution of the appropriate antigen solution. Alternatively, specific immunoglobulin E (IgE) levels to antigens can be measured in serum. If challenge tests are undertaken for patients with suspected allergy, these must be performed under controlled conditions due to the potential risk of triggering a severe reaction. More details of IgE testing are provided in [Chapter 4](#).

## Phototesting

Phototesting is extremely valuable in the assessment of suspected photosensitivity. The mainstay investigation is monochromator phototesting, which involves exposing the patient's back to increasing doses of irradiation using narrow wavebands across the solar spectrum and then assessing responses at each waveband, using the minimal erythema dose (MED) as the endpoint. This is the dose required to cause just perceptible skin reddening (erythema) and is compared with values for the normal population. If a patient has reduced MEDs (develops erythema at lower doses than healthy subjects), this indicates abnormal photosensitivity. Thus, monochromator phototesting can be used to determine whether a patient is abnormally photosensitive, which wavebands are involved and how sensitive the patient is. Provocation testing can be performed with a broadband (usually UVA) source to induce rash at a test site (most useful for polymorphic light eruption) and is a helpful diagnostic

test. Provocation testing to a variety of light sources, including artificial compact fluorescent lamps, may also be indicated, the latter being most relevant in patients with severe photosensitivity.

Patients who are referred for phototherapy will also commonly undergo an MED test, in which they are exposed to a series of test doses of the light source that will be used therapeutically (often narrowband UVB); the MED is determined 24 hours later (or 72–96 hours for the psoralen-ultraviolet A (PUVA) minimal phototoxic dose. This allows treatment regimens to be individualised, based on a patient's erythral responses. The MED can also detect abnormal photosensitivity, and represents a safety measure prior to starting a course of phototherapy.

## Blood tests

Although most patients presenting with a skin problem do not need blood tests as part of their investigations, there are many systemic diseases that can present with skin features and, indeed, blood tests may also be indicated in the investigation of primary skin disease. A wide range of possible investigations may be required and some examples include haemoglobin, iron studies and thyroid function tests in pruritus or hair loss; autoantibody screening if lupus is suspected; measurement of porphyrins for skin fragility and hypertrichosis; and hepatitis screening in lichen planus. These diverse examples emphasise the importance of considering an underlying systemic disease when assessing a patient with a dermatological presentation.

## Imaging

Imaging techniques are not typically required but X-rays, ultrasound, magnetic resonance imaging (MRI) or computed tomography (CT) may occasionally be indicated in specific situations, such as in metastatic melanoma or in a patient presenting with a diagnosis of cutaneous sarcoid.

## Presenting problems in skin disease

The major presentations in dermatology are outlined below. Detail of the underlying disorders is mostly provided in the disease-specific sections further on in the chapter.

## Lumps and lesions

The term lump or lesion is typically used to describe a papule or nodule, although sometimes may refer to a macule or plaque. A new or changing lump is one of the key dermatology presentations.

### Clinical assessment

Detailed history-taking and examination are essential:

- **Change:** Is the lump new or has there been a change in a pre-existing lesion? What is the nature of the change – size, colour, shape or surface change? Has change been rapid or slow? Are there other features – pain, itch, inflammation, bleeding or ulceration (**definition** of 'ulcer': an area from which the epidermis and at least the upper part of the dermis have been lost – see [Fig. 27.9](#))?
- **Patient:** What is the patient's age? Are they fair-skinned and freckled? Have they got multiple naevi? Has there been much sun exposure? Have they used sunbeds or lived and worked in sunny climates? Have they used photoprotection? Have they had skin cancer before or is there a family history of skin cancer? What medications are they taking? Are they immunosuppressed?
- **Site:** Is it on a sun-exposed or covered site? The scalp, face, upper limbs and back in men, and face, hands and lower legs in women, are the most chronically sun-exposed sites.
- **Are there other similar lesions?** These might include actinic keratoses (see [Fig. 27.14](#)) or basal cell papillomas (see [Fig. 27.18](#)).

**Fig. 27.2 Dermatoscopy.** **A** A changing lesion. **B** Dermatoscopy highlights the abnormal pigment network and other features suggestive of melanoma. Excision biopsy confirmed the diagnosis of superficial spreading malignant melanoma (Breslow thickness 0.8 mm). **C** Another changing lesion. **D** Dermatoscopy highlights the vascular lacunae of this benign angioma and the patient was reassured.

- *Morphology*: Tenderness, size, symmetry, regularity of border, colour, surface characteristics and the presence of features such as crust (**definition**: dried exudate of blood or serous fluid – see Fig. 27.20), scale (**definition**: a flake arising from the stratum corneum; any condition with a thickened stratum corneum can cause scaling – see Fig. 27.14) and ulceration must be assessed. Stretching the skin and using a magnifying lens can be helpful, such as for detecting the raised, pearly edge of a basal cell carcinoma (see Fig. 27.12).
- *Dermatoscopy*: This can be used to detect the presence of abnormal vessels, such as in basal cell carcinoma or the characteristic keratin cysts in basal cell papillomas. It is invaluable for assessing pigmented and vascular lesions (Fig. 27.2).

#### Is it a melanocytic naevus or a malignant melanoma?

This is a common clinical scenario and one that it is critical to resolve correctly.

- The precise nature of the change should be determined (as above). Listen to the patient and pay attention to subtle changes, as people know their skin well.
- If the patient has other pigmented lesions, then these should be examined too, as they may be informative. For example, if the presenting lesion looks different from the others, then suspicion of melanoma is increased; conversely, if the patient has multiple basal cell papillomas, this may be reassuring – although do not be falsely reassured.
- Is there a positive family history of melanoma? A suspicious naevus in a patient with a first-degree relative with melanoma probably warrants excision.

#### **i** 27.3 ABCDE features of malignant melanoma

- Asymmetry
- Border irregular
- Colour irregular
- Diameter >0.5 cm
- Elevation irregular
- (+ Loss of skin markings)

The ABCDE 'rule' is a guide to the characteristic features of melanoma (Box 27.3 and see Figs. 27.2 and 27.16), although melanomas should ideally be diagnosed before the diameter is greater than 0.5 cm. Loss of normal skin markings in a pigmented lesion may be suggestive of melanoma. Conversely, normal skin markings and fine hairs dispersed evenly over a lesion are reassuring but do not exclude melanoma. The Glasgow seven-point checklist is another useful guide:

- *major features*: change in size, shape and colour
- *minor features*: diameter >0.5 cm, inflammation, oozing, bleeding, itch or altered sensation.

Patients with one major or one minor feature should be referred for further evaluation.

#### **Investigations and management**

If a benign diagnosis, such as basal cell papilloma, is made on clinical grounds, then the patient can be reassured and the lesion either left or treated: for example, with cryotherapy. If there are concerns about

the diagnosis or malignancy is suspected, then skin biopsy in order to obtain a tissue diagnosis is the usual approach. An incisional biopsy may be indicated, although if the lesion is small, excision may be most appropriate. If significant concern exists about the possibility of malignant melanoma, initial excision with a 2 mm margin would usually be undertaken prior to more definitive management once histology was confirmed. Further management of a changed lesion would, of course, depend on histological analysis of the diagnostic biopsy.

## Rash

A rash is the other common presentation in dermatology. The main categories of scaly rashes are listed in [Box 27.4](#). The most common type of rash presentation is maculopapular. Diagnosis can often be made on clinical grounds, although a biopsy may be required.

### Clinical assessment

Important aspects of the history include:

- *Age at onset and duration of rash.* Atopic eczema often starts in early childhood and psoriasis between 15 and 40 years, and both may be chronic. Infective or drug-induced rashes are more likely to be of short duration and the latter to occur in relation to drug ingestion. Duration of individual lesions is also important, as in urticaria, for example, where lesions will come and go over short periods of time and do not persist beyond 24 hours.
- *Body site at onset and distribution.* Flexural sites are more typically involved in atopic eczema, and extensor surfaces and scalp in psoriasis. Symmetry is often indicative of an endogenous disease, such as psoriasis, whereas asymmetry is more common with exogenous causes, such as contact dermatitis or infections like herpes zoster.
- *Itch.* Eczema is usually extremely itchy and psoriasis may be less so.
- *Preceding illness and systemic symptoms.* Guttate psoriasis may be precipitated by a  $\beta$ -haemolytic streptococcal throat infection; almost

all patients with infectious mononucleosis treated with amoxicillin will develop an erythematous maculopapular eruption; a history of chancre at the site of inoculation may be elicited in a presentation of secondary syphilis; malaise and arthralgia are common in drug eruptions and vasculitis.

The morphology of the rash and the characteristics of individual lesions are important (see [Box 27.4](#)).

### Investigations and management

It is important to have a short differential diagnosis based on clinical assessment in order to direct investigations. For example, in psoriasis, no investigations may be needed and initial management with patient counselling and topical therapies may suffice. If the diagnosis is unclear, then a diagnostic skin biopsy and other targeted investigations based on the clinical picture may be required. An initial management plan should also be implemented. For example, in a child presenting with a rash that has features suggestive of impetigo, skin and nasal swabs should be performed and, once these have been taken, topical or systemic antibiotics should be introduced, depending on clinical extent of disease, and management should be adjusted accordingly, dependent on investigation findings and clinical course. In contrast, if a patient presents with a maculopapular rash shortly after introduction of a new drug, then drug withdrawal, diagnostic biopsy, full blood count, including eosinophil count, and liver and renal function tests, in parallel with topical emollients and glucocorticoids, may be indicated.

## Blisters

A blister is a fluid-filled collection in the skin. The term vesicle is used for small lesions and bulla for larger lesions. Blistering occurs due to loss of cell adhesion within the epidermis or subepidermal region (see [Fig. 27.1](#)). The clinical presentation depends on the site or level of blistering within the skin, which in turn reflects the underlying cause. There are a limited number of conditions that present with blisters ([Box 27.5](#)):

### 27.4 Causes and clinical features of common scaly rashes

Diagnosis	Distribution	Morphology	Associated signs
Atopic eczema (p. 1096)	Face and flexures	Poorly defined erythema, scaling Vesicles Lichenification if chronic	Shiny nails Infra-orbital crease 'Dirty neck' (grey-brown discoloration)
Psoriasis (p. 1099)	Extensor surfaces Lower back	Well-defined Erythematous plaques Silvery scale	Nail pitting, onycholysis Scalp involvement Axillae and genital areas often affected Joint involvement Köbner phenomenon (p. 1103)
Pityriasis rosea (p. 1102)	'Fir tree' pattern on trunk	Well-defined Small, erythematous plaques Collarette of scale	Herald patch
Drug eruption (p. 1115)	Widespread	Macules and papules Erythema and scale Exfoliation	Possible mucosal involvement or erythroderma
Pityriasis versicolor (p. 1093)	Upper trunk and shoulders	Hypo- and hyper-pigmented scaly patches	
Lichen planus (p. 1103)	Distal limbs Flexural aspect of wrists Lower back	Shiny, flat-topped, violaceous papules Wickham's striae	White, lacy network on buccal mucosa Nail changes Scarring alopecia Köbner phenomenon
Tinea corporis (p. 1092)	Asymmetrical Often isolated lesions	Erythematous, often annular plaques Peripheral scale (sometimes pustules) Expansion with central clearing	Possible nail, scalp, groin involvement
Secondary syphilis (p. 377)	Trunk and proximal limbs Palms and soles	Red macules and papules, which become 'gun-metal' grey	History of chancre Systemic symptoms, e.g. malaise and fever

27.5 Causes of acquired blisters		
	Localised	Generalised
<b>Vesicular</b>	Herpes simplex Herpes zoster Impetigo Pompholyx	Eczema herpeticum* Dermatitis herpetiformis Acute eczema
<b>Bullous</b>	Impetigo Cellulitis Stasis oedema Acute eczema Insect bites Fixed drug eruption	Toxic epidermal necrolysis* Erythema multiforme Stevens–Johnson syndrome* Bullous pemphigoid Pemphigus* Epidermolysis bullosa acquisita Lupus erythematosus Porphyria cutanea tarda Pseudoporphyria Drug eruptions

\*Usually with mucosal involvement too.

- Intact blisters are not often seen if the split is high in the epidermis (below the stratum corneum), as the blister roof is so fragile that it ruptures easily, leaving erosions (**definition**: an area of skin denuded by complete or partial loss of the epidermis). This occurs in pemphigus foliaceus, staphylococcal scalded skin syndrome (see Fig. 27.21) and bullous impetigo.
- If the split is lower in the epidermis, then intact flaccid blisters and erosions may be seen, as occurs in pemphigus vulgaris and toxic epidermal necrolysis (see Fig. 27.41).
- If the split is subepidermal, then tense-roofed blisters are seen. This occurs in bullous pemphigoid (see Fig. 27.42), epidermolysis bullosa acquisita and porphyria cutanea tarda (see Fig. 27.53).
- If there are foci of separation at different levels of the epidermis, such as may occur in eczema, then multilocular bullae made up of coalescing vesicles can occur.

### Clinical assessment

Detailed history-taking and examination are critical. A history of onset, progression, mucosal involvement, drugs and systemic symptoms should be sought. Clinical assessment of the distribution, extent and morphology of the rash should be made. The Nikolsky sign is useful: sliding lateral pressure from a finger on normal-looking epidermis can dislodge and detach the epidermis in conditions with intra-epidermal defects, such as pemphigus and toxic epidermal necrolysis. A systematic approach to diagnosis is required (Fig. 27.3).

### Investigations and management

Investigations and initial management will be guided by the clinical presentation and differential diagnosis, and are described in more detail under the specific diseases. For example, an initial approach may include

directed investigations, such as incisional diagnostic skin biopsy for histology and direct immunofluorescence, indirect immunofluorescence and other targeted blood tests or skin swabs. Management should be based on the likely diagnosis and begin in parallel with investigations, until the diagnosis is confirmed.

### Itch

Itch describes the unpleasant sensation that leads to scratching or rubbing. The terms 'itch' and 'pruritus' are synonymous; however, 'pruritus' is often used when itch is generalised. Itch can arise from primary cutaneous disease or be secondary to systemic disease, which may cause itch by central or peripheral mechanisms. Even when the mechanism is peripheral, there are not always signs of primary skin disease.

The nerve endings that signal itch are in the epidermis or near the dermo-epidermal junction. The underlying mechanisms of itch are not fully understood. Transmission is by unmyelinated slow-conducting C fibres through the spinothalamic tract to the thalamus and then the cortex. Aδ fibres also seem to be involved in transmitting signals to the spinal cord, and the heat-sensitive transient receptor potential (TRP) channels 1–4 are important. There is an inhibitory relationship between pain and itch. Scratching may relieve the symptom of itch after the sensation has ceased and this is either by stimulation of ascending sensory pathways that inhibit itch-transmitting neurons at the spinal cord (Wall's 'gate' mechanism), or by direct damage to cutaneous sensory nerves.

The mechanisms of itch in most systemic diseases remain unclear. The itch of kidney disease, for example, may be mediated by circulating endogenous opioids. The clinical observation that peritoneal dialysis helps reduce itch more frequently than haemodialysis is consistent with this, with smaller molecules generally being dialysed more readily if the peritoneal membrane is used rather than a dialysis machine membrane.

### Clinical assessment

It is important to determine whether skin changes are primary (a process in the skin causing itch) or secondary (skin changes caused by rubbing and scratching because of itch). This requires a thorough history and examination, sometimes with investigations, to exclude systemic disease. Many common primary skin disorders are associated with itch (Box 27.6). If itch is not connected with primary skin disease, other causes

27.6 Primary skin diseases causing pruritus	
<b>Generalised pruritus</b>	
• Scabies	• Urticarias
• Eczemas	• Xeroderma of old age
• Pre-bullous pemphigoid	• Psoriasis
<b>Localised pruritus</b>	
• Eczemas	• Pediculosis
• Lichen planus	• Tinea infections
• Dermatitis herpetiformis	

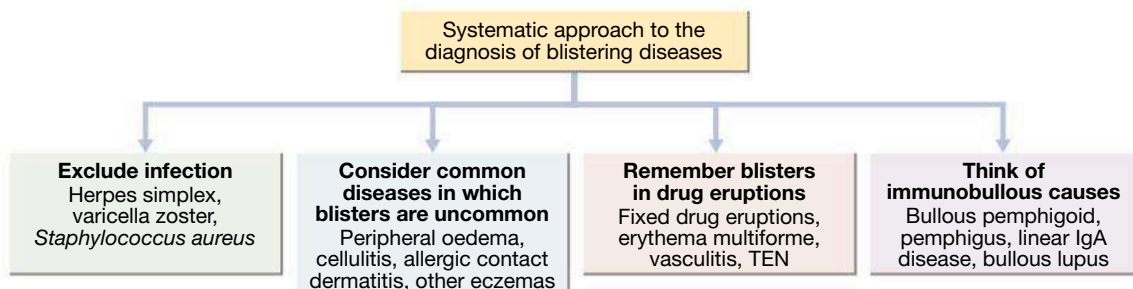

Fig. 27.3 A systematic approach to the diagnosis of blistering diseases. (TEN = toxic epidermal necrolysis)

## i

## 27.7 Secondary causes of pruritus

Medical condition	Cause of pruritus	Treatment*	Medical condition	Cause of pruritus	Treatment*
<b>Liver disease</b>	Central opioid effect Elevation in bile salts may contribute	Naltrexone Colestyramine Rifampicin Sedative antihistamines UVB	Thyrotoxicosis	Unknown	
			Hypothyroidism	Unknown	
<b>Renal failure</b>	Unknown; uraemia contributes	UVB Oral activated charcoal	<b>HIV infection</b>	Infection, infestation Eosinophilic folliculitis Seborrhoeic dermatitis Unknown	Treatment of infection Local corticosteroids, UVB Anti-pityrosporal treatment UVB
			<b>Malignancy</b>	Unknown	
<b>Haematological disease</b>			<b>Psychogenic</b>	Unknown	Psychotherapy, anxiolytics, antidepressants
Anaemia	Iron deficiency	Iron replacement			
Polycythaemia rubra vera	Unknown (often aquagenic pruritus)				
Lymphoma	Unknown				
Leukaemia					
Myeloma					
<b>Endocrine disease</b>					
Diabetes mellitus	Infections such as candidiasis and tinea	Treatment of infection			

\*In addition to specific treatment of the primary condition and symptomatic treatments, such as emollients. (5-HT = 5-hydroxytryptamine, serotonin; HIV = human immunodeficiency virus; UVB = ultraviolet B)

## 27.8 Causes of pruritus in pregnancy

Diagnosis	Pregnancy, gestation and features	Treatment
<b>Polymorphic eruption of pregnancy</b> (pruritic urticarial papules and plaques, PUPP)	Typically first pregnancy and uncommonly recurs during third trimester and after delivery Polymorphic urticated papules and plaques, start in striae	Chlorphenamine, emollients Topical glucocorticoids
<b>Acute cholestasis of pregnancy</b>	Third trimester and commonly recurs in subsequent pregnancies Abnormal liver function tests Increased fetal and maternal risk	Emollients Chlorphenamine Colestyramine UVB Early delivery
<b>Pemphigoid gestationis</b>	Any stage, often second trimester and commonly recurs in subsequent pregnancies Urticated erythema, blistering initially periumbilical Characteristic histology and immunofluorescence	Topical or oral glucocorticoids
<b>Prurigo gestationis</b>	Second trimester Excoriated papules	Emollients Topical glucocorticoids Chlorphenamine UVB
<b>Pruritic folliculitis</b>	Third trimester Sterile pustules on trunk	Topical glucocorticoids UVB

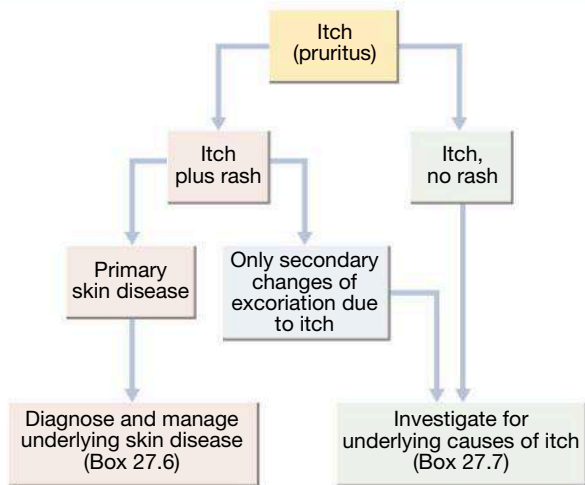

(UVB = ultraviolet B)

should be considered (Box 27.7). These include liver diseases (mainly cholestatic diseases, such as primary biliary cholangitis), malignancies (generalised itch may be the presenting feature of lymphoma), haematological conditions (generalised itch in chronic iron deficiency or water contact-provoked (aquagenic) intense itch in polycythaemia), endocrine diseases (including hypo- and hyperthyroidism), chronic kidney disease (in which severity of itch is not always clearly associated with plasma creatinine concentration) and psychogenic causes (such as in 'delusions of infestation'). Itch is common in pregnancy and may be due to one of the pregnancy-specific dermatoses. Making a correct diagnosis is particularly important in pregnancy, as some disorders can be associated with increased fetal risk (Box 27.8).

### Investigations and management

Investigations should be directed towards finding an underlying cause and there will be a different approach for itch with rash, as opposed to itch with no signs of primary skin disease (Fig. 27.4). If there are no signs of primary

skin disease, investigations should be undertaken to exclude systemic disease or iatrogenic causes. Psychogenic itch should be considered only if organic disease has been ruled out. There are no consistently effective therapies to suppress itch, and so establishing the underlying cause is critical. If a clear-cut diagnosis cannot be made, non-specific approaches can be used for symptom relief. These include sedation, often with H<sub>1</sub>-receptor antihistamines, along with emollients and counter-irritants (such as topical menthol-containing preparations). UVB phototherapy is useful for generalised itch due to a variety of causes but the only randomised controlled study of efficacy is in chronic kidney disease. Other treatments include low-dose tricyclic antidepressants (probably through similar mechanisms to those involved when these drugs are used for chronic pain) and opiate antagonists. If a psychogenic itch is considered likely, antidepressants and/or cognitive behavioural therapy may be effective. Itch of any cause can be severe and its potentially major adverse effects on quality of life are not always fully appreciated. Assessments of impact on quality of life, such as Dermatology Life Quality Index (DLQI) scores, are essential.

**Fig. 27.4** An overall approach to the investigation and management of itch (pruritus).

## Photosensitivity

Cutaneous photosensitivity is an abnormal response of the skin to UVR or visible radiation. The sun is the natural source but patients may also be exposed to artificial sources of UVR through the use of sunbeds and/or phototherapy. Chronic UVR exposure increases skin cancer risk and photo-ageing. Acute exposure can induce erythema (redness) as a normal response (Fig. 27.5). However, abnormal photosensitivity occurs when a patient reacts to lower doses than would normally cause a response, either with a heightened erythematous reaction or the development of a rash. Photo-aggravated skin diseases are exacerbated by sunlight but not caused by it. The main photosensitive and photo-aggravated diseases are listed in Box 27.9.

Sunlight consists mainly of visible light, and the UVR component is divided into three wavebands (Fig. 27.6), according to the Commission Internationale de l'Eclairage (CIE):

**Fig. 27.5** Sunburn. Acute exposure to ultraviolet radiation results in an erythematous response that peaks 12–24 hours later. Sensitivity depends on the individual's constitutive skin phototype.

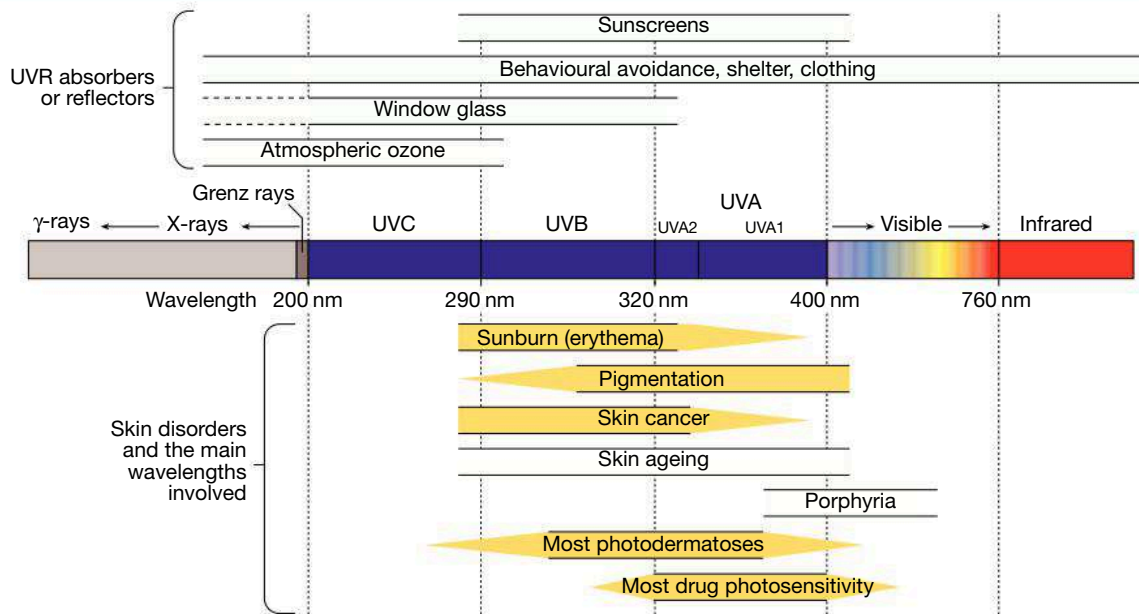

- **UVC** (200–280nm), which is absorbed by ozone and does not reach the Earth's surface.
- **UVB** (280–315 nm), which constitutes less than 10% of UVR exposure but is around 1000-fold more potent than UVA and so accounts for the erythematous 'sunburning' effects of sunlight.
- **UVA** (315–400 nm), which is the most abundant UVR component reaching the Earth's surface.

The arbitrary division between UVB and UVA regions is more often considered to be at 320nm by photobiologists, and the UVA region can be further subdivided into UVA2 (320–340 nm) and UVA1 (340–400 nm). UVA2 behaves biologically more like UVB, and UVA1 can be used therapeutically for several skin conditions, such as morphea and eczema.

Patients with photosensitivity diseases can be abnormally sensitive to UVB, UVA, visible light (over 400nm) or, commonly, a combination of wavebands. UVB is absorbed by window glass, whereas UVA and visible light are transmitted through glass.

27.9 The photosensitivity and photo-aggravated diseases		
Cause	Condition	Clinical features
<b>Immunological</b> (previously known as idiopathic)	Polymorphic light eruption (PLE)	Seasonal, itchy, papulovesicular rash on photo-exposed sites; face and back of hands often spared. Often hours of UVR exposure needed to provoke; lasts a few days; affects about 20% in Northern Europe, more common in young women
	Chronic actinic dermatitis (CAD)	Chronic dermatitis on sun-exposed sites. Most common in older adult males. Predominantly UVB, but also often UVA and visible light photosensitivity. Most also have contact allergies
	Solar urticaria	Immediate-onset urticaria on photo-exposed sites. Usually UVA and visible light photosensitivity. Can occur at any age
	Actinic prurigo	Uncommon, presents in childhood. Often familial, with strong HLA association. Some similarities to PLE, although scarring occurs
	Hydroa vacciniforme	Rare childhood photodermatosis. Varioliform scarring
<b>Drugs</b> (variety of mechanisms)	Phototoxicity	Usually UVA (and visible light) photosensitivity Most common. Exaggerated sunburn and exfoliation. Many drugs such as thiazides, tetracyclines, fluoroquinolones, quinine, NSAIDs
	Pseudoporphyria Photoallergy	NSAIDs, retinoids, tetracyclines, furosemide are examples Usually to topical agents, particularly sunscreens and NSAIDs
<b>Metabolic</b>	Porphyrias Pellagra	Mainly porphyria cutanea tarda and erythropoietic protoporphyria Photo-exposed site dermatitis due to tryptophan deficiency (see Fig. 22.14)
<b>Photogenodermatoses</b>	Xeroderma pigmentosum	Rare. Defect in DNA excision repair, abnormal photosensitivity, photo-ageing and skin cancer. There may be neurological features
<b>Photo-aggravation of pre-existing conditions</b>	Lupus erythematosus Erythema multiforme Rosacea	Can also be drug-induced (see Box 27.36)

(HLA = human leucocyte antigen; NSAIDs = non-steroidal anti-inflammatory drugs; UVA/UVB = ultraviolet A/B; UVR = ultraviolet radiation)

**Fig. 27.6 The electromagnetic spectrum.** The action spectrum is not well defined for many conditions and, for some, is approximate and may vary between patients. The action spectrum for non-melanoma skin cancer mirrors that for erythema. The action spectrum for melanoma is not known but includes UVA and UVB. Photoprotection measures vary, depending on condition, although the mainstay always includes behavioural modification, clothing cover and appropriate sunscreen choices. (UV = ultraviolet; UVR = ultraviolet radiation)

**Fig. 27.7 Chronic actinic dermatitis.** Note the sharp cut-off and sparing behind the ear in the shadow cast by the earlobe (Wilkinson's triangle).

### Clinical assessment

Taking a careful history is essential, as the patient may not have the rash when assessed. Seasonal pattern and distribution of rash are important. Key sites are the face (particularly nose, cheeks and forehead), top of ears, neck (Fig. 27.7), bald scalp, back of hands and forearms. Sparing is often seen under the chin and nose, behind the ears, on the upper eyelids and the distal digits – as we normally walk about with our eyes open and fingers flexed! It can be misleading if there is covered site involvement. Patients who are sensitive to UVA and visible light may be affected through clothing. These patients commonly experience perennial symptoms and may not be aware of the association with daylight exposure. Other photosensitivity diseases, such as actinic prurigo or chronic actinic dermatitis, may also involve covered sites. Sparing of habitually exposed sites, such as the face and back of hands, occurs most commonly in polymorphic light eruption (PLE) and is called the

'hardening phenomenon'. Importantly, some conditions, such as solar urticaria, develop rapidly after sunlight exposure, whereas others, such as cutaneous lupus, can take several days to evolve.

### Investigations and management

If photosensitivity is suspected, the patient should be referred to a specialist centre for assessment and investigation, usually involving monochromator phototesting. Other investigations will often include provocation, patch or photopatch testing and screening for lupus and the porphyrias. Rarely, investigations such as human leucocyte antigen (HLA) typing in suspected actinic prurigo, or DNA excision repair functional activity or genotyping in suspected xeroderma pigmentosum, may be required.

Management depends on the cause. If there is a phototoxic drug or chemical cause, this must be identified and addressed: for instance, by stopping the drug or treating the porphyria. Counselling in regard to sun avoidance is essential: keeping out of direct sun in the middle of the day, covering up with clothing, wearing hats with a wide brim and careful use of high-factor sunscreens. Paradoxically, in some conditions, particularly PLE and solar urticaria, phototherapy can be used to induce 'hardening', which is a term used to describe the process by which phototherapy cross-links structures in the skin; in these circumstances the mechanism of desensitisation is unclear. Other approaches may be necessary, depending on disease and severity, and may include antihistamines (useful in two-thirds of patients with solar urticaria) and systemic immunosuppression (sometimes required in the immunological photodermatoses, such as chronic actinic dermatitis). Patients with photosensitivity are at risk of vitamin D deficiency due to reduced vitamin D synthesis by the skin and often require vitamin D supplements.

### Sunscreens

Sunscreens can be divided into two categories: chemical sunscreens, which absorb specific wavelengths of UVR, and physical sunscreens, which reflect UVR and the shorter visible wavelengths (see Fig. 27.6). Sunscreens are now highly sophisticated and most offer protection against UVB and most UVA wavelengths. If a patient is abnormally photosensitive to the longer wavelengths of UVA and the visible part of the spectrum (for example, in cutaneous porphyrias and solar urticaria), then conventional sunscreens are not beneficial and specific reflectant

sunscreens are required. Historically, these agents were less cosmetically acceptable due to visible light reflection, but current formulations, some of which are tinted, have reduced this problem.

Sunscreen protection levels are described by sun protection factor (SPF). This is the ratio of the dose of UVR required to produce skin erythema in the presence and absence of the sunscreen. A sunscreen of SPF20 means that it would take 20 times as long for a person to develop sunburn in the presence of the sunscreen, as compared to not using it. Therefore, SPF is really a sunburn protection factor and is not a good guide to how well a sunscreen will perform in protecting against other reactions (such as skin pain in erythropoietic protoporphyria or UVR-induced immunosuppression). SPF values are determined under experimental conditions whereas, in practice, people tend to use 25%–33% of the amount of sunscreen required to achieve the stated SPF and it is easy to be lulled into a false sense of security of believing that higher levels of sun protection will be achieved than in reality will be the case. Patient counselling is therefore important with regard to adequate application of sunscreen. Importantly, there is no such thing as a complete 'sunblock' as sunscreens offer, at best, partial protection and are no substitute for modifying behaviour and covering up.

## Leg ulcers

Leg ulcer is not a diagnosis, but a symptom of an underlying disease in which there is complete loss of the epidermis, leaving dermal layers exposed. Ulcers on the lower leg are frequently caused by vascular disease but there are other causes, as summarised in [Box 27.10](#).

### Clinical assessment

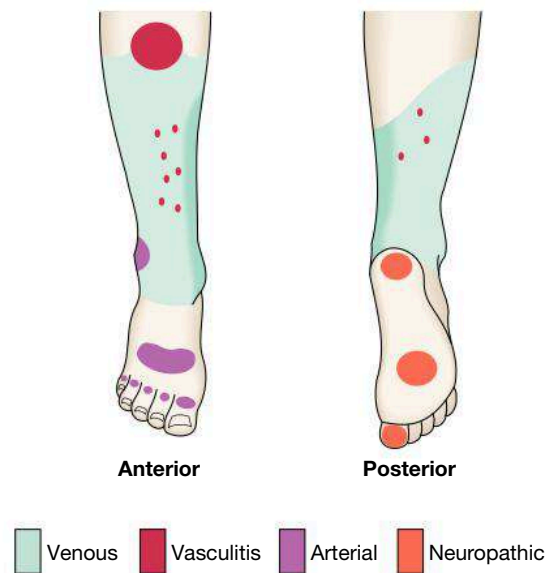

A detailed history of the onset and course of leg ulceration and predisposing conditions should be elicited. The site and surrounding skin should be assessed. Varicose veins are often present, although not inevitably. Assessment of the venous and arterial vasculature and neurological examination are critical. The site of ulceration may also help to indicate the underlying primary cause ([Fig. 27.8](#)). Full clinical examination is essential as the ulcer may be arising in the context of systemic disease, such as vasculitis.

### Leg ulceration due to venous disease

Varicose veins, a history of deep venous thrombosis and obesity are predisposing factors. Incompetent valves in the deep and perforating veins of the lower leg result in retrograde flow of blood to the superficial system, and a rise in capillary pressure ('venous hypertension'). Pericapillary fibrin cuffing occurs, leading to impairment of local tissue oxygenation and homeostasis.

The first symptom in venous ulceration is often heaviness of the legs, followed by oedema. Haemosiderin pigmentation, pallor and firmness of surrounding skin, and sometimes venous/gravitational eczema subsequently develop. This progresses to lipodermatosclerosis – firm induration due to fibrosis of the dermis and subcutis, which may produce the well-known 'inverted champagne bottle' appearance. Ulceration, often precipitated by trauma or infection, follows. Venous ulcers typically occur on the medial lower leg ([Fig. 27.9](#)).

**Fig. 27.8** Causes of lower limb ulceration. The main types of leg ulcer tend to affect particular sites.

**Fig. 27.9** Patient with chronic venous insufficiency who has chronic venous stasis skin changes and venous ulceration. From Braddom RL, Chan L, Harrast MA. *Physical medicine and rehabilitation*, 4th edn. Elsevier; 2011.

Complications of venous leg ulceration include bacterial colonisation and infection, and contact allergic dermatitis to topical medicaments, dressings and bandages. Lipodermatosclerosis may cause lymphoedema and hyperkeratosis; rarely, a squamous cell carcinoma (SCC) may develop in a long-standing venous ulcer (Marjolin's ulcer).

### Leg ulceration due to arterial disease

Deep, painful, punched-out ulcers on the lower leg, especially the shin and foot and in the context of intermittent claudication, are likely to be due to arterial disease. Risk factors include smoking, hypertension, diabetes and hyperlipidaemia. The foot is cold and dusky, and the skin atrophic and hairless. Peripheral pulses are absent or reduced. In these circumstances a vascular surgical assessment should be sought urgently.

### Leg ulceration due to vasculitis

Vasculitis can cause leg ulceration either directly through epidermal necrosis due to damage to the underlying vasculature, or indirectly due to neuropathy.

### Leg ulceration due to neuropathy

The most common causes of neuropathic ulcers are diabetes and leprosy. Microangiopathy also contributes to ulceration in diabetes. The ulcers occur over weight-bearing areas, such as the heel. In the presence of neuropathy, protection of skin from trauma is essential to prevent ulceration.

### Investigations

Appropriate investigations include:

- *Full blood count* to detect anaemia and blood dyscrasias.
- *Urea and electrolytes* to assess renal function.
- *Urinalysis* for glycosuria.
- *Bacterial swab* if there is a purulent discharge, rapid extension, cellulitis, lymphangitis or sepsis. This can guide antibiotic therapy for secondary infection but pathogenic bacteria are not always the same as those identified from the ulcer surface.
- *Doppler ultrasound* to assess arterial circulation. An ankle systolic pressure to brachial systolic pressure index (ABPI) of below 0.8 suggests significant arterial disease and a vascular surgery opinion should be sought. However, arterial calcification, such as in diabetes, can produce a spuriously high ABPI. Pulse oximetry may also be useful, although ABPI is the preferred investigation if feasible.

### Management

General advice on exercise, weight loss and smoking cessation is important in all cases. Specific management depends on making the correct diagnosis to identify the cause(s) of ulceration. Underlying factors, such as diabetes or anaemia, must be treated. Oedema must be reduced by leg elevation and, if there is no arterial compromise, graduated compression bandaging from toes to knees to enhance venous return and improve healing. Compression bandaging is effective for individuals with an ABPI of more than 0.8 but should be avoided if the ABPI is less than 0.8.

If the ulcer is purulent, weak potassium permanganate soaks may help, and exudate and slough can be removed with normal saline or clean water. Dressings do not themselves heal leg ulcers, but can reduce discomfort and odour and, by reducing colonisation by potential pathogens, may reduce the frequency of secondary infection. A variety of dressings may be used, including non-adherent and absorbent (alginates, hydrogels, hydrocolloids) types. The frequency of dressing changes varies; heavily exudative ulcers may need daily dressings, whereas changes once weekly may suffice for drier ulcers. Occasionally, leeches may be used topically for ulcers with heavy adherent exudate.

Surrounding eczema should be suppressed with a topical glucocorticoid. Commonly, this is venous eczema, but there should be a low threshold for referral for patch testing, as contact allergy to topical applications is common. Systemic antibiotics are indicated only if there is

evidence of infection, as opposed to colonisation. Various techniques of split-thickness grafting (such as pinch and mince grafts) may hasten healing of clean ulcers but do not reduce recurrence risk. Leg ulcers can be very persistent but with accurate diagnosis and optimal management, healing is usually achievable. Symptomatic relief, including oral analgesics and sometimes chronic pain management, is important. Once the ulcer has healed, ongoing use of compression hosiery is advised to limit the risk of recurrence.

## Abnormal pigmentation

Loss of skin pigmentation (depigmentation), reduction in pigmentation (hypopigmentation) and increased pigment (hyperpigmentation) are features of a variety of disorders. A detailed history and examination, including use of a Wood's light, are required to establish the diagnosis. Investigations will depend on the presentation. For example, microscopy of skin scrapings should be undertaken if hypopigmentation is associated with inflammation and scaling; screening for autoimmune disease may be required if vitiligo is suspected; and investigation for endocrine disease or the porphyrias may be appropriate in hyperpigmentation. Further details of the specific conditions are discussed later in this chapter.

## Hair and nail abnormalities

Many conditions affect the skin appendages, particularly hair and nails. Conditions causing hair loss (alopecia) are listed in [Box 27.31](#). Nail changes may be a marker for systemic disease, such as iron deficiency, or be a feature of certain skin conditions, such as psoriasis.

## Acute skin failure

Acute skin failure is a medical emergency. Several conditions can cause widespread and acute failure of many skin functions (see [Box 27.1](#)), including thermoregulation, fluid balance control and barrier to infection. Many of these conditions involve widespread dilatation of the dermal vasculature and can provoke high-output cardiac failure; they are also associated with increased protein loss from the skin and often from the gut. Many lead to acute skin failure by causing erythroderma (erythema affecting at least 90% of the body surface area), although severe autoimmune blistering diseases and the spectrum of Stevens–Johnson syndrome/toxic epidermal necrolysis (TEN) disease can produce acute skin failure without erythroderma.

### Clinical assessment

Detailed history-taking and full examination are required. Particular attention should be paid to drug history, chronology and history of any preceding skin disease. Eczema, psoriasis, drug eruptions and cutaneous T-cell lymphoma (Sézary syndrome) are among the diseases that can either present with, or progress to, erythroderma. Other causes include the psoriasis-like condition pityriasis rubra pilaris, and rare types of ichthyosis. Erythroderma may occur at any age and is associated with severe morbidity and significant mortality (see [Fig. 27.36D](#)). Older people are at greatest risk, especially if they have comorbidities. Erythroderma may appear suddenly or evolve slowly. In dark skin, the presence of pigmentation may mask erythema, giving a purplish hue.

Erythrodermic patients are usually systemically unwell with shivering and hypothermia, secondary to excess heat loss. However, they may also be pyrexial and unable to lose heat due to damage to sweat gland function and sweat duct occlusion. Tachycardia and hypotension may be present because of volume depletion. Peripheral oedema is common in erythroderma, owing to low albumin and high-output cardiac failure. Lymph nodes may be enlarged, either as a reaction to skin inflammation or, rarely, due to lymphomatous infiltration.

## Investigations and management

Investigations are required to establish the underlying cause and to identify systemic involvement, such as hypoalbuminaemia, deranged liver and renal function and electrolyte imbalance. Skin biopsy may be necessary if the cause is unclear. Regardless of the cause, important aspects of the management of erythroderma include supportive measures to ensure adequate hydration, maintenance of core temperature and adequate nutrition. Insensible fluid loss can be many litres above normal losses. Protein may be lost directly from the skin and through the gut because of the protein-losing enteropathy that often accompanies conditions such as erythrodermic psoriasis. To reduce the risks of infection, any intravenous cannulae should be sited in peripheral veins, if possible. In the initial management of acute erythroderma, urinary catheterisation is often required (for patient comfort and accurate fluid balance monitoring) but catheters should be removed as soon as possible. Frequent application of a simple ointment emollient (such as white soft paraffin/liquid paraffin mix) is usually appropriate.

## Principles of management of skin disease

### General measures

General measures that apply in all skin diseases include establishment of the correct diagnosis, removal of precipitating or aggravating factors, use of safe, effective treatments and consideration of the patient holistically, taking into account the impact of the disease on quality of life and the person's support network. The psychological impact of chronic skin diseases should not be under-estimated and it is important to remember that psychiatric illness can also manifest as a skin disease, such as in delusions of infestation or trichotillomania. Careful clinical assessment is essential and any management strategy must also include approaches to address the psychological well-being of the patient.

### Topical treatments

Topical treatments are first-line therapy for most skin diseases, many of which can be treated effectively by topical agents alone. Selection of

the appropriate active drug/ingredient and vehicle is essential. Ointments are preferred to creams for dry skin conditions, such as chronic eczemas, as they are more hydrating and contain fewer preservatives than creams, and so allergy risk is reduced. However, patients find creams easier to apply and so adherence may be better. Gels and lotions can be easier to use on hair-bearing sites. The molecular weight and lipid-water coefficient of a drug determine its skin penetration, with larger, water-soluble, polar molecules penetrating poorly. In skin disease, if the stratum corneum is impaired – as in eczema – increased drug absorption occurs. Occlusion under dressings also increases absorption. Drugs can be used in different potencies or concentrations, or in combination with other active ingredients, and many are available in more than one formulation. The properties of different vehicles are listed in [Box 27.11](#). Overall, adherence to topical treatments can be problematic, so it is essential for patients to know exactly what is required of them and for regimens to be kept as simple as possible. Emollients, topical glucocorticoids and other selected key topical therapies that are widely used in a diverse range of skin conditions are detailed below. For the more disease-specific therapies, detailed descriptions are included in the disease sections.

### Emollients

These are mainstays in the treatment of eczema, psoriasis and many other conditions, and are used to moisturise, lubricate, protect and 'soften' skin. They are essentially vehicles without active drug and are available in many formulations: creams, ointments, gels and bath, shower and soap substitutes. White soft paraffin is the most effective and is widely used.

### Topical glucocorticoids

Glucocorticoids are available in a variety of formulations, potencies and strengths, most commonly as creams and ointments ([Box 27.12](#)). Selection of the correct product depends on the condition being treated, body site and duration of expected use. Mild topical glucocorticoids are used in delicate areas, such as the face or genitals, and close supervision of glucocorticoid use at these sites is required. In contrast, very potent glucocorticoids may be required under occlusion for chronic resistant disease such as nodular prurigo.

Adverse cutaneous effects of chronic glucocorticoid use include atrophy (**definition**: an area of thin, translucent skin caused by loss of

## 27.11 Characteristics of vehicles used in topical treatments

Vehicle	Definition	Use	Site	Cosmetic acceptability	Risk of contact sensitisation
<b>Creams</b>	Emulsions of oil and water (aqueous cream)	Acute presentations Cooling, soothing Well absorbed Mild emollients	All sites, including mucous membranes and flexures, but not hair-bearing areas	Very good Helps adherence	Significant, due to preservatives, antimicrobials and often lanolin
<b>Ointments</b>	Greasy preparations Insoluble in water (white soft paraffin) Soluble (emulsifying ointment)	Chronic dry skin conditions Occlusive and emollient Hydrating Mildly anti-inflammatory	Avoid hair-bearing areas and flexures	Moderate	Low
<b>Lotions</b>	Water-based Liquid formulation Often antiseptic and astringent (potassium permanganate)	Cooling effect Cleans the skin and removes exudates	Large areas of the skin and the scalp	Good, but can sting if in an alcoholic base	Rare
<b>Gels</b>	Thickened lotions Hydrophilic and hydrophobic bases	For specific sites	Hair-bearing areas and the face	Good	Low
<b>Pastes</b>	Semi-solid preparations consisting of finely powdered solids suspended in an ointment	Occlusive, protective Hydrating Circumscribed skin lesions, (psoriasis, lichen simplex chronicus)	Any area of skin Often used in medicated bandages	Moderate	Moderate

## 27.12 Potencies and strengths of commonly used topical glucocorticoid preparations\*

### Mild

- Hydrocortisone 0.5%, 1%, 2.5%
- Hydrocortisone 1% and fusidic acid 2% (Fucidin H)

### Moderate

- Clobetasone butyrate 0.05% (Eumovate)
- Betamethasone valerate 0.025% (Betnovate-RD)
- Fluocinolone acetonide 0.00625% (Synalar 1:4)

### Potent

- Betamethasone valerate 0.1% (Betnovate)
- Betamethasone valerate 0.1% and clioquinol 3% (Betnovate-C)
- Fluocinolone acetonide 0.025% (Synalar)
- Hydrocortisone butyrate 0.1% (Locoid)
- Mometasone furoate 0.1% (Elocon)

### Very potent

- Clobetasol propionate 0.05% (Dermovate)

\*UK proprietary names are given in brackets.

**Fig. 27.10** Striae and atrophy induced by excess prolonged potent topical glucocorticoid use.

epidermis, dermis or subcutaneous fat – Fig. 27.10), striae (**definition:** linear, atrophic, pink, purple or white bands caused by connective tissue changes – Fig. 27.10), petechiae and purpura (**definition:** haemorrhagic macules or papules caused by extravasated blood) and telangiectasiae (**definition:** visible dilatations of small cutaneous blood vessels – see Fig. 27.12A), increased risk of infection and systemic absorption, causing Cushingoid features and suppression of the hypothalamic–pituitary–adrenal axis. However, under-treatment with glucocorticoids is more common than over-treatment in routine clinical practice. In general, the lowest potency of glucocorticoid should be used for the shortest period to gain control of the disease; this can be achieved by initial use of a more potent glucocorticoid, with reduction in potency or frequency of application as control is gained. Tolerance or tachyphylaxis can develop with chronic use, so intermittent courses of treatment are advised. Caution is required with glucocorticoids in psoriasis, as rebound, unstable or pustular psoriasis can occur with sudden cessation of use. Nevertheless, glucocorticoids are invaluable for many sites, particularly the flexures. Topical glucocorticoids are often formulated in combination with antiseptics, antibiotics or antifungals, and their controlled use may be appropriate in infected eczema or flexural psoriasis. Intralesional injections of

## 27.13 Indications for dressings

- Protection
- Symptomatic relief from pain or itch
- Maintenance of direct application of topical treatment
- Possible improvement in healing time
- Reduction of exudate
- Reduction of odour

glucocorticoids can be used in a variety of indications, including nodular prurigo, keloid scar (**definition** of 'scar': replacement of normal structures by fibrous tissue at the site of an injury, although keloid scar describes a pathological process extending beyond the site of injury), acne cysts and alopecia areata.

### Anti-infective agents

Antiseptics should be considered before antibiotics, as they cover a wide range of organisms and help to reduce the risk of antibiotic resistance. Antibiotics can be used either for their anti-infective properties or for their anti-inflammatory properties. Topical antiviral and antifungal agents are also widely used for a range of mild skin infections.

### Calcineurin inhibitors

The topical calcineurin inhibitors tacrolimus and pimecrolimus can be used to treat eczema and a variety of other conditions, through local cutaneous immunosuppression.

### Immune response modifiers

Topical imiquimod was introduced for the treatment of anogenital warts but can be used for a diverse range of other skin diseases, including actinic keratosis, Bowen's disease, basal cell carcinoma, lentigo maligna, cutaneous lupus and common and planar warts. Its mechanism of action is via stimulation of endogenous Th2 immune responses and release of cytokines, including interferon-gamma (IFN- $\gamma$ ). It can cause significant inflammation, requiring dose adjustments, but subclinical disease may respond to treatment.

### Dressings

A 'wound' covering is called a dressing. Box 27.13 shows the indications for their use. The active agent, vehicle and 'wound' type should be considered. Wet lesions should be treated with wet dressings. Paste bandages can be used in conjunction with topical emollients and glucocorticoids to soothe and cool, ease pruritus and scratching, and reduce inflammation. Dressings for venous leg ulcers are described later in this chapter.

### Phototherapy and photochemotherapy

Ultraviolet radiation (UVR) treatments (most commonly, narrowband ultraviolet B and psoralen–ultraviolet A (PUVA)) are used in the management of many different diseases. The best evidence for their efficacy is in psoriasis, atopic eczema, vitiligo and chronic urticaria, although there is also evidence that UVB is helpful in treating generalised itch associated with chronic kidney disease and a range of other diverse skin conditions.

Psoralens are natural photosensitisers found in a number of plants. They intercalate between the strands of DNA and, on excitation with UVA, cross-link the DNA strands. Psoralens are therefore prodrugs that are activated only in skin that is exposed to UVA. Psoralens can also be applied topically in a bath before irradiation with UVA (bath PUVA) or can

be applied in creams or gels for localised topical PUVA. PUVA is a more complex treatment than UVB and has more adverse effects; in particular, cumulative exposure to PUVA increases the risk of skin cancer, particularly squamous cell carcinoma. Therefore, PUVA is generally used for poor responders to UVB, or in diseases such as plaque-stage cutaneous T-cell lymphoma or pityriasis rubra pilaris, where it is the phototherapy of first choice. Phototherapy or PUVA may be offered as a whole-body or localised treatment.

Longer-wavelength UVA1 (340–400nm) is also used for several conditions, particularly the fibrosing skin diseases such as morphea, where efficacy has been shown and there is a lack of other well-proven therapies. The evidence base for its place in the management of several diseases, such as eczema, is not fully proven and availability of UVA1 is mainly through tertiary referral centres with expertise in photodermatology and phototherapy.

## Systemic therapies

General information is provided here for drugs used in a range of skin diseases; details of other drugs are provided in disease-specific sections.

### Antibiotics

Antibiotics are widely used for their anti-infective properties, particularly for staphylococcal and streptococcal skin infections. In these indications, the correct antibiotic should be selected, based on bacterial sensitivity and patient factors. As examples, oral flucloxacillin may be indicated for clinically infected eczema, intravenous flucloxacillin for cellulitis, and clarithromycin for a patient with a staphylococcal carbuncle who is penicillin-allergic. Optimal therapeutic doses and courses must be chosen, based on local antimicrobial prescribing guidelines. Several antibiotics, such as tetracyclines, erythromycin and co-trimoxazole are used predominantly for their anti-inflammatory effects in indications such as acne vulgaris, bullous pemphigoid and pyoderma gangrenosum.

### Antihistamines

A range of H<sub>1</sub>- and H<sub>2</sub>-receptor antagonists are used in dermatology. For diseases in which histamine in the skin is relevant (such as urticaria), non-sedating antihistamines should be given: for example, fexofenadine or cetirizine. For pruritic conditions such as eczema, the sedating effect of antihistamines like hydroxyzine or chlorphenamine is important. However, antihistamines are widely used in older patients for the symptom of pruritus due to a variety of causes such as xeroderma, metabolic impairment, malignancy or concomitant drugs. Sedating antihistamines should be used with caution in older patients, as they may increase the risk of falls and accidents in the home, with disastrous consequences. Careful choice of drug and dose is therefore essential. Leukotriene receptor antagonists, such as montelukast, may be added to antihistamine regimens, for additional mast cell stabilising effects.

### Retinoids

Oral retinoids are used in a range of conditions, including acne, psoriasis and other keratinisation disorders. They promote differentiation of skin cells and have anti-inflammatory effects. Isotretinoin (13-*cis*-retinoic acid) is widely used for moderate to severe acne. Acitretin can be effective in psoriasis and other keratinisation disorders, such as ichthyosis, as can alitretinoin (9-*cis*-retinoic acid) in hand and foot eczema and bexarotene in cutaneous T-cell lymphoma.

Adverse effects of retinoids include dryness of the skin and mucous membranes, abnormalities in liver function or hepatitis, increase in serum triglycerides (levels should be checked before and during therapy) and mood disturbances. Alitretinoin and bexarotene can cause hypothyroidism. Systemic retinoids are teratogenic and must be prescribed along

with a robust form of contraception. Females must have a negative pregnancy test before, during and after therapy, and pregnancy must be avoided for 2 months after stopping isotretinoin and 2 years after stopping acitretin.

## Immunosuppressants

Systemic glucocorticoids, particularly prednisolone, are widely used in inflammatory skin diseases, such as eczema, immunobullous disease and connective tissue disorders. Methotrexate, azathioprine and mycophenolate mofetil are effective in eczema and psoriasis either alone or as glucocorticoid-sparing agents. Further details on the mechanism of action, adverse effects and monitoring requirements for these agents are provided in [Chapter 26](#) (see [Box 26.33](#)). Hydroxycarbamide is an alternative immunosuppressant to methotrexate in psoriasis, but is not licensed for this indication and appears to be less effective than methotrexate. The risk of myelosuppression is greater. Dimethyl fumarate is also used off label in the treatment of psoriasis. Cyclosporin has a rapid onset of action and is effective in inducing clearance of psoriasis and eczema. Monitoring of blood pressure and renal function is required. Cyclosporin should be used only with caution after phototherapy, particularly PUVA, because of the increased risk of skin cancer. Long-term use of cyclosporin is not advised. Dapsone is an immunomodulator and may be used in diseases in which neutrophils are implicated, such as dermatitis herpetiformis. Haemolysis, methaemoglobinaemia and hypersensitivity can occur, and monitoring is required. Hydroxychloroquine is of particular value in cutaneous lupus.

## Biologic and other advanced therapies

Major advances in the treatment of inflammatory skin diseases have been made in recent years through increased understanding of pathophysiology, the identification of new molecular targets for drug design and the introduction of biological treatments and small molecules that target specific signalling pathways involved in the inflammatory response. Biologic treatments work by binding to and neutralising pro-inflammatory cytokines or components of their receptors whereas small molecule inhibitors target intracellular signalling pathways situated downstream of cytokine receptors.

Multiple biologics are available for the treatment of severe or treatment-resistant psoriasis. These include multiple inhibitors of tumour necrosis factor alpha (TNF- $\alpha$ ) (adalimumab, certolizumab, etanercept and infliximab), ustekinumab, which inhibits interleukin (IL)-12 and IL-23 by binding to the p40 component of both cytokines; guselkumab, which is a specific inhibitor of IL-23; ixekizumab and secukinumab, which are inhibitors of IL-17; and brodalumab, which inhibits the IL-17 receptor ([Fig. 27.11](#)).

Dupilumab is an antibody that targets the IL-4 receptor alpha chain subunit, which is common to both IL-4 and IL-13 receptors. It has been shown to be efficacious in the treatment of severe atopic dermatitis resistant to standard therapies. Tralokinumab and lebrikizumab are specific inhibitors of IL-13 which are also showing promise in the treatment of severe atopic dermatitis but these are not yet licensed for clinical use ([Box 27.14](#)). Omalizumab, a monoclonal antibody directed against immunoglobulin E (IgE), which is used in severe asthma, also has a role in the treatment of urticaria and some patients with atopic dermatitis. Small molecule targeted synthetic immunosuppressives have also been developed. Apremilast inhibits phosphodiesterase-E4 (PDE-4) reducing cytokine production by immune cells and is used in psoriasis. Crisaborole, another PDE-4 inhibitor, is under development for the treatment of psoriasis. Baricitinib and upadacitinib, which inhibit Janus activated kinase (JAK) enzymes that are involved in signalling downstream of several cytokine receptors, are also used in psoriasis and atopic dermatitis. Rituximab, which binds to CD20 causing depletion of B cells, is used in pemphigus vulgaris. Intravenous immunoglobulin, pooled from donor plasma, may be used in the treatment of dermatomyositis and occasionally may be indicated in other dermatological diseases. More detail on the dosages, mechanism of action and adverse effects of these agents

**Fig. 27.11** Biologic and targeted therapies in inflammatory skin diseases.

Biologic treatments for inflammatory rheumatic diseases work by targeting key cytokines or their receptors involved in regulating the immune response. (IL = interleukin; Th = T-helper cell subtype; TNF $\alpha$  = tumour necrosis factor alpha; TNFi = inhibitor of tumour necrosis factor alpha; PDE4 = phosphodiesterase E4; JAK = Janus activated kinase; PKA = protein kinase A; STAT = signal transducers and activators of transcription; cAMP = cyclic adenosine monophosphate)

are provided in [Chapter 26](#) (see [Box 26.35](#)). Other new treatments that are under development include: nemolizumab, which targets the IL-31 receptor and improves itching in atopic dermatitis; ponesomid and fingolimod, which target the sphingosine-1-phosphate pathway, which is involved in trafficking immune cells into the skin; fezakinumab, which inhibits IL-22, a proinflammatory cytokine implicated in the pathogenesis of psoriasis and atopic dermatitis; and tapinarof, a small molecule modulator of the aryl hydrocarbon receptor which is a transcription factor

27.14 New and emerging therapies for inflammatory skin disease				
Drug	Class and type of drug	Molecular target	Function of target	Indication
Tralokinumab	Mab inhibitor	IL-13	Pro-inflammatory cytokine	Atopic dermatitis
Lebrikizumab	Mab inhibitor	IL-13	Pro-inflammatory cytokine	Atopic dermatitis
Fezakinumab	Mab inhibitor	IL-22	Pro-inflammatory cytokine	Atopic dermatitis
Nemolizumab	Mab inhibitor	IL-31	Mediator of itch	Atopic dermatitis
Crisabrole	Small molecule inhibitor	PDE4	Regulates cytokine production by immune cells	Atopic dermatitis Psoriasis
Fingolimod	Small molecule inhibitor	S1PR	Trafficking of immune cells to the skin	Atopic dermatitis
Ponesimid	Small molecule inhibitor	S1PR	Trafficking of immune cells to the skin	Atopic dermatitis
Tapinarof	Small molecule agonist	Aryl hydrocarbon receptor	Inhibits production of inflammatory cytokines	Atopic dermatitis Psoriasis

(Mab = monoclonal antibody)

involved in regulating production of IL-17 and other cytokines in the skin. Tumour targeted kinase inhibitors and biologics directed against CTLA-4 and the programmed cell death (PD1) pathways which are used in the treatment of melanoma are discussed later in this chapter.

## Dermatological surgery

Most dermatological surgical procedures are performed under local anaesthetic. Knowledge of local anatomy is essential, particularly the locations of vessels and nerves. In certain sites, such as the fingers, soles of the feet and the nose, local cutaneous nerve blocks are useful. Some sites are associated with particular risks, such as keloidal scarring on the upper trunk of young patients, unsightly scars over the scapulae, and poor healing and risk of ulceration following procedures on the lower legs.

## Excision biopsy

This involves surgical removal of the lesion followed by histological examination. The most common indication is suspicion of malignancy. The lesion and line of excision should be marked out and the margin of excision decided before the procedure. It is important to excise down to the appropriate anatomical plane. Depending on body site, a range of procedures can minimise the resulting defect. Healing by secondary intention may also achieve good cosmetic results.

## Curettage

Curettage involves using a small, spoon-shaped implement (curette), not only as a definitive treatment but also to obtain histology. Curettage does not preserve tissue architecture very well, however, and it may be difficult to distinguish between dysplasia and invasive malignancy. It can be an effective treatment for basal cell papilloma, actinic keratosis, intra-epidermal carcinoma and superficial basal cell carcinoma.

## Shave excision

Shave excision using local anaesthetic may be used for simple and effective treatment of raised superficial benign skin lesions affecting epidermis and upper dermis, such as benign naevi and skin tags.

## Mohs' micrographic surgery

Mohs' micrographic surgery is employed to ensure adequate tumour excision margins, while conserving unaffected tissue. It is most commonly used for basal cell carcinoma.

## Non-surgical treatments

### Cryotherapy

Cryotherapy is a destructive treatment using liquid nitrogen to cause cell-wall and membrane destruction and cell death. Liquid nitrogen can be applied either with a cotton bud or, more effectively, with a spray gun. A wide variety of conditions can be treated but it is essential for the correct diagnosis to be made first, if necessary by diagnostic biopsy. Cryotherapy should not be used to treat melanocytic naevi. Benign lesions, such as viral warts and basal cell papilloma, respond well, and cryotherapy can also be effective for actinic keratosis, Bowen's disease or superficial non-melanoma skin cancer. Malignant indications require more vigorous treatment, usually with two cycles, and this is normally carried out in secondary care. Considerable inflammation, blistering and pigmentary change, particularly hypopigmentation, can occur. Caution is required to avoid damage to tendons and nerves, especially when using cryotherapy on digits.

### Laser therapy

Laser therapy involves treatment with monochromatic light. Skin components (chromophores), such as haemoglobin and melanin, absorb specific wavelengths of electromagnetic radiation, and these wavelengths can therefore be used to destroy these targets selectively and to treat certain skin disorders. Lasers targeting haemoglobin are employed for vascular abnormalities, such as spider naevi, telangiectasiae and port-wine stains, and lasers targeting melanin can treat benign pigmentary disorders or pigment in tattoos or drug-induced hyperpigmentation (for example, secondary to minocycline). Melanin-targeted lasers can also be used for hair removal if the hair is pigmented. Light delivery in short pulses restricts damage to the treated site.

The carbon dioxide laser emits infrared light that is absorbed by water in tissues and can therefore be used for destructive purposes. The depth of effect can be controlled, such that the carbon dioxide laser is widely employed for resurfacing in photorejuvenation or acne scarring. Significant morbidity is associated with this destructive laser, although this may be minimised with fractionated regimens, and general anaesthesia may be required.

### Photodynamic therapy

Photodynamic therapy (PDT) is widely used in dermatology, predominantly for actinic keratoses, Bowen's disease and superficial basal cell carcinoma.

### Radiotherapy and grenz (Bucky) ray therapy

Radiotherapy can be employed for several skin conditions, including non-melanoma skin cancer or lentigo maligna that is not suitable for surgical treatment, but its use in dermatology has declined. Scarring and poikiloderma can occur at treated sites, although these are minimised if fractionated regimens are chosen. Superficial radiotherapy is now rarely

employed to treat benign dermatoses. Even more superficial ionising radiation (grenz (Bucky) rays) can be useful for localised dermatoses that are having severe effects on quality of life, if conventional treatments have been inadequate; for example, it may avoid the need for systemic immunosuppression in a patient with severe recalcitrant localised scalp psoriasis.

## Skin tumours

### Pathogenesis

Skin cancer is the most common malignancy in fair-skinned populations. It is subdivided into non-melanoma skin cancer (NMSC) and melanoma. NMSC is further subdivided into the most common skin cancer, basal cell carcinoma (BCC), and squamous cell carcinoma (SCC). The latter has precursor non-invasive states of intra-epithelial carcinoma (Bowen's disease, BD) and dysplasia (actinic keratosis, AK). Melanoma is much less common than NMSC, but because of its metastatic risk it is the cause of most skin cancer deaths.

UVR is a complete carcinogen and is the main environmental risk factor for skin cancer, which is much more common in countries with high ambient sun exposure, such as Australia. Skin cancer risk also increases if an individual migrates to such a country when young, particularly if less than 10 years of age. Epidemiological evidence supports a close link between chronic UVR exposure and risk of SCC and AK, and a modest link between sun exposure and BCC risk. Melanoma usually arises on sites that are intermittently exposed to UVR, and episodes of sunburn and recreational sun exposure have been implicated as risk factors for melanoma. There is good evidence to show that sunbed exposure is also a risk for both melanoma and NMSC, particularly when exposure starts in adolescence and early adult life. Strategies to reduce sun exposure are therefore important for skin cancer prevention, with reliance mainly on behavioural modification, covering up and judicious sunscreen use. Indeed, there is evidence to show that sunscreen use reduces naevi development in children, and in adults regular sunscreen use reduces the risk of AK and SCC and is likely also to have preventative roles in melanoma and BCC development.

There are identifiable genetic predispositions for some skin cancers, such as in xeroderma pigmentosum, an autosomal recessive condition caused by an inherited defect in DNA excision repair, and basal cell naevus (Gorlin) syndrome, an autosomal dominant disorder caused by loss-of-function mutations affecting the *PTCH1* tumour suppressor genes, with consequent activation of the Hedgehog pathway. Interestingly, the Hedgehog pathway is also almost invariably activated in sporadic BCC, which usually contain somatic mutations in *PTCH1* and less commonly in the *SMO* gene, which lies in the same signalling pathway. The genetics of SCC are heterogeneous and less clearly defined, with several mutations and pathways implicated, including *TP53*, *CDKN2A/p16*, *NOTCH*, *EGFR* and the *MAPK* signalling pathways. Interestingly, many of the mutations seen in SCC also occur in the pre-cancers AK and BD. The genetics of melanoma are discussed later in this chapter.

Cutaneous immune surveillance is also critical and immunosuppressed organ transplant recipients have a greatly increased risk of skin cancer, particularly SCC. Interestingly, patients who have received high treatment numbers of PUVA (more than 150), which is immunosuppressive, are also at increased risk of skin cancer, particularly SCC.

Although UVB can increase the risk of skin cancer, there is no evidence to date that UVB phototherapy significantly increases skin cancer risk. Likewise, there is no evidence that UVA1 phototherapy increases skin cancer risk, although ongoing vigilance is required. Ionising radiation, notably radiotherapy, thermal radiation and chemical carcinogens, such as arsenic or coal tar, can increase NMSC risk, particularly SCC. A role for oncogenic human papillomaviruses in SCC development is also implicated, particularly in immunosuppressed patients, where viral DNA is detected in more than 80% of tumours. Chronic inflammation

is a risk factor for SCC, which may arise in chronic skin ulcers, discoid lupus erythematosus or vulgaris, and the scarring genetic skin disease dystrophic epidermolysis bullosa (see Box 27.26), in which up to 50% of patients develop SCC.

## Malignant tumours

### Basal cell carcinoma

The incidence of NMSC has increased dramatically in recent decades and basal cell carcinoma (BCC) accounts for more than 70% of cases. In Europe, the ratio of BCC to SCC is 4–5:1 in immunocompetent patients. It is a malignant tumour that rarely metastasises; it is thought to derive from immature pluripotent epidermal cells and is composed of cells with similarities to basal layer epidermis and appendages. Lesions typically occur at sites of moderate sun exposure, particularly the face, and are slow-growing. The incidence increases with age and males are more commonly affected. Lesions may ulcerate and invade locally; hence the term ‘rodent ulcer’.

#### Clinical features

Early BCCs usually present as pale, translucent papules or nodules, with overlying superficial telangiectatic vessels (nodular BCC). If untreated, they increase in size and ulcerate, to form a crater with a rolled, pearly edge and telangiectatic vessels (Fig. 27.12). There may be some pigmentation or a cystic component. A superficial multifocal type can occur, frequently on the trunk, and may be large (up to 10 cm in diameter); often there are multiple lesions. Superficial BCC usually presents as a red/brown plaque or patch with a raised, thread-like edge, which is often best seen by stretching the skin; this helps to distinguish it from Bowen’s disease. Less commonly, a morpheic, infiltrative BCC presents as a poorly defined, slowly enlarging, sclerotic yellow/grey plaque.

#### Diagnosis and management

The diagnosis is often obvious clinically, based on the features mentioned above, although a diagnostic confirmatory biopsy may be required prior to definitive treatment. Management depends on the characteristics of the tumour and on patient factors, including comorbidities and patient wishes. Essentially, treatment will be either surgical or, in some cases, medical (Box 27.15). Surgical excision, ideally with a 4–5 mm margin, is the treatment of choice, with a cure rate of approximately 95%. Curettage and cautery may also be effective for selected lesions. Management of infiltrative morpheic BCC and/or lesions at difficult sites, such as around

the eye, may require more complex techniques, such as Mohs’ micrographic surgery, to ensure adequate tumour excision margins, while conserving unaffected tissue. This involves processing of frozen sections of all margins in stages (usually on the same day) until all the tumour is removed. The procedure is time-consuming (so can be difficult for older, frail patients) and requires particular surgical and pathology skills, but is associated with the highest long-term cure rates, with 98%–99% clear at 5-year follow-up.

If a surgical approach is used for management of BCC and the primary tumour is not completely excised, re-excision may be required, although follow-up may be appropriate as not all tumours that are incompletely excised recur. However, this is not recommended for tumours at high-risk sites or for infiltrative morpheic BCC, where complete excision is advisable. Cryotherapy may be effective for BCC but can cause blistering and scarring, so is best suited to small, superficial lesions at low-risk sites.

Radiotherapy can be invaluable for large BCC lesions in frail patients but is less commonly used because of the risk of scarring.

Medical therapies can be used to treat low-risk BCC, particularly when surgery is not appropriate for a patient. Topical immunomodulators, such as imiquimod, are effective for low-risk BCC and may be particularly useful for patients who are not able to attend a hospital clinic setting but are able to apply a topical preparation at home over a 6-week period. Imiquimod usually induces a prominent inflammatory reaction and patients should be advised that dose adjustments may be required. Topical 5-fluorouracil can also be effective for low-risk small lesions of superficial BCC, although this usually provokes an intense inflammatory reaction. Intralesional interferon- $\alpha$ 2b has been used for BCC but multiple treatments and high cost preclude its regular use.

PDT is an effective treatment for low-risk, predominantly superficial BCC, as well as AK and BD. Usually, topical porphyrin PDT is employed, which involves application of a porphyrin prodrug to the lesion to be treated. The prodrug is taken up and converted by the cell’s haem cycle to protoporphyrin IX, a photosensitiser. This is

**Fig. 27.12** Basal cell carcinoma. **A** A nodular BCC showing the translucent nature of the tumour and the abnormal arborising vessels. **B** An ulcerated BCC showing the raised, rolled edge.

### 27.15 Management of non-melanoma skin cancer and pre-cancer

#### Basal cell carcinoma

- Excision results in the lowest recurrence rates
- Mohs’ micrographic surgery is effective for high-risk BCC
- Medical treatments are often appropriate for low-risk superficial tumours in patients with comorbidities
- Cryotherapy and topical 5-fluorouracil can be used for superficial BCC
- Topical photodynamic therapy and topical imiquimod are both effective in superficial BCC
- BCC in patients with Gorlin syndrome should not be treated with radiotherapy
- Hedgehog pathway inhibitors can induce clinical response in patients with advanced inoperable BCC

#### Squamous cell carcinoma

- Excision is the treatment of choice for invasive SCC
- Most recurrences or metastases occur within 5 years
- Medical management is not usually considered for invasive SCC

#### Carcinoma in situ (Bowen’s disease)

- For single/few lesions on good healing sites, cryotherapy, curettage, photodynamic therapy, topical imiquimod and 5-fluorouracil are options
- For multiple lesions and/or poor healing sites such as the lower leg, photodynamic therapy, where feasible, is the treatment of choice, although topical 5-fluorouracil or imiquimod are alternative treatments

#### Actinic keratosis

- For single/few lesions on good healing sites, cryotherapy, curettage and 5-fluorouracil + salicylic acid are options, especially if hyperkeratotic
- For multiple lesions/field change, topical 5-fluorouracil, conventional or daylight photodynamic therapy, imiquimod or diclofenac in hyaluronic acid gel may be effective

photochemically activated by visible (normally red) light, usually delivered by a light-emitting diode (LED), in the presence of oxygen, causing the production of reactive oxygen species, which cause destruction of treated tissue. The photosensitiser is taken up preferentially by diseased skin, and adverse effects in normal skin are minimised. PDT is at least as effective as cryotherapy and surgery for superficial BCC and may be preferred at sites of poor healing, such as the lower leg, or where cosmetic outcome is important. PDT is not as effective as surgery for long-term clearance of nodular BCC but can be considered if surgery is not appropriate. Pain during irradiation may occur during PDT, although adjustments to the irradiation regime can reduce discomfort and treatment is usually well tolerated. PDT is typically undertaken in the outpatient clinic setting and is well suited to frail patients and those unable to undertake treatment with topical agents at home.

Rarely, advanced BCC may be locally invasive or even metastasise. Major advances have been made in targeted drug development, and Hedgehog pathway inhibitors, such as vismodegib and sonidegib, can be used effectively for disease control and palliation in this setting, although there may be significant associated drug-induced toxicity.

## Squamous cell carcinoma

Squamous cell carcinoma (SCC) is a malignancy that arises from epidermal keratinocytes and is the second most common skin cancer, occurring most frequently in older adult males and smokers. There is a close association between cumulative UVR exposure and SCC risk, with most SCC lesions occurring on chronically sun-exposed sites in light-skinned populations and often arising at sites of field-change carcinogenesis, with coexistent precursors of AK and BD commonly evident. In the immunosuppressed patient population, such as organ transplant recipients, SCC is the most common skin cancer and its incidence is dramatically increased, particularly in association with the duration of immunosuppression and the degree of sun exposure and damage accrued pre-transplant. The risk of SCC is also increased in HIV infection. Furthermore, SCC arising in the immunosuppressed is more likely to behave aggressively or to metastasise.

### Clinical features

The tumours usually occur on chronically sun-exposed sites, such as bald scalp, tops of ears, face and back of hands. The clinical presentation may be diverse, ranging from rapid development of a painful keratotic nodule in a pre-existing area of dysplasia (Fig. 27.13) to the de novo presentation of an erythematous, infiltrated, often-warty nodule or plaque that may ulcerate. The clinical appearance depends on histological grading; well-differentiated tumours more often present as defined

**Fig. 27.13 Squamous cell carcinoma.** **A** A centrally keratinous, symmetrical, well-differentiated SCC. Clinically, this could be confused with keratoacanthoma. **B** An SCC arising from an area of epidermal dysplasia.

keratotic nodules (Fig. 27.13A), whereas poorly differentiated tumours tend to be ill defined and infiltrative, and may ulcerate. SCC has metastatic potential; some tumours, such as those on lips and ears and in immunosuppressed patients, behave more aggressively and are more likely to metastasise to draining lymph nodes.

### Management

Early diagnosis is important and complete surgical excision is the usual treatment of choice (see Box 27.15). Standard excision with a 4–6 mm margin is advised and the cure rate is approximately 90%–95%. Mohs' surgery is an option but is used less frequently for SCC than for BCC. High-risk SCC should be treated aggressively, with a wider margin of excision of at least 6 mm where feasible. This may include larger, thicker lesions, tumours at sites where metastases are more likely, such as the ear, lip or non-sun-exposed sites, and those occurring in the immunosuppressed and/or with histology showing the tumour to be poorly differentiated, with evidence of lymphatic, vascular or perineural involvement or a high mitotic index. Such patients and those with metastatic disease require management via a multidisciplinary team. In patients who are at high risk for further SCC, systemic retinoids may have a role in reducing the rate of SCC development, but rapid appearance of tumours occurs on drug cessation. Occasionally, curettage and cautery may be appropriate if the tumour is small and low-risk and either surgical excision is contraindicated or the patient is unwilling to proceed with excision. Radiotherapy may be indicated if surgical excision is not feasible. Cryotherapy and topical non-surgical therapies are not usually used in invasive SCC because of risk of recurrence and metastasis.

## Actinic keratosis

Actinic keratoses (AK) are scaly, erythematous lesions arising on chronically sun-exposed sites. Histology shows dysplasia, although the diagnosis of typical AK is usually made on clinical grounds (Fig. 27.14). They are common in fair-skinned people who have had significant sun exposure, are often multiple and increase with age. The prevalence is much higher in Australia than in the UK and some surveys have shown a prevalence of more than 50% in those over 40 years old. The rate of progression to SCC is less than 0.1% and spontaneous resolution is possible. However, SCC can also arise de novo and without progression from AK. Increase in size, ulceration, bleeding, pain or tenderness can be indicative of transformation into SCC.

**Fig. 27.14 Actinic keratosis.** Close-up of a hyperkeratotic AK on the ear.

## Management

Several treatments are available for AK (see [Box 27.15](#)). Emollients and photoprotection, including high-factor sunscreens, may suffice for mild disease. Single or low numbers of lesions of AK can be effectively treated with cryotherapy. Hyperkeratotic lesions may be treated with the antimetabolite 5-fluorouracil, combined with salicylic acid, or may require curettage and cautery.

Multiple lesions require field-directed therapy; 5-fluorouracil is widely used in this setting as an effective initial therapeutic approach and topical imiquimod is an alternative. Diclofenac in a hyaluronic acid gel base can also be used topically for low-grade maintenance control of AK, the rationale for its use being the over-expression of cyclo-oxygenase (COX)-2 in AK lesions. PDT is widely used for field-change multiple AK, with high efficacy rates; it is at least as effective as cryotherapy or 5-fluorouracil. The relative selectivity of treatment allows subclinical disease to be treated, while sparing normal skin. A regimen using daylight to activate the photosensitiser is increasingly and widely used for extensive mild AK, with high efficacy rates, comparable to hospital-based PDT but without the need for specialised equipment and allowing patients to be treated at home.

## Bowen's disease

### Clinical features

Bowen's disease (BD) is the name given to an intra-epidermal carcinoma that usually presents as a slowly enlarging, erythematous, scaly plaque on the lower legs of fair-skinned older women ([Fig. 27.15](#)) but other sites can also be involved. It can be confused with eczema or psoriasis, but is usually asymptomatic and does not respond to topical glucocorticoids. It may also be hard to distinguish from superficial BCC. Transformation into SCC occurs in 3% or less.

### Diagnosis

Incisional biopsy is usually undertaken to confirm the diagnosis. This shows an intra-epidermal carcinoma with no invasion through the basement membrane. Histology may also be obtained by curettage but this does not allow distinction from invasive SCC to be made, due to loss of tissue orientation and architecture.

### Management

While curettage or excision may be appropriate in some settings, non-surgical therapies are generally preferred (see [Box 27.15](#)), especially on the lower legs. PDT, in particular, may be advantageous for BD on the lower leg because of relative selectivity of treatment and sparing of normal tissue, thus reducing the risk of poor healing and ulceration at this vulnerable site. Given the low risk of malignant transformation, the option of no active treatment may also be appropriate for some frail patients with multiple co-morbidities.

## Cutaneous lymphomas

The most common form of cutaneous T-cell lymphoma is mycosis fungoides (MF). This can persist for years in patch and plaque stages,

**Fig. 27.15** Intra-epidermal carcinoma (Bowen's disease). The lower leg is a common site and lesions are often treated non-surgically.

often resembling eczema or psoriasis. Only sometimes does it progress through to nodules and finally a systemic stage, Sézary syndrome. B-cell lymphomas, on the other hand, usually present as nodules or plaque-like tumours. The diagnosis of cutaneous T-cell lymphoma requires a high index of suspicion, particularly in patients thought to have unusual recalcitrant forms of eczema or psoriasis.

Treatment is symptomatic and there is no evidence that it alters prognosis. In the early stages of cutaneous T-cell lymphoma, systemic or local glucocorticoids may be indicated; alternatively, narrowband UVB phototherapy (for patch-stage MF) or PUVA (for plaque-stage MF) may be used. Once lesions have moved beyond plaque stage, localised radiotherapy, electron beam radiation, the synthetic retinoid bexarotene, interferon- $\alpha$ , extracorporeal photopheresis and systemic anti-lymphoma chemotherapy regimens may be needed. Management of advanced disease invariably requires a multidisciplinary team approach, with collaboration between dermatologists, pathologists and haematological oncologists.

## Melanoma

Melanoma is a malignant tumour of epidermal melanocytes. While only 4% of skin cancers are melanomas, they account for 80% of skin cancer deaths. There has been a steady rise in the incidence of melanoma in fair-skinned populations over recent decades, with the highest incidence in Australasia. Primary prevention and early detection are essential, as therapy for advanced and metastatic disease, whilst being a rapidly evolving field, remains challenging and unsatisfactory.

### Pathophysiology

Risk factors for melanoma include fair skin, freckles, red hair, number of naevi and sunlight exposure. The type of sunlight exposure is under debate but intermittent exposure, such as recreational time in the sun, sunburn and sunbed use, is implicated. Patients with multiple atypical naevi (dysplastic naevus syndrome) and fair-skinned people, often with variant alleles in the melanocortin-1 gene, are at increased risk of melanoma. A family history of melanoma increases the risk but a strong family history is unusual. Rarely, autosomal dominant inheritance of melanoma with incomplete penetrance can occur due to mutations in *CDKN2A*, which encodes the p16 tumour suppressor protein. In these patients, the lifetime risk of melanoma is more than 50%. Several other susceptibility genes and potential genetic targets for therapeutic intervention in advanced disease have also been identified.

### Clinical features

Melanoma can occur at any age and site and in either sex, but typically affects the leg in females and back in males. It is rare before puberty. The classification of invasive malignant melanoma is shown in [Box 27.16](#). Early lesions may be in situ and pre-invasive before becoming invasive melanoma with metastatic potential. Any change in naevi or development of new lesions should be assessed to exclude malignancy and, for this, the dermatoscope is invaluable (see [Fig. 27.2](#)). Real-time non-invasive imaging techniques are being investigated as tools to assist in diagnosis but are largely experimental. If there is any doubt, excision is advised.

### Superficial spreading melanoma

Superficial spreading melanoma (SSM) is the most common type in light-skinned populations. It usually presents as a slowly enlarging, macular, pigmented lesion, with increasing irregularity in shape and pigment; this superficial, radial growth phase can last for approximately 2 years. Subsequently, the lesion may become palpable and this is indicative of a vertical growth phase, with dermal invasion; when this occurs, the tumour has the potential to invade lymphatics and vessels and to become metastatic ([Fig. 27.16A](#)). Approximately 50% of melanomas arise from a pre-existing naevus.

### Nodular melanoma

Nodular melanoma is most common in the fifth and sixth decades, particularly in men and on the trunk ([Fig. 27.16B](#)). This may account in part

27.16 Classification of cutaneous malignant melanoma	
<b>Melanoma without metastatic potential</b>	
• Melanoma in situ	• Lentigo maligna
<b>Melanoma with metastatic potential</b>	
• Superficial spreading melanoma	• Acral lentiginous melanoma
• Nodular melanoma	• Subungual melanoma
	• Lentigo maligna melanoma

**Fig. 27.16 Superficial spreading melanoma.** **A** A superficial spreading malignant melanoma with a palpable area indicative of vertical growth phase (Breslow thickness 1.3 mm). **B** A nodular malignant melanoma arising de novo and with Breslow thickness of 3.5 mm.

for the increased mortality rates from melanoma in men, as these are tumours with greater metastatic risk. They often present as a rapidly growing nodule that may bleed and ulcerate. Nodular melanomas may be heavily pigmented, or relatively amelanotic and erythematous, and be confused with benign vascular lesions. A rim of pigmentation may, however, be seen under the dermatoscope. Lesions may develop de novo or from a pre-existing naevus or SSM.

#### Lentigo maligna melanoma

This arises from a prolonged pre-invasive phase termed lentigo maligna. It occurs as a very slowly expanding, pigmented, macular lesion, usually on photo-exposed head and neck sites of older patients; histology shows in situ changes only. This phase may last for several years before a nodule of invasive melanoma develops in a proportion of cases (lentigo maligna melanoma).

#### Acral lentiginous or palmoplantar melanoma

This accounts for only approximately 10% of melanomas in light-skinned races and is more common in dark-skinned people, in whom it is responsible for 50% of cases. This indicates that UVR exposure may not be implicated in acral melanoma risk.

#### Subungual melanoma

This form of melanoma is rare. It may present as a painless, proximally expanding streak of pigmentation arising from the nail matrix, and progresses to nail dystrophy and involvement of the adjacent nail fold (Hutchinson's sign).

#### Diagnosis and management

The diagnosis is made by excision biopsy of a suspicious lesion. The initial biopsy should include a 2 mm margin, followed up where possible by wider excision if the diagnosis is confirmed. Occasionally, radiotherapy or imiquimod may be used for lentigo maligna, if surgery is not feasible. The Breslow thickness of the tumour (the maximal depth from epidermal granular cell layer to deepest tumour cells) is critical for management and prognosis. The presence of ulceration may lead to under-estimation of the Breslow thickness and may also adversely affect prognosis. The mitotic rate and the presence or absence of any evidence

of lymphovascular or perineural involvement should also be ascertained. The clinical staging of melanoma extent is essential, in order to establish whether disease is primary and localised, or if there is nodal or metastatic spread.

Wide excision of melanoma with a low risk of metastasis (stage 1 disease, Breslow thickness <1 mm) with a 1 cm clear margin is accepted practice. The margin of excision for more advanced disease is controversial, although a 2–3 cm margin for thicker tumours is generally advised as an attempt to reduce risk of local recurrence. There is no evidence that more radical surgery with 4–6 cm margins is beneficial. The majority of tumours can be excised without the need for grafting. For tumours with a Breslow thickness of 0.8–1 mm or more, a sentinel lymph node biopsy is indicated and should be considered on a case-by-case basis as, in addition to provision of prognostic information, a positive sentinel node biopsy facilitates access to adjuvant treatment with either targeted therapy and/or immune checkpoint inhibitors and is often required before entry to clinical trials of new treatments. Patients must be counselled about the sentinel node biopsy procedure, which is usually performed at the time of wider excision. It involves injection of radio-labelled blue dye at the site of the primary melanoma, allowing identification of the draining 'sentinel' node by radioscintigraphy; this sentinel node is then removed and examined in detail by histology, immunohistochemistry and/or PCR of melanocyte gene products to look for tumour deposits.

If the biopsy is positive, adjuvant therapy should be considered as described below and has largely replaced the need for complete local lymphadenectomy, which is a procedure that is associated with high morbidity in terms of lymphoedema and has no proven survival benefit. Nowadays it is only undertaken if there is a high risk of bulky locoregional recurrence.

Localised cutaneous or nodal recurrence may be treated surgically and cutaneous metastases or in transit disease may be amenable to palliation with electrochemotherapy if there is no evidence of widespread metastatic disease.

There have been major advances in treatment options for advanced melanoma, such that patients are often now able to have extended survival, sometimes for many years. However, ultimately the overall prognosis for metastatic disease remains poor and treatment options remain palliative, with disease control as opposed to cure. Genetic developments have facilitated the introduction of tumour-targeted treatments for advanced, unresectable and/or metastatic disease, such as the *B-Raf* and *c-Kit* kinase inhibitors for patients expressing these gene mutations, notably dabrafenib and vemurafenib, with demonstrable clinical responses. Combined BRAF and MEK targeted inhibition, with drugs such as trametinib, may also be used. Immune checkpoint inhibition with ipilimumab, which causes T-cell activation by inhibiting CTLA-4, alone or in combination with the programmed cell death (PD1) pathway blockers nivolumab or pembrolizumab, provides clinically meaningful improvements in quality of life and survival to patients with advanced disease. Standard chemotherapy may also be used in some cases of metastatic disease, although outcomes are poor. Other biologic and gene therapies and vaccines are also being investigated. It is important for patients with advanced melanoma to be managed through a multidisciplinary team in order to optimise care, provide access to adjuvant therapy and facilitate their inclusion in clinical trials.

All patients should be advised regarding ongoing photoprotection, with sensible behaviour in the sun, covering up, wearing hats and high-factor sunscreen use. However, evidence has shown that despite patients with melanoma being advised to photoprotect, many follow this advice only for the first year following diagnosis, thus emphasising the need for ongoing reinforcement of guidance with regard to photoprotection. It is also prudent to advise patients who are photoprotecting to optimise oral vitamin D through diet and/or supplements.

#### Prognosis

Prognosis is influenced by several factors, including tumour characteristics and thickness (Breslow thickness) and the presence or absence of regional, nodal or metastatic disease. Patients with in situ melanoma do

not have risk of metastasis and those with an invasive primary tumour of less than 1 mm Breslow thickness have more than a 90% chance of 5-year disease-free survival, but this figure drops to approximately 50% for a tumour of greater than 3.5 mm thickness. Survival rates fall to less than 10% for those with advanced nodal or metastatic disease.

## Benign skin lesions

In practice, it is often difficult to distinguish between skin cancer and a benign lesion on clinical grounds; if there is any doubt, biopsy and histology are required. Benign melanocytic naevi and basal cell papilloma, in particular, can often be mistaken for melanoma, even by dermatologists. Keratoacanthoma, while benign, is also commonly considered to be invasive SCC on clinical grounds.

### Keratoacanthoma

This benign tumour has a striking clinical presentation of rapid growth over weeks to months and subsequent spontaneous resolution. It is thought to be associated with chronic sun exposure and most commonly occurs on the central face. The classical appearance is of an isolated dome-shaped nodule often of 5 cm or more in diameter, with a central keratin plug (Fig. 27.17). Clinically and histologically, the lesion often resembles SCC (see Fig. 27.13A). Most are treated surgically, either by curettage and cautery or by excision, to rule out SCC and to avoid the unsightly scar after spontaneous resolution.

### Freckle

Histologically, a freckle (ephelis) consists of normal numbers of melanocytes, but with focal increases in melanin in keratinocytes. They are most common on sun-exposed sites in fair-skinned individuals, particularly children and those with red hair, and on the face. There is a familial tendency. Clinically, freckles are brown macules that darken following UVR exposure.

### Lentigo

A lentigo (plural lentiginos) consists of increased numbers of melanocytes along the basement membrane, but without formation of the nests that occur in melanocytic naevi. These lesions usually occur at sites of chronic sun exposure (see the background skin changes in Fig. 27.13A), become more common with age, and are often referred to as 'liver spots' or 'age spots'. They can vary in colour from light to very dark brown. Distinction from melanoma is essential and histology may be required.

Fig. 27.17 Keratoacanthoma.

## Haemangiomas

Benign vascular tumours or hamartomas are common and include Campbell de Morgan spots (see Fig. 27.18), which present as pink/red papules on the upper half of the body. They can sometimes be difficult to distinguish from melanocytic lesions, particularly if they are thrombosed or occur on particular sites, such as the lip or genitalia. The dermatoscope is helpful for this (see Fig. 27.2).

## Basal cell papilloma

Basal cell papillomas (also known as seborrhoeic warts or keratoses) are common, benign epidermal tumours (Fig. 27.18). They may be flat, raised, pedunculated or warty-surfaced, and can appear to be 'stuck on'. They occur in both sexes and with increasing age, and are most common on the face and trunk. The colour may vary from yellow to almost black and the surface may seem 'greasy', with pinpoint keratin plugs visible, particularly with a magnifying lens. If there is no doubt about the diagnosis, they can be left alone or treated by cryotherapy or curettage if they are cosmetically troublesome. If there is a suspicion of melanoma, excision or diagnostic biopsy should be undertaken.

## Melanocytic naevi

Melanocytic naevi (moles) are localised benign clonal proliferations of melanocytes. It is thought that they may arise as the result of abnormalities in the normal migration of melanocytes during development. It is quite normal to have 20–50, although, interestingly, individuals with red hair have fewer. Genetic and environmental factors are implicated. Monozygotic twins have higher concordance in naevi numbers than dizygotic twins. Individuals who have had greater sun exposure have higher numbers of naevi. Most melanocytic naevi appear in childhood and early adult life, or during pregnancy or oestrogen therapy. The onset of a new mole is less common after the age of 25 years. Congenital melanocytic naevi occur at or shortly after birth.

### Clinical features

Acquired melanocytic naevi are classified according to the microscopic location of the melanocyte nests (Fig. 27.19). Junctional naevi are usually macular, circular or oval, and mid- to dark brown. Compound and intradermal naevi are nodules because of the dermal component, and may be hair-bearing. Intradermal naevi are usually less pigmented than compound naevi. Their surface may be smooth, cerebriform, hyperkeratotic or papillomatous.

Some individuals have large numbers of naevi, often at unusual sites, such as the scalp, palms or soles, and these may frequently appear 'atypical' in terms of variability in pigmentation, size and shape. Some may be very dark or pink and may show a depigmented or inflamed halo.

Fig. 27.18 A typical basal cell papilloma. Note the neighbouring basal cell papillomas and the coincidental benign angiomas (Campbell de Morgan spots).

**Fig. 27.19** Classification of melanocytic naevi. Classification is based on microscopic location of the nests of naevus cells.

If these naevi are removed, then 'dysplastic changes' are often seen. Such naevi are known to occur in some rare families with an inherited melanoma predisposition. However, the significance of such changes in non-familial cases is unclear and there is no consensus on management and follow-up.

Although approximately 50% of melanomas arise in pre-existing naevi, most naevi do not become malignant; although a changing naevus must be taken seriously, most will not be melanomas. Malignant change is most likely in large congenital melanocytic naevi (risk may correlate with size of lesion) and possibly in families where there is a history of large numbers of atypical naevi and/or a history of melanoma.

### Diagnosis and management

Melanocytic naevi are normal and do not require excision, unless malignancy is suspected or they become repeatedly inflamed or traumatised. Advice on photoprotection is important for fair-skinned individuals with multiple naevi.

### Blue naevi

These are melanocytic naevi in which there is a proliferation of spindle melanocytes relatively deep within the dermis. Light scattering means that the pigment appears blue rather than brown. They may be difficult to distinguish from nodular melanoma and are therefore often excised.

### Dermatofibroma

A dermatofibroma is a characteristically firm, often pigmented, raised lesion, most commonly found on the lower legs. Its aetiology is unclear, although a reactive process secondary to insect bites or trauma is one hypothesis. There is frequently a ring of pigment around the lesion and dimpling when the skin is pinched, reflecting epidermal tethering.

### Acrochordon

Acrochordons, or skin tags, are benign pedunculated lesions; they are most common in skin flexures and usually have a very characteristic clinical appearance. However, they may sometimes be confused with melanocytic naevi. Treatment is not required unless there is diagnostic doubt or they are causing symptoms, such as irritation, or for cosmetic reasons. Cryotherapy or snip or shave excision may be appropriate in that situation.

### Lipoma

Lipomas are benign tumours of adipocytes that are characteristically soft and lie more deeply in the skin than epidermal tumours; they are usually diagnosed easily on clinical grounds. A variant, angiolipoma, is typically

painful. Treatment is not required unless there is diagnostic doubt or they are symptomatic or cosmetically troublesome, in which case a diagnostic biopsy or surgical excision may be required.

## Common skin infections and infestations

### Bacterial infections

#### Impetigo

Impetigo is a common and highly contagious superficial bacterial skin infection. There are two main presentations: bullous impetigo, caused by a staphylococcal epidermolytic toxin, and non-bullous impetigo (Fig. 27.20), which can be caused by either *Staphylococcus aureus* or streptococci, or both together. *Staphylococcus* spp. are the most common agents in temperate climates, whereas streptococcal impetigo is more often seen in hot, humid areas. All ages can be affected but non-bullous disease particularly affects young children, often in late summer. Outbreaks can arise in conditions of overcrowding and poor hygiene or in institutions. A widespread form can occur in neonates. Predisposing factors are minor skin abrasions and the existence of other skin conditions, such as infestations or eczema.

In non-bullous impetigo, a thin-walled vesicle develops; it rapidly ruptures and is rarely seen intact. Dried exudate, forming golden crusting, arises on an erythematous base. In bullous disease, the toxins cleave desmoglein-1, causing a superficial epidermal split and the occurrence of intact blisters with clear to cloudy fluid, which last for 2–3 days. The face, scalp and limbs are commonly affected but other sites can also be involved, particularly if there are predisposing factors such as eczema. Lesions may be single or multiple and coalesce. Constitutional symptoms are uncommon. A bacterial swab should be taken from blister fluid or an active lesion before treatment commences. Around one-third of the population is a nasal carrier of *Staphylococcus*, so swabs from the nostrils should also be obtained.

In mild, localised disease, topical treatment with mupirocin or fusidic acid is usually effective and limits the spread of infection. The use of topical antiseptics and soap and water to remove infected crusts is also helpful. Staphylococcal carriage should be treated, with mupirocin topically to the nostrils, if swabs are positive. In severe cases, an oral antibiotic, such as flucloxacillin or clarithromycin, is indicated. If nephritogenic streptococci are isolated then systemic antibiotics should be considered to reduce the risk of streptococcal glomerulonephritis. Underlying disease, such as infestations, must be treated and cross-infection minimised. Scarring does not occur but there may be temporary dyspigmentation.

**Fig. 27.20** Non-bullous impetigo.

**Fig. 27.21** Staphylococcal scalded skin syndrome. **A** Extensive erythema and superficial peeling of the skin. **B** The condition was rapidly diagnosed by examination of a frozen section of skin snip. (A) From Savin JA, Dahl M, Hunter JAA. *Clinical dermatology*, 3rd edn. Oxford: Blackwell; 2002.

### Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome (SSSS) is a potentially serious exfoliating condition occurring predominantly in children, particularly neonates (Fig. 27.21). It is caused by systemic circulation of epidermolytic toxins from a *Staph. aureus* infection. The same toxins are implicated in bullous impetigo, which is a localised form of SSSS. The focus of infection may be minor skin trauma, the umbilicus, urinary tract or nasopharynx. The child presents with fever, irritability and skin tenderness. Erythema usually begins in the groin and axillae, and around the mouth. Blisters and superficial erosions develop over 1–2 days and can rapidly involve large areas, with severe systemic upset. Bacterial swabs should be obtained from possible primary sites of infection. A skin snip should also be taken for urgent histology. This is a sample of the superficial peeling skin removed by 'snipping with scissors', without the need for local anaesthetic. It shows a split beneath the stratum corneum, and differentiates SSSS from toxic epidermal necrolysis, in which the whole epidermis is affected (see Fig. 27.41). Systemic antibiotics and intensive supportive measures should be commenced immediately. Bacterial swabs from nostrils, axillae and groins should be taken from family members to exclude staphylococcal carriage. Although the acute presentation of SSSS is often severe, rapid recovery and absence of scarring are usual, as the epidermal split is superficial.

### Toxic shock syndrome

This condition is characterised by fever, desquamating rash, circulatory collapse and multi-organ involvement. It is caused by staphylococcal

toxins and early cases were thought to arise with tampon use. Intensive supportive care and systemic antibiotics are required.

### Ecthyma

Ecthyma is caused by either staphylococci or streptococci, or both together, and is characterised by adherent crusts overlying ulceration. It occurs worldwide but is more common in the tropics. In Europe, it occurs more frequently in children. Predisposing factors include poor hygiene, malnutrition and underlying skin disease, such as scabies. It is commonly seen in drug abusers, and minor trauma can predispose to lesion development. Management approaches are similar to impetigo as ecthyma can be considered as a deeper version of impetigo. Crust removal, antiseptics and systemic antibiotics may be required.

### Folliculitis, furuncles and carbuncles

Hair follicle inflammation can be superficial, involving just the ostium of the follicle (folliculitis), or deep (furuncles and carbuncles).

#### Superficial folliculitis

The primary lesions are follicular pustules and erythema. Superficial folliculitis is often infective, caused by *Staph. aureus*, but can also be sterile and caused by physical (for example, traumatic epilation) or chemical (for example, mineral oil) injury. Staphylococcal folliculitis is most common in children and often occurs on the scalp or limbs. Pustules usually resolve without scarring in 7–10 days but can become chronic. In older children and adults, they may progress to a deeper form of folliculitis. The condition is often self-limiting and may respond to irritant removal and antiseptics. More severe cases may require topical or systemic antibiotics and treatment of *Staph. aureus* carrier sites.

#### Deep folliculitis (furuncles and carbuncles)

A furuncle (boil) is an acute *Staph. aureus* infection of the hair follicle, usually with necrosis. It is most common in young adults and males. It is usually sporadic but epidemics occasionally occur. Malnutrition, diabetes and HIV predispose, although most cases arise in otherwise healthy people. All body sites can be involved but neck, buttocks and anogenital areas are commonly affected areas. Infection is often associated with chronic *Staph. aureus* carriage in the nostrils and perineum, and may be due to resistant strains, such as methicillin-resistant organisms (MRSA). Friction caused by tight clothing may be contributory. Initially, an inflammatory follicular nodule develops and becomes pustular, fluctuant and tender. Crops of lesions sometimes occur. There may be fever and mild constitutional upset. Lesions rupture over days to weeks, discharge pus, become necrotic and leave a scar.

If a deep *Staph. aureus* infection of a group of contiguous hair follicles occurs, this is termed a carbuncle and is associated with intense deep inflammation (Fig. 27.22). This usually occurs in middle-aged men, often

**Fig. 27.22** Staphylococcal carbuncle.

**Fig. 27.23 Severe right orbital cellulitis.** There is proptosis, chemosis, reduced ocular motility and reduced vision. From Yanoff M, Duker JS. *Ophthalmology*, 5th edn. Elsevier; 2019.

**Fig. 27.24 Erysipelas.** From Schwarzenberger K, Werchniak A, Ko C. *General dermatology*. Elsevier; 2009.

with predisposing conditions such as diabetes or immunosuppression. A carbuncle is an exquisitely tender nodule, usually on the neck, shoulders or hips, associated with severe constitutional symptoms. Discharge, necrosis and scarring are usual. Bacterial swabs must be taken and treatment is with anti-staphylococcal antibiotics, e.g. flucloxacillin, and sometimes incision and drainage.

Other staphylococcal toxins may also be pathogenic. For example, Pantón–Valentine Leukocidin (PVL)-producing *Staph. aureus* can cause recurrent abscesses (**definition:** localised collections of pus in cavities) and may be difficult to eradicate.

### Cellulitis and erysipelas

Cellulitis is inflammation of subcutaneous tissue, due to bacterial infection (Fig. 27.23). In contrast, erysipelas is bacterial infection of the dermis and upper subcutaneous tissue (Fig. 27.24), although in practice it may be difficult to distinguish between them. These conditions are most commonly caused by group A streptococci but culture of swabs from affected sites is often negative. There is frequently a source of organism entry, such as an ear infection, varicose eczema/ulcer or tinea pedis, and swabs should also be taken from these sites. Diabetes and immunosuppression are predisposing factors. The patient usually has malaise, fever and leucocytosis, and streptococcal serology will often be positive. The face (erysipelas) and legs (cellulitis) are most often affected and the site is hot, painful, erythematous and oedematous. Blistering often occurs and may be haemorrhagic. Regional lymphadenopathy is common. Erysipelas typically has a well-defined edge due to its more superficial level of involvement, whereas cellulitis is typically ill defined. Treatment is usually with intravenous flucloxacillin, with clarithromycin, clindamycin and vancomycin as alternatives for penicillin-allergic patients. Milder

cases may be treated with oral antibiotics. If cases are untreated, sequelae include lymphoedema, cavernous sinus thrombosis, sepsis and glomerulonephritis.

### Mycobacterial infections

*Mycobacterium leprae* infection may involve the skin and its manifestations will be influenced by host immunity, patients with high levels of immunity presenting with paucibacillary tuberculoid leprosy and those with low immune resistance developing multibacillary lepromatous leprosy. Hypopigmented or erythematous patches, with associated altered or lost sensation, or skin thickening, nodules and infiltration should raise suspicion of a diagnosis of leprosy. The skin may also be an extrapulmonary site of involvement in tuberculosis, usually due to infection with *Mycobacterium tuberculosis*. Skin manifestations depend on the route of infection, previous sensitisation and host immunity. There may be a variety of cutaneous features, including the red–brown scarring inflammatory plaques seen in lupus vulgaris due to direct skin inoculation; scrofuloderma, which describes the skin changes overlying lymph nodes or joints infected with tuberculosis; and the reactive nodular and ulcerated changes seen in patients with high levels of immune response, notably the tuberculids and erythema induratum (Bazin's disease). On diascopy, an 'apple jelly' appearance is typically seen, indicating the granulomatous nature of skin involvement. Granulomas evident on skin biopsy should certainly raise suspicion of a diagnosis of mycobacterial infection. Culture of organisms may be tricky but PCR can assist with diagnosis. Patients should be thoroughly investigated for signs of tuberculosis at pulmonary or other extrapulmonary sites. Reactivation of latent tuberculosis is a particular concern for patients receiving treatment with immunosuppressants and biologic agents, particularly TNF- $\alpha$  antagonists for conditions such as psoriasis. Vigilance is required in screening and workup of such patients prior to consideration of these therapeutic agents. Management of tuberculosis is discussed in Chapter 17.

Other mycobacterial skin infections may occur, such as *Mycobacterium marinum*, typically seen in those who clean tropical fish tanks. Sporotrichoid spread of granulomatous nodules from the site of inoculation along lymphatics is typical; granulomatous changes are seen on histology and resolution usually occurs with a prolonged course of antibiotics such as doxycycline or minocycline. Resolution may also take place spontaneously or after destructive therapies, such as cryotherapy.

### Leishmaniasis

This protozoan infection may be restricted to the skin or there may be systemic features depending on the species, which occur in different geographical areas. The clinical features and management of this condition are discussed in Chapter 13.

### Necrotising soft tissue infections and anthrax

These conditions are discussed in more detail in Chapter 13.

### Erythrasma

Erythrasma is a mild, chronic, localised, superficial skin infection caused by *Corynebacterium minutissimum*, which is part of the normal skin flora. Warmth and humidity predispose to this infection, which usually occurs in flexures and toe clefts. It is asymptomatic or mildly itchy and lesions are well defined, red–brown and scaly. *C. minutissimum* has characteristic coral-pink fluorescence under Wood's light. Microscopy and culture of skin scrapings can confirm the diagnosis but are not usually needed if Wood's light examination is positive. A topical azole (clotrimazole or miconazole) or fusidic acid is usually effective. Oral erythromycin can be used for extensive or resistant disease. Antiseptics can be used to prevent disease recurrence.

## Pitted keratolysis

This is another superficial skin infection caused by *Corynebacterium* and *Streptomyces* spp., and possibly other organisms, producing characteristic circular erosions ('pits') on the soles. It is usually asymptomatic. The bacterium can be identified in skin scrapings and typically occurs in association with hyperhidrosis, which must be treated to prevent recurrence. Treatment is as for erythrasma.

## Other bacterial skin infections

Syphilis and the non-venereal treponematoses are discussed in Chapter 15. There has been a marked increase in incidence of syphilis. Skin signs may be subtle; for example, secondary syphilis may be misdiagnosed as pityriasis rosea. Lesions on palms, soles and mucosae should raise suspicion. Microscopic identification of the spirochaete may be possible and syphilitic serology should be undertaken using enzyme immunoassay or PCR-based techniques, depending on availability. Lyme disease can also cause a skin rash; the clinical features and management are described in Chapter 13.

## Viral infections

### Herpesvirus infections

The cutaneous manifestations of the human herpesviruses are described in more detail in Chapter 13. Topical antivirals may suffice for prophylaxis or treatment of mild viral disease, such as herpes simplex cold sore virus infection. Systemic antivirals are indicated for significant viral skin disease. For example, systemic aciclovir should be prescribed for eczema herpeticum (see Fig. 13.15C).

### Papillomaviruses and viral warts

Viral warts are extremely common and are caused by the DNA human papillomavirus (HPV). There are over 90 subtypes, based on DNA sequence analysis, causing different clinical presentations. Transmission is by direct virus contact, in living or shed skin, and is encouraged by trauma and moisture, such as in swimming pools. Genital warts are spread by sexual activity and show a clear relationship with cervical and intra-epithelial cancers of the genital area. HPV-16 and 18 appear to inactivate tumour suppressor gene pathways and lead to squamous cell carcinoma of the cervix or intra-epithelial carcinoma of the genital skin. Vaccinations are available against HPV-16 and 18 and are recommended for females and males aged 12–13 years, before they become sexually active, with the objective of offering protective effects against cervical, genital, anal and some head and neck malignancies. The relationship between skin HPV and skin cancer is unclear. Individuals who are systemically immunosuppressed – after organ transplantation, for example – have greatly increased risks of skin cancer and HPV infection but a causal link is not certain.

### Clinical features

Common warts are initially smooth, skin-coloured papules, which become hyperkeratotic and 'warty'. They are most common on the hands (Fig. 27.25) but can occur on the face, genitalia and limbs, and are often multiple. Plantar warts (verrucae) have a slightly protruding rough surface and horny rim, and are often painful on walking. Paring reveals capillary loops that distinguish plantar warts from corns. Other varieties of wart include:

- *mosaic warts*: mosaic-like sheets of warts
- *plane warts*: smooth, flat-topped papules, usually on the face and backs of hands, which may be pigmented and therefore misdiagnosed
- *facial warts*: often filiform
- *genital warts*: may be papillomatous and exuberant.

**Fig. 27.25** Viral wart on the finger. The capillary loops are evident within the warty hyperkeratosis. Periungual sites are common and more difficult to treat.

### Management

Most viral warts resolve spontaneously, although this may take years and active treatment is therefore often sought. However, asymptomatic warts generally should not be treated. Viral warts are particularly problematic and more recalcitrant to treatment in immunosuppressed patients following organ transplantation.

Treatments are destructive. Salicylic acid or salicylic/lactic acid combinations and regular wart paring for several months are the most consistently effective treatments. For certain types of warts, such as filiform facial warts, cryotherapy is generally the treatment of choice, but for common hand and foot warts salicylic acid wart paint should be used first. Cryotherapy is usually the next step and is repeated 2–4-weekly. However, caution is required, particularly on the hands, as over-vigorous cryotherapy can lead to scarring, nail dystrophy and even tendon rupture. Periungual and subungual warts can be problematic and nail cutting and subsequent electrodesiccation may help. Several other therapies have been used for recalcitrant warts, including topical formaldehyde, glutaraldehyde, podophyllotoxin, trichloroacetic acid, cantharidin, topical or systemic retinoids, intralesional bleomycin or interferon injections, and contact sensitisation with, for example, diphencyprone. Imiquimod and PDT may also be beneficial, particularly for multiple warts in immunosuppressed patients, and laser therapy can have a role in some cases.

### Molluscum contagiosum

Molluscum contagiosum is caused by a DNA poxvirus skin infection. It is most common in children over the age of 1 year, particularly those with atopic dermatitis. It also occurs frequently in immunosuppressed patients, including those with HIV. Lesions are dome-shaped, 'umbilicated', skin-coloured papules with central punctum (Fig. 27.26). They

**Fig. 27.26** Molluscum contagiosum. Some of the pearly lesions show characteristic umbilication. From Lissauer T, Carroll W. *Illustrated textbook of paediatrics*, 6th edn. Elsevier; 2022.

are often multiple and found at sites of apposition, such as the side of the chest and the inner arm. Spontaneous resolution occurs but can take months. Prior to resolution, they often become inflamed and may leave small, atrophic scars. Destructive therapies may be painful and risk scarring, and the decision not to treat is often sensible. Gentle squeezing with forceps after bathing can hasten resolution. If active treatment is needed, topical salicylic acid, potassium hydroxide, podophyllin, cantharidin, trichloroacetic acid, imiquimod, cryotherapy, diathermy, curettage or laser treatment are therapeutic approaches that can be considered.

## Orf

Orf is a parapoxvirus skin infection and is an occupational risk for those who work with sheep and goats. Inoculation of virus, usually into finger skin, causes significant inflammation and necrosis, which typically resolves within 2–6 weeks. No specific treatment is required, unless there is secondary infection. Erythema multiforme can be provoked by orf.

## Other viral exanthems

Skin rash can be a feature of various other virus infections and these are discussed in more detail in [Chapter 13](#).

## Fungal infections

Fungal skin infections can be superficial (dermatophytes and yeasts) or, less commonly, deep (chromomycosis or sporotrichosis); the latter are seen more often in tropical climates or in the immunocompromised. Dermatophyte infections (ringworm) are extremely common and usually caused by fungi of the *Microsporum*, *Trichophyton* and *Epidermophyton* species. The fungi can originate from soil (geophilic) or animals (zoophilic), or be confined to human skin (anthropophilic). Dermatophyte infections usually present with skin (tinea corporis), scalp (tinea capitis), groin (tinea cruris), foot (tinea pedis) and/or nail (onychomycosis) involvement ([Fig. 27.27](#)).

### Diagnosis

Skin scrapings, hair pluckings or nail clippings must be taken from areas of disease activity – typically, the advancing lesion edge for skin involvement, the crumbling dystrophic nail and subungual hyperkeratosis for nail involvement, and plucked hair from scalp or other affected hair-bearing sites – in order to confirm the diagnosis by microscopy and culture.

### Management

The azoles (ketoconazole, miconazole), triazoles (itraconazole, fluconazole) and triallylamines (terbinafine) are used most widely in fungal skin disease. Topical antifungals such as terbinafine or miconazole may suffice, although systemic treatment (terbinafine, itraconazole or

griseofulvin) may be required for stubborn or extensive disease and scalp or nail involvement. Indeed, prolonged courses of systemic treatment may be needed for nail involvement. The fungistatic agent griseofulvin, given orally, is usually used for fungal infection of scalp or nails in children in the UK, as it is the only drug licensed in children for this indication; outside the UK, and in adults, terbinafine is usually the treatment of choice as it has broader range of activity and shorter treatment duration. Itraconazole is also an effective alternative. In addition to systemic antifungals, short courses of systemic or topical glucocorticoid are often used in kerion on the basis of reducing inflammation and possible hair loss. However, glucocorticoid use is controversial, with no good evidence of benefit.

## Tinea corporis

Tinea corporis should feature in the differential diagnosis of a red, scaly rash. Typically, lesions are erythematous, annular and scaly, with a well-defined edge and central clearing. There may also be pustules at the active edge. Lesions are usually asymmetrical and may be single or multiple. The degree of inflammation is dependent on the organism involved and the host immune response. *Microsporum canis* (from dogs) and *T. verrucosum* (from cats) are common culprits. Ill-advised use of topical glucocorticoids can modify the clinical presentation and increase disease extension (tinea incognita).

## Tinea cruris

This is extremely common worldwide and is usually caused by *T. rubrum*. Itchy, erythematous plaques develop in the groins and extend on to the thighs, with a raised active edge (see [Fig. 27.27A](#)).

## Tinea pedis

Tinea pedis or ‘athlete’s foot’ is the most common fungal infection in the UK and USA, and is usually caused by anthropophilic fungi, such as *T. rubrum*, *T. interdigitale* and *E. floccosum*. It typically presents as an itchy rash between the toes, with peeling, fissuring and maceration. Involvement of one sole or palm (tinea manuum) with fine scaling is characteristic of *T. rubrum* infection. Vesiculation or blistering is more often seen with *T. mentagrophytes*.

## Tinea capitis

This is a dermatophyte infection of scalp hair shafts and is most common in children. It typically presents as an area of scalp inflammation and scaling, often with pustules and partial hair loss ([Fig. 27.27B](#)). Infection may be within the shaft (endothrix, most commonly caused by *T. tonsurans*), causing patchy hair loss with broken hairs at the surface (‘black dot’), little inflammation and no fluorescence with Wood’s light. Infection

**Fig. 27.27** Dermatophyte infections. **A** *Trichophyton rubrum* infection of the groin (tinea cruris). **B** *Microsporum canis* infection of the scalp (tinea capitis).

outside the hair shaft (ectothrix, most commonly caused by *M. audouinii* (anthropophilic)) shows minimal inflammation; *M. canis* (from dogs and cats) infections are more inflammatory and can be identified by green fluorescence with Wood's light. Kerion is a boggy, inflammatory area of tinea capitis, usually caused by zoophilic fungi such as cattle ringworm (*T. verrucosum*).

### Onychomycosis

This is a fungal infection of the nail plate and the species involved are generally those that cause tinea capitis or tinea pedis. Onychomycosis usually presents with yellow/brown nail discoloration, crumbling, thickening and subungual hyperkeratosis. Usually, some nails are spared, there is asymmetry and toenails are more commonly involved.

### Candidiasis

This is a superficial skin or mucosal infection caused by a yeast-like fungus, *Candida albicans*. Infections are usually not serious, unless the patient is immunocompromised, in which case deeper tissues can be involved. The organism has a predilection for warm, moist environments and typical presentations are napkin candidiasis in babies, genital and perineal candidiasis, intertrigo and oral candidiasis. The diagnosis can be confirmed by microscopy and culture of skin swabs, and treatment is with topical or systemic antifungals, such as azoles.

### Pityriasis versicolor

Pityriasis versicolor is a persistent, superficial skin condition caused by various species of the commensal yeast *Malassezia*, most commonly *Malassezia globosa*, but sometimes *M. sympadialis* or *M. furfur*. It occurs in men and women and in different races. It is found more frequently in warmer, humid climates, and is usually more severe and persistent in the immunocompromised. It is characterised by scaly, oval macules on the upper trunk, usually hypopigmented but occasionally hyperpigmented. Hypopigmentation is more obvious after sun exposure and tanning. The diagnosis can be confirmed by microscopy of skin scrapings, showing 'spaghetti and meatballs' hyphae. Treatment with selenium sulphide or ketoconazole shampoos and topical or systemic azole antifungal agents is usually effective, although recurrence is common because these yeasts are skin commensals, and maintenance topical therapy may be required. Altered pigmentation can persist for months after treatment.

## Infestations

### Scabies

Scabies is caused by the mite *Sarcoptes scabiei*. It spreads in households and environments where there is intimate personal contact. The diagnosis is made by identifying the scabietic burrow (**definition:** a linear or curvilinear papule, caused by a burrowing scabies mite – Fig. 27.28) and visualising the mite (by extracting with a needle or using a dermatoscope). In small children, the palms and soles can be involved, with pustules. Pruritus is prominent. The clinical features include secondary eczematization elsewhere on the body; the face and scalp are rarely affected, except in infants. Involvement of the genitals in males and of the nipples commonly occurs. Even after successful treatment, itch can continue and occasionally nodular lesions persist.

Topical treatment of the affected individual and all asymptomatic family members/physical contacts is required to ensure eradication. Two applications 1 week apart of an aqueous solution of permethrin or malathion to the whole body, excluding the head, are usually successful. If there is poor adherence, immunosuppression or heavy infestation (crusted 'Norwegian' scabies), systemic treatment with a single oral dose of ivermectin is sometimes appropriate.

**Fig. 27.28 Scabies.** **A** Scabies in a young child affecting the palm. **B** A mite still in its egg, seen on light microscopy of scrapings over a burrow. Note that the mite has only six legs, unlike adult mites, which have eight. (A) From Lissauer T, Carroll W. *Illustrated textbook of paediatrics*, 5th edn. Elsevier; 2018.

### Head lice

Infestation with the head louse, *Pediculus humanus capitis*, is common. It is highly contagious and spread by direct head-to-head contact. Scalp itch leads to scratching, secondary infection and cervical lymphadenopathy. The diagnosis is confirmed by identifying the living louse or nymph on the scalp or on a black sheet of paper after careful fine-toothed combing of wet hair following conditioner application. The empty egg cases ('nits') are easily seen on the hair shaft and are hard to dislodge.

Treatment is recommended for the affected individual and any infected household/school contacts. Eradication in school populations is difficult because of poor adherence and treatment resistance. Topical treatment with dimeticone, permethrin, carbaryl or, less often, malathion in lotion or aqueous formulations may be effective and should be applied twice at an interval of 7–10 days. Rotational treatments within a community may avoid resistance. 'Wet-combing' (physical removal of live lice by regular combing of conditioned wet hair – 'bug busting') can suffice but may be less effective than pharmacological treatments. Vaseline should be applied to eyelashes/brows twice daily for at least a fortnight. High-temperature washing of clothing and bedding is required. Treatment resistance and recurrence can be problematic.

### Body lice

These are similar to head lice but live on clothing, particularly in seams, and feed on the skin. Poor hygiene and overcrowded conditions predispose. Itch, excoriation (**definition:** a linear ulcer or erosion resulting from scratching) and secondary infection occur. Dry-cleaning and high-temperature washing or insecticide treatment of clothes are required. Treatment options are as for head lice. For heavy infestation, oral ivermectin may be indicated.

### Pubic (crab) lice

Usually, these are sexually acquired and very itchy. Management is as for head and body lice and whole-body treatment should be undertaken. Pubic hair may need to be shaved. Sexual and other close contacts

should also be treated and patients should also be screened for sexually transmitted diseases.

## Acne and rosacea

### Acne vulgaris

Acne is chronic inflammation of the pilosebaceous units. It is extremely common, generally starts during puberty and has been estimated to affect over 90% of adolescents. It is usually most severe in later adolescence but can persist into the thirties and forties, particularly in females (Box 27.17).

#### Pathogenesis

The key components are increased sebum production; colonisation of pilosebaceous ducts by *Propionibacterium acnes*, which in turn causes inflammation; and hypercornification and occlusion of pilosebaceous ducts (Fig. 27.29). Severity of acne is associated with sebum excretion rate, which increases at puberty. Both androgens and progestogens increase sebum excretion and oestrogens reduce it, but most patients with acne have normal hormone profiles. There may be a positive family history and there is high concordance in monozygotic twins, indicating that genetic factors are important, but the candidate genes are poorly defined.

#### Clinical features

Acne usually affects the face and often the trunk. Greasiness of the skin may be obvious (seborrhoea). The hallmark is the comedone (**definition:**

open comedones (blackheads) are dilated keratin-filled follicles, which appear as black papules due to the keratin debris; closed comedones (whiteheads) usually have no visible follicular opening and are caused by accumulation of sebum and keratin deeper in the pilosebaceous ducts – see Fig. 27.29). Inflammatory papules, nodules and cysts occur and may arise from comedones (Fig. 27.30). Scarring may follow deep-seated or superficial acne and may be keloidal.

There are also distinct clinical variants:

- *Acne conglobata*: characterised by comedones, nodules, abscesses, sinuses (**definition:** cavities or channels that permit the escape of pus or fluid) and cysts, usually with marked scarring. It is rare, usually affecting adult males, and most commonly occurs on trunk and upper limbs. It may be associated with *hidradenitis suppurativa (acne inversa)* (an occlusive follicular chronic inflammatory condition affecting apocrine glands; this predominantly affects axillae, groins, perineal and perianal sites and follows a relapsing and remitting course and often requires complex medical and surgical management approaches), scalp folliculitis and pilonidal sinus.
- *Acne fulminans*: a rare but severe presentation of acne, associated with fever, arthralgias and systemic inflammation, with raised neutrophil count and plasma viscosity. It is usually found on the trunk in adolescent males. Costochondritis can occur.
- *Acne excoriée*: self-inflicted excoriations due to compulsive picking of pre-existing or imagined acne lesions. It usually affects adolescent girls, and underlying psychological problems are common.
- *Secondary acne*: comedonal acne can be caused by greasy cosmetics or occupational exposure to oils, tars or chlorinated aromatic hydrocarbons. Predominantly pustular acne can occur in patients using systemic or topical glucocorticoids, oral contraceptives, anticonvulsants, lithium or antineoplastic drugs, such as the epidermal growth factor receptor (EGFR) inhibitors. Most patients with acne do not have an underlying endocrine disorder but acne is a common feature of polycystic ovary syndrome which should be suspected if acne is moderate to severe and associated with hirsutism and menstrual irregularities. Virilisation should also raise suspicion of an androgen-secreting tumour.

### 27.17 Acne in adolescence

**Epidemiology:** acne vulgaris is most common between the ages of 12 and 20. It often begins around 10–13 years of age, lasts 5–10 years and usually resolves by age 20–25.

**Emotional effects:** at all ages acne can have negative effects on self-esteem, but it is especially important to assess how it affects an adolescent. Depression and suicidal ideation may occur. The consequences (whether acne is objectively severe or not) can be devastating, leading to embarrassment, school avoidance, and life-long effects on ability to form friendships, attract partners, and acquire and keep employment.

**Treatment:** effective treatments aim to improve the condition, prevent worsening (including later scarring) and restore emotional well-being and self-esteem.

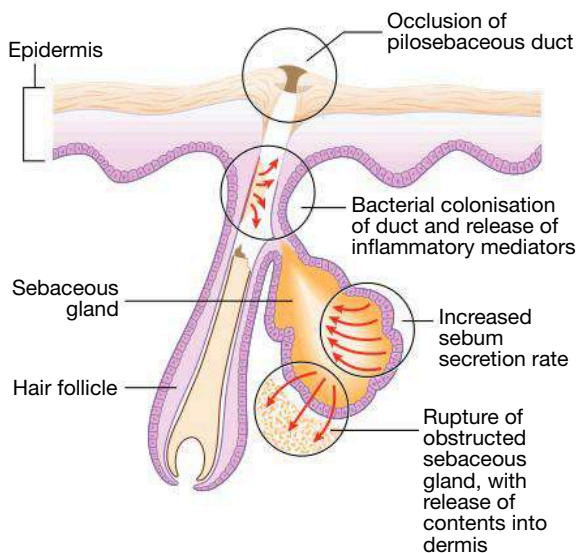

Fig. 27.29 Pathogenesis of acne.

Fig. 27.30 Cystic acne in an adolescent girl. **A** Before treatment. **B** After prolonged systemic antibiotic treatment.

### Investigations

Investigations are not required in typical acne vulgaris. Secondary causes and suspected underlying endocrine disease or virilisation should be investigated.

### Management

#### Mild to moderate disease

Mild disease is usually managed with topical therapy. If comedones predominate, then topical benzoyl peroxide or retinoids should be used. Benzoyl peroxide has both anti-comedogenic and antiseptic effects. It is an irritant, which may contribute to the therapeutic response, but this can be minimised by adjusting treatment regimens. Azelaic acid may also be used for mild acne and has both antimicrobial and anti-comedogenic action. Topical retinoids, in particular *all-trans* retinoic acid and adapalene, are widely employed for mild to moderate comedonal acne vulgaris. Treatment should be initially applied at low concentrations for short duration and increased as tolerated. Patients with mild inflammatory acne should respond to topical antibiotics, such as erythromycin or clindamycin, which can be used in combination with other treatments.

For moderate inflammatory acne, a systemic tetracycline should be used at adequate dose for 3–6 months in the first instance (Fig. 27.30B). Oxytetracycline must be taken on an empty stomach, in a dose of up to 1.5 g a day. It has a good safety profile, even with long-term use, but adherence may be a challenge. Lymecycline is an alternative and is taken once daily, with or without food, thereby improving adherence. Doxycycline is another option but commonly causes photosensitivity. Minocycline is used less frequently, as it can cause hyperpigmentation, autoimmune hepatitis and drug-induced lupus, and monitoring is required. If the patient fails to respond, then alternatives include erythromycin or trimethoprim.

In women with acne, oestrogen-containing oral contraceptives can be a useful adjunct, as they are associated with a small reduction in sebum production. Combined oestrogen and anti-androgen (such as cyproterone acetate) contraceptives may provide additional efficacy, particularly in women with acne and hirsutism, as seen in polycystic ovary syndrome.

Patients should be referred for consideration of isotretinoin (13-*cis*-retinoic acid) if there is a failure to respond adequately to 6 months of therapy with these combined systemic and topical approaches.

#### Moderate to severe disease

Isotretinoin (13-*cis*-retinoic acid) has revolutionised the treatment of moderate to severe acne that has not responded adequately to other therapies. It has multifactorial mechanisms of action, with reduction in sebum excretion by over 90%, follicular hypercornification, *P. acnes* colonisation and inflammation. Oral isotretinoin is usually used at a dose of 0.5–1 mg/kg over 4 months. Sebum excretion typically returns to baseline within a year after treatment cessation, although clinical benefit is usually longer-lasting. Many patients will not require further treatment, although a second or third course of isotretinoin may be needed. A low-dose continuous or intermittent-dose regimen may occasionally be considered for a longer duration in patients who relapse after a higher-dose regimen, and may also be beneficial for older females with persistent acne. Combination with systemic glucocorticoid may be required in the short term for severe acne, in order to minimise the risk of disease flare early in the treatment course. Thorough screening and monitoring are required, given the side-effect profile of isotretinoin, particularly with respect to teratogenicity and possible mood disturbance. Pregnancy must be avoided during treatment and for a minimum of 2 months after drug cessation, and a strict pregnancy prevention programme and regular pregnancy testing are required. Depression and suicide have been reported in association with isotretinoin, although a causal role has not been established. However, pre-drug screening for depressive symptoms should be undertaken and mood monitored during therapy.

#### Other treatments and physical measures

Intralesional injections of triamcinolone acetonide may be required for inflamed acne nodules or cysts, which can also be incised and drained, or excised under local anaesthetic. Scarring may be prevented by

adequate treatment of active acne. Keloid scars may respond to intralesional glucocorticoid and/or silicone dressings. Carbon dioxide laser, microdermabrasion, chemical peeling or localised excision can also be considered for scarring. UVB phototherapy or PDT can occasionally be used in patients with inflammatory acne who are unable to use conventional therapy, such as isotretinoin. There is no convincing evidence to support a causal association between diet and acne. The psychological impact of acne must not be underestimated and should be considered in management decisions (see Box 27.17).

## Rosacea

This chronic inflammatory condition affects the central face and consists of flushing, erythema, papules, pustules and telangiectasiae. The cause is unknown. Rosacea is distinct from acne vulgaris; sebum excretion is normal and comedones are absent. The relative contribution of *Demodex* mite and cutaneous vasomotor instability to the pathogenesis of rosacea remains poorly defined.

### Clinical features

Rosacea most commonly affects fair-skinned, middle-aged females and can be exacerbated by heat, sunlight and alcohol. The convexities of nose, forehead, cheeks and chin are typically involved (Fig. 27.31). The condition is heterogeneous and intermittent flushing, followed by fixed erythema and telangiectasiae, predominates in some; in others, papules and pustules are prominent. Sebaceous gland hyperplasia and soft tissue overgrowth of the nose (rhinophyma) can occur, particularly in males. Conjunctivitis and blepharitis may also occur. Facial lymphoedema can be an added complication.

### Investigations

Usually, no investigations are required and the diagnosis is obvious clinically. However, rosacea must be distinguished from acne vulgaris, systemic lupus erythematosus, photosensitivity disorders and seborrhoeic dermatitis (the latter may coexist with rosacea).

### Management

Mild disease may respond to topical antimicrobials, such as metronidazole or azelaic acid. Topical ivermectin may be beneficial in some cases, supporting a contributory role of *Demodex* in pathogenesis. Tetracycline or erythromycin for 3–6 months is usually effective in inflammatory

Fig. 27.31 Glandular rosacea. Showing prominent rhinophyma. From James W, Elston D, McMahon PJ. *Andrews' diseases of the skin clinical atlas*. Elsevier; 2018.

pustular disease resistant to topical therapy. Relapse may require intermittent or chronic antibiotic use. Erythema and telangiectasiae do not usually respond well to antibiotics but vascular laser therapy may be effective. Topical vasoconstrictors, such as the  $\alpha_2$ -adrenoceptor agonist brimonidine, may be of benefit in some cases where erythema and telangiectasiae predominate. Systemic isotretinoin may be helpful in severe resistant disease and rhinophyma may require laser therapy or surgery.

## Eczemas

The term 'eczema' derives from the Greek word 'to boil' and is synonymous with the other descriptive term, 'dermatitis'. Eczema describes a clinical and histological pattern, which can be acute or chronic and has several causes. Acutely, epidermal oedema (spongiosis) and intra-epidermal vesiculation (producing multilocular blisters) predominate, whereas with chronicity there is more epidermal thickening (acanthosis). Vasodilatation and T-cell lymphocytic infiltration of the upper dermis also occur.

### Clinical features

There are several patterns of eczema (Box 27.18) but the clinical features are similar, irrespective of the cause (Box 27.19). Some subtypes of eczema have specific distinguishing features and these are discussed in more detail below.

### Investigations

Bacterial and viral swabs for microscopy and culture are important in suspected secondary infection. Bacterial swabs are commonly positive, particularly for staphylococci, although clinical assessment is required in order to ascertain whether swab results are of clinical significance and whether antibiotic treatment is required. Individuals with atopic eczema have an increased susceptibility to herpes simplex virus (HSV) and are at risk of developing a widespread infection, eczema herpeticum. The presence of small, punched-out lesions on a background of worsening eczema suggests the possibility of secondary HSV infection. Skin scrapings to rule out secondary fungal infection should also be considered. Total IgE and specific IgE tests and skin prick tests are not routinely undertaken in atopic eczema as they are not usually helpful, although they may occasionally be indicated in some cases as directed by the history. Patch tests should be performed if contact allergic dermatitis is suspected (see Box 27.23 below). Skin biopsy is not usually required unless there is diagnostic doubt.

## Management

A general approach to the management of eczema includes advice, education and support, required for patients with eczema of any type (Fig. 27.32). Input from patient support groups, such as the National Eczema Society in the UK, can be very helpful. Intensive and prolonged treatments are often required and chronic eczema can have a major and devastating adverse impact on personal and family lives. Emollients and topical glucocorticoids are mainstays of treatment for all eczema types, in order to improve skin barrier function, limit transepidermal water loss and reduce inflammation. Emollients can be used as bath additives and soap substitutes, and applied directly to the skin, often combined with antiseptics. Sedative antihistamines are useful if sleep is interrupted but non-sedating antihistamines are ineffective, as the itch of eczema is not primarily mediated by histamine.

Ointments are preferred for chronic eczema, whereas cream- or lotion-based treatment may be more appropriate for acute eczema (see Box 27.11). Treatment is once to twice daily. Hydrocortisone (1%) or clobetasone butyrate is generally used on the face, with more potent glucocorticoids restricted to trunk and limbs (see Box 27.12). A good strategy is to employ an intensive regimen with more potent glucocorticoids initially and then taper use according to response. A key principle is to use the least potent glucocorticoid that is effective for the shortest possible time. The patient should be given instructions on how much to apply, using the fingertip unit for guidance (a strip of glucocorticoid cream on distal phalanx pulp should cover two palm-size areas). It is also important to monitor glucocorticoid use and the easiest way to do this is ask the patient how long it takes them to use a specific size of glucocorticoid tube. The side-effects of topical glucocorticoid therapy need to be considered but glucocorticoid phobia and under-treatment of eczema are often more of a problem than over-treatment. Particular care should be taken on certain sites, such as the face and flexures, and in children and older adults (see Box 27.2 and Fig. 27.10).

The clinical features of eczema influence the choice of topical treatment. For example, appropriate treatment of acute exudative eczema could be with potassium permanganate soaks, emollients and topical glucocorticoids under wet wraps. Chronic eczema may be best treated with a potent topical glucocorticoid in an ointment formulation and occlusion with a paste bandage to ease itching and scratching.

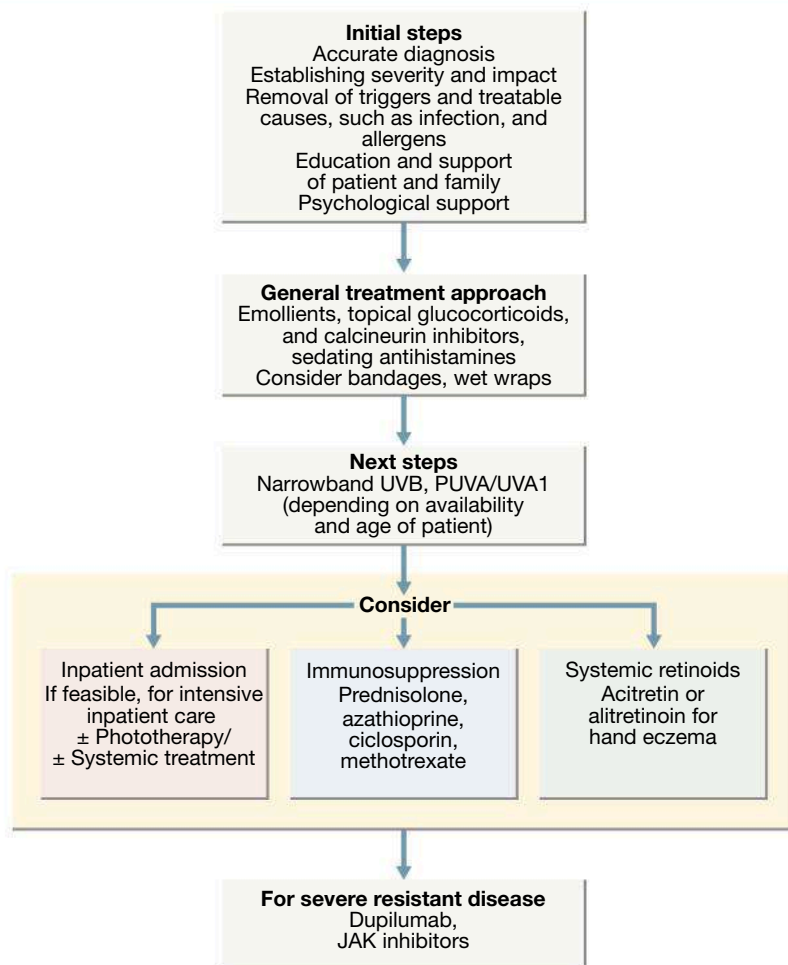

The topical calcineurin inhibitors tacrolimus and pimecrolimus may be useful glucocorticoid-sparing agents for eczema, particularly on the face; they cause local cutaneous immunosuppression. Initial burning and stinging may limit use but are usually transient side-effects. Bacterial and viral skin infection risk may be increased due to immunosuppression. Caution should be employed with sun exposure and these agents should not be used in combination with phototherapy because of their immunosuppressive effects.

## Atopic eczema

This is the most common subtype of eczema. The prevalence has increased dramatically since the early 1980s, and the disease now affects at least 20% of schoolchildren and 5%–10% of adults in the UK.

### Pathogenesis

Generalised prolonged hypersensitivity to common environmental antigens, such as pollen and house-dust mite, is the hallmark of atopy, in which there is a genetic predisposition to produce excess IgE. Atopic individuals manifest one or more of a group of diseases that includes asthma, hay fever, food and other allergies, and atopic eczema. Genetic factors play an important role in all of these conditions, supported by higher concordance of atopic disease in monozygotic twins compared with dizygotic twins. Filaggrin gene mutations increase the risk of developing atopic eczema by more than threefold, emphasising the importance of epidermal barrier impairment in this disease. Other genes are also likely to be implicated, with many other susceptibility loci identified, although these studies require further replication. Decreased skin barrier

**Fig. 27.32** General management approaches: atopic eczema.

(JAK = Janus kinase; PDE = phosphodiesterase; PUVA = psoralen-ultraviolet A; UVA1 = ultraviolet A1; UVB = narrowband ultraviolet B)

function may also allow greater penetration of allergens through the epidermis, and thus cause immune stimulation and subsequent inflammation. The interaction between genes and environment is important; it has been estimated that 60%–80% of individuals are genetically susceptible to the induction of IgE-mediated sensitisation to environmental allergens such as food and animal hair. Eczema is characterised by infiltration of Th2 cells, which are known to play a role in activating mast cells and eosinophils, as well as stimulating IgE production by IgE-producing B cells. The therapeutic inhibition of IL-4 and IL-13 and promising trials of phosphodiesterase-4 and JAK inhibitors, highlights the involvement of these targets in atopic dermatitis pathogenesis. Emerging therapeutic targets for atopic eczema both in terms of targeting Th2-driven inflammation and skin barrier dysfunction is a rapidly evolving field and further informs our understanding at a mechanistic level (see Fig. 27.34). The contributing roles of the microbiome are also being explored. Thus, the pathogenesis of atopic eczema is complex and multifactorial, involving an interplay of contributing factors.

### Clinical features

Atopic eczema is extremely itchy and scratching accounts for many of the signs (Fig. 27.33). Widespread cutaneous dryness (also known as xeroderma or xerosis) is another feature. The distribution and character of the rash vary with age (Box 27.20). Complications are listed in Box 27.21.

### Investigations

The diagnosis of atopic eczema is made using clinical criteria (Box 27.22). Interestingly, while most patients with atopic eczema have raised total IgE levels and IgE-specific antibodies, this is not a prerequisite for the diagnosis, as a significant minority have normal levels of IgE.

### Management

The general principles of management are as described in Figure 27.32. Emollients and topical glucocorticoids, tar and ichthammol paste bandages, or wet wraps in children, are often required and are mainstays in improving barrier function and reducing inflammation, although have not been shown to have a preventative effect against

**Fig. 27.33** Atopic eczema. **A** This patient had life-long chronic atopic eczema and experienced a generalised flare of disease triggered by infection. **B** Lichenification of chronic flexural eczema secondary to rubbing and scratching.

i 27.20 Atopic eczema: distribution and character of rash
<b>Babies and infants</b>
<ul style="list-style-type: none"> <li>• Often acute and facial involvement prominent</li> <li>• Trunk involved but nappy area usually spared</li> </ul>
<b>Children</b>
<ul style="list-style-type: none"> <li>• Flexures: behind knees, antecubital fossae, wrists and ankles</li> </ul>
<b>Adults</b>
<ul style="list-style-type: none"> <li>• Face and trunk usually involved, limb involvement not restricted to flexures</li> <li>• Lichenification common</li> </ul>

i 27.21 Complications of atopic eczema
<b>Secondary infection</b>
<b>Bacterial</b>
<ul style="list-style-type: none"> <li>• <i>Staphylococcus aureus</i> most common</li> </ul>
<b>Viral</b>
<ul style="list-style-type: none"> <li>• Herpes simplex virus can cause a widespread severe eruption – eczema herpeticum</li> <li>• Papillomavirus and molluscum contagiosum are more common in atopic eczema, especially if treated with topical glucocorticoids</li> </ul>
<b>Increased susceptibility to irritants</b>
<ul style="list-style-type: none"> <li>• Defective barrier function</li> </ul>
<b>Increased susceptibility to allergy</b>
<ul style="list-style-type: none"> <li>• Food allergy – mainly relevant in infants; eggs, cow's milk protein, nuts, fish, wheat and soya may cause an immediate reaction with angioedema and/or urticaria rather than exacerbation of eczema</li> <li>• Anaphylaxis in severe allergy</li> <li>• Increased risk of sensitisation to type IV allergens because of impaired barrier function</li> </ul>
<b>Impact on life and health</b>
<ul style="list-style-type: none"> <li>• Poor sleep, loss of schooling, behavioural difficulties, failure to thrive in children</li> <li>• Impact on sleep, work, relationships, hobbies, psychology and quality of life in adults</li> </ul>

i 27.22 Diagnostic criteria for atopic eczema
Itchy skin rash (or history of itch or rubbing from parent) and at least three of the following:
<ul style="list-style-type: none"> <li>• History of involvement of skin creases (or cheeks if &lt;4 years)</li> <li>• History of atopic disease (asthma, hay fever) (or in a first-degree relative if &lt;4 years)</li> <li>• Dry skin (xeroderma)</li> <li>• Visible flexural eczema (cheeks, forehead, outer limbs if &lt;4 years)</li> <li>• Onset in first 2 years of life</li> </ul>

the subsequent development of atopic eczema when used in babies. Topical calcineurin inhibitors may be used as glucocorticoid-sparing agents but should not be used in infected eczema. Secondary infection should be treated but positive skin swabs in isolation, without clinical evidence of infection, do not necessarily require treatment with antibiotics, although antiseptics would be appropriate. Sedating antihistamines may help to break the itch/scratch cycle. Identification and avoidance of allergens are important.

Phototherapy is generally the next step, if topical therapies are insufficient (see Fig. 27.32). Narrowband UVB is usually the initial phototherapy of choice and can also be used in children. PUVA or UVA1 can also be used if UVB is ineffective, although mainly in adults as PUVA is generally

avoided in children. Localised phototherapy may be used for eczema on hands and feet and PUVA may be more effective in that situation. Systemic immunosuppression with, for example, oral glucocorticoids, intermittent ciclosporin, azathioprine or methotrexate may be needed if the response to topical therapies and phototherapy is inadequate. Systemic retinoids, such as acitretin or alitretinoin, may be indicated: for example, in hand and foot eczema.

Dupilumab, which blocks the IL-4 receptor alpha chain subunit common to both IL-4 and IL-13 receptors, is now licensed for clinical use in patients with severe disease, as are the JAK inhibitors baricitinib and upadacitinib. The anti-IL-13 agents tralokinumab and lebrikizumab are also showing promise in clinical trials, as are phosphodiesterase-4 inhibitors and other therapeutic targets (see Fig. 27.11 and Box 27.14).

## Seborrhoeic eczema

This is an erythematous scaly rash affecting the scalp (dandruff), central face, nasolabial folds, eyebrows, central chest and upper back. It is associated with, and may be due to, overgrowth of *Malassezia* yeasts. When severe, it may resemble psoriasis. Severe or recalcitrant seborrhoeic eczema can be a marker of immunodeficiency, including HIV infection. Topical azoles, such as ketoconazole shampoo and cream, often combined with mild glucocorticoid, are mainstays. Treatment often needs to be repeated due to disease recurrence.

## Discoid eczema

Discoid eczema, which is also known as nummular eczema, is common and characteristically consists of discrete, coin-shaped eczematous lesions, which are often impetiginised and most commonly occur on the limbs of men. It is an eczema type that can be due to any chronic itchy condition, whether primarily of the skin or secondary to an underlying disease. Initial management should include topical antiseptics, in addition to emollients and topical glucocorticoids. Judicious antibiotic use may also be required for acute flares.

## Irritant eczema

Detergents, alkalis, acids, solvents and abrasives are common irritants. Strong irritants have acute effects, whereas weaker irritants commonly cause chronic eczema, especially of the hands, after prolonged exposure. Individual susceptibility varies and older adults, atopic and fair-skinned individuals are predisposed. Irritant eczema accounts for most occupational cases of eczema and is a significant cause of time off work. Irritant avoidance, including protective clothing (such as gloves), is essential. Emollients and topical glucocorticoids are indicated.

## Allergic contact eczema

This occurs due to a delayed hypersensitivity reaction following contact with antigens or haptens. Previous allergen exposure is required for sensitisation and the reaction is specific to the allergen or closely related chemicals. Common allergens are listed in Box 27.23.

Allergy persists indefinitely and eczema occurs at sites of allergen contact and can secondarily spread beyond this. The distribution of eczema can be very informative with regard to possible culprits. There are many recognisable patterns of sites of eczema involvement, such as earlobes, wrists and umbilicus due to contact with nickel in earrings, watches and jeans studs; hands and wrists due to rubber gloves; and upper eyelids due to colophony from rubbing of the eyes in nail varnish wearers. Oedema may also be a feature (Fig. 27.34). Allergen avoidance is key and may involve a change of occupation, recreational activities or hobbies. It is important to ensure that patients are fully informed as to the nature and likely occurrence of allergens and good detective work is required to scrutinise lifestyle and daily activities. Treatment with emollients and topical glucocorticoids helps but will not suffice if there is continued allergen exposure.

### 27.23 Common type IV delayed hypersensitivity allergens

Allergen	Source
Nickel	Jewellery, jean studs, bra clips, watches
Dichromate	Cement, leather, matches
Rubber chemicals	Clothing, shoes, rubber gloves, tyres
Colophony	Sticking plaster, collodion, nail varnish
Paraphenylenediamine	Hair dye, clothing, tattoos
Balsam of Peru	Perfumes, citrus fruits, shower/bath products
Neomycin, benzocaine	Topical medications
Parabens	Preservative in cosmetics and creams
Wool alcohols	Lanolin, cosmetics, creams
Epoxy resin	Resin adhesives, glues
Methyl- and chloromethyl-isothiazolinone	Preservatives, with increasing numbers of cases of allergy reported

**Fig. 27.34 Allergic contact eczema.** This was caused by the application of an antihistamine cream. The acute eczematous reaction and bilateral periorbital oedema are typical.

### Asteatotic eczema

This occurs in dry skin and is common in older adults. Low humidity caused by central heating, over-washing, diuretics and cholesterol-lowering drugs predispose. The most common site is the lower legs, and a 'crazy paving' pattern of fine fissuring on an erythematous background is seen. Emollients are a mainstay, in combination with topical glucocorticoids. Patients must be advised to use caution with flammable emollients and to avoid bathroom slippages related to emollients on floor and feet, and this is particularly relevant for older individuals.

### Gravitational eczema
